The over-all length of the broach suitable for the gears shown in Fig. 8 is about 26 inches, the cutting portion being about 17 inches, and the teeth of ⅝-inch pitch, cut straight and backed off. The pilot should be about 3 inches long. The teeth should never on any account be cut spiral, as this tends to twist the broach while in operation, and consequently the castellation would not be true. To produce an accurate castellated hole, as shown by Fig. 8, in nickel steel, it is necessary to use about ten roughing broaches and one finishing broach, especially when this operation is to be performed to very fine limits, as in the case of the gears in question. The last four teeth in each broach should be parallel, and the rest tapered in equal progression. On the first broach the pilot should be round and of the same diameter as the hole in the gear to be broached. On the following ones the pilot should be a sliding fit in the hole produced by the previous broach, and should at the same time be located from the castellations.

The finishing broach should have a piece at the rear end, about 3 inches long, of the exact size of the castellated shaft on which the gear is to be fitted when finished. This will act as a burnisher. The broaches are pulled through the work, which is quite a good feature, as it tends to keep them straight while in operation. The cutting portion being so long enables the operation to be performed without previous rough-slotting, which is required when the gears are drifted on the power press. After broaching, the gears should be turned.

Finish-turning

Castellated gears should be turned on a mandrel, locating from the castellations. The parts required to be hard, such as the top diameter of the gears, which should have an allowance of 0.005 inch for gear-cutting purposes, and the sides of the teeth and fork groove are then finished, leaving the gear as shown in Fig. 5. In the case of the gear in Fig. 1, the top diameter should be finish-turned with an allowance of 0.005 inch, and the sides of the teeth and the bore with an allowance of 0.125 inch, so that the latter can be bored out again after carbonizing, which would leave the hole soft, as it is not required to be hard. The finish-turning leaves the gear as shown in Fig. 4. Gears such as shown in Fig. 2 can be finish-turned and bored complete at this operation.

Cutting the Teeth

One of the most important operations is the cutting of the teeth after annealing. The method to be described is at present in practice and gives very successful results. The teeth should be roughed out on the hobbing machine and, where possible, several gears should be placed on the work-arbor at one setting. A great deal of time is saved by placing several gears on the work-arbor, which should always be steadied at the top. Suppose six are to be cut at one setting; this would mean that the hob would only have to travel into and clear the work once instead of six times, which would be necessary if they were cut singly. When putting several gears on the arbor, they must be faced exceedingly true, or the arbor will be bent. This is especially true when the hole is small and the gears large in diameter. Plenty of lubricant should be applied in this operation, oil being most commonly used. The hob should be made of high-speed steel, a six-pitch hob being 3 inches in diameter, and a five-pitch hob, 3½ inches in diameter. On account of the accuracy required, single-threaded hobs are preferable. For the roughing operation a cutting speed of sixty feet per minute of the hob, and 0.020 inch feed per revolution, are considered good practice for a nickel steel six-pitch gear.

For the finishing operation at least 0.010 inch should be allowed for a six-pitch gear and other pitches in proportion. If the finishing cut is merely a scraping cut and not enough stock is removed to let the cutter get a real chip, the cutter may glaze over the work, especially if the cutter and the work-arbor are not held rigidly. The gears should be finished one at a time, excepting plate gears, in which case several can be placed on the arbor at one setting. For this purpose a Fellows gear shaper should be used, because the cutter can be made far more accurate than a hob or a rotary cutter. The teeth of this cutter can be ground after hardening, and this

corrects any inaccuracies that may have crept in. On the cutter-arbor, at the back of the gear-cutter, should be placed a round disk made of high-speed steel, hardened, ground and backed off, which will act as a shaving tool and will take off the 0.005 inch left on the top diameter, as previously stated. This will make the outside diameter true with the pitch line. The teeth should be cut about 0.001 inch thin at the pitch line to produce a running fit. The gears should now be tested for center distance, for which purpose a plate with two pins for the bores, set at the correct center distance, should be used.

Owing to the courtesy of Mr. Ward, of the Universal Gear Grinding Co., the author has had the opportunity of seeing in

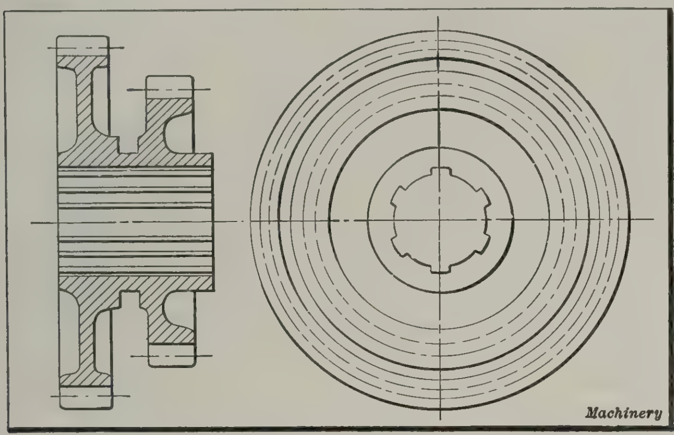

Fig. 8. Completed Gear, shown in Progress of Evolution in Figs. 3, 5 and 7

operation a machine for grinding gear teeth, which has the appearance of filling a long-felt want in the automobile industry. If it is—and the author believes it is—what the makers claim for it, it would not be necessary to finish-cut the teeth, as, with the exception of those of the gear shown in Fig. 8, they could be ground after hardening. This would obviate the final process of "grinding-in" with emery and oil, a process which at present is so unsatisfactory. In the case of the gear teeth shown in Fig. 8, the grinding wheel would foul the large gear when grinding the small one, to overcome which it would be necessary to re-design the gear and make it in two parts. The machine has many good features, the main one being that the shape of the wheel is maintained by three diamonds which dress the wheel, and which are controlled by one former. One is used for truing up the top diameter of the wheel, and one is placed on each side for truing the curvature.

The tooth-rounding should be performed on an automatic tooth-rounding machine. Several gears should be mounted on the same arbor, and the teeth of the wheels may be rounded in succession at one setting. No doubt most readers are quite familiar with the reason for this operation, which, therefore, requires little explanation, unless it be to say that it is done to facilitate the changing of the gears, and also to prevent the teeth from being chipped when engaging, which would occur if the corners were left square. The sides of the teeth which are not rounded should be fraised before carbonizing, which is the next operation.

The Carbonizing Process

In carbonizing, great care should be taken, as, to a very great extent, the life of the gear depends on this process. The result of the process is determined by four factors, namely: the nature of the steel; the nature of the carbonizing materials; the temperature of the carbonizing furnace; and the time taken by the process. The carbonizers in general use at the present time are animal charcoal, hydro-carbonated bone-black, charred leather, and a few other compositions sold under various names. Owing to the various conditions under which the operation is carried out, experience must largely guide the operator. Theoretically, the perfect carbonizer should be a simple form of carbon, and charred leather gives very satisfactory results. Care should be taken to avoid poorly charred leather, or that made from old boots, belting, etc. Good charred leather should contain about 88 per cent of carbonizing matter.

As it is essential that the core of the gears should be left soft in order to withstand the high speed and sudden shocks to which they are subjected, the carbon content in the core should be low. For this reason preference is given to 0.20 per cent carbon steel. The carbonizing pots are made from both cast and wrought iron; the former are cheaper in first cost, but the latter bear reheating so many times that they are really cheaper in the end. The carbonizer having been thoroughly dried and reduced to a fine powder, a layer of not less than 1½ inch in depth is placed in the carbonizing pot and well pressed down. Upon this, are placed the articles to be treated. Care must be taken to have sufficient space all around each piece so as to prevent them from touching each other or the walls of the pot. About 1½ inch is sufficient. Another layer of carbonizing material is then put in and well pressed down, care being taken not to displace any of the gears. The process is then continued until the pot is full, finishing with a layer of about 1½ inch at the top.

The object in view is to make the contents of the pot as compact as possible, consistent with a sufficiency of carbonizer in contact with the gears. The more solidly the pot is packed, the more complete the exclusion of air. The lid is then put on, and the joint all round luted with clay. The pot should be placed in a furnace similar to that used for annealing, and heated to about 1700 degrees F., which heat should be maintained constant for from six to ten hours. The length of time occupied is regulated by the depth of casing required, which

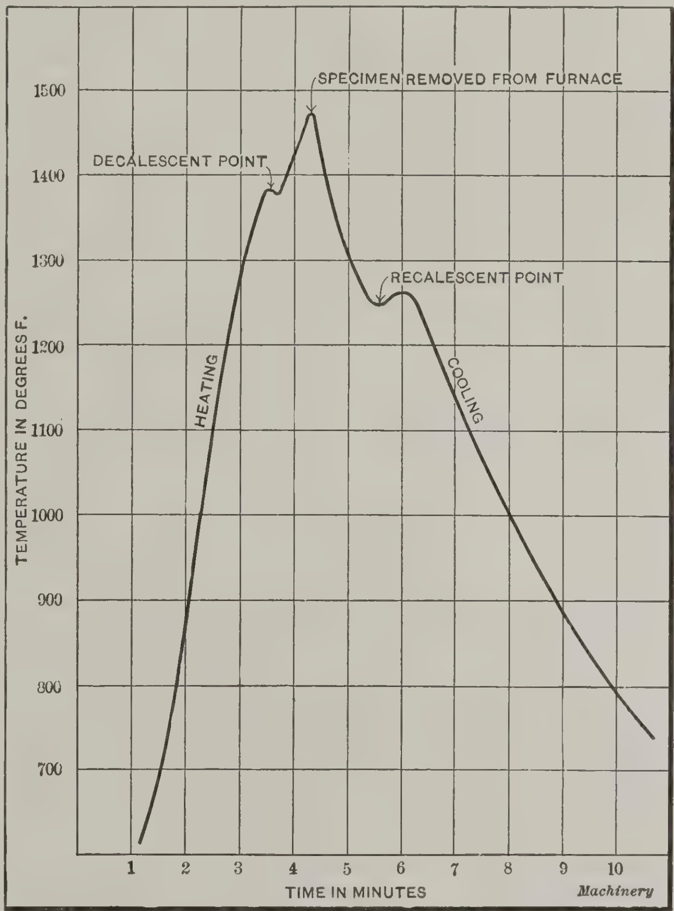

Fig. 9. Curve showing the Decalescent and Recalescent Points for Low Carbon Nickel Steel

should be about three-sixty-fourths inch, and also by the dimensions of the gears. At the close of the carbonizing period, the pot is withdrawn and put in a dry place where it is allowed to cool to atmospheric temperature. It is then opened, the articles are taken out, and the process is completed by brushing to remove all adhering matter.

It may be noted here that the case should only be deep enough to resist wear and battering. If the case is so deep as to form a considerable part of the cross-section of the teeth, the teeth may break unless the case is considerably tempered.

Turning Operations Preceding Hardening

The next operation is to turn out the carbon from the parts required to be soft. In the case of the plate gear shown in Fig. 1, which is to be bolted to another gear or center, as

previously stated, the hole need not be hard. For this reason, it was left with an allowance of 1/8 inch at the previous turning operation. It should now be bored with an allowance of 0.015 inch for grinding after hardening, and faced down on both sides. This refers to both plate and castellated gears as shown in Figs. 6 and 7. The boring operations should be performed while the gear is held in a collet-chuck, locating from the top of the teeth, which were trued up with the pitch line by the shaving tool used when cutting the teeth, as previously explained. This method has been found to be more efficient than locating with balls or rollers on the pitch line. The penetration of carbon being only about three-sixty-fourths inch it is now removed from the parts which have just been turned. Consequently these parts will not be hardened. The excess metal is left as shown in Figs. 6 and 7 until after hardening, in order to prevent warping, which would undoubtedly happen if the gears were finished as shown by Figs. 1 and 8.

The Casehardening and Oil Tempering

Steel of the composition mentioned can be hardened as follows: Heat from 1450 to 1525 degrees F. and quench in water; re-heat to about 1400 to 1450 degrees F., and quench in water. The re-heating must be conducted at the lowest possible temperature at which the steel will harden. It will be found that this is sometimes as low as 1300 degrees F. Then, as a safeguard, re-heat to a temperature of between 250 and 500 degrees F., in accordance with the requirements of the case, and cool slowly in oil. Parts of intricate shape, such as the gears dealt with, having sudden changes of thickness, sharp corners and the like, should always be tempered or drawn in order to relieve internal strains.

Another method of procedure is as follows: Heat from 1450 to 1525 degrees F., and quench in hot brine. Re-heat from 1450 to 1525 degrees F., and quench in oil. The temperature need not be drawn when the gears are quenched in oil. The final quenching should be done at the lowest temperature at which the piece will harden, as stated in the first method.

A small gas muffle should be used for hardening. A properly constructed gas muffle can be regulated with the greatest nicety, and in hardening this is most important. When steel is gradually heated, there is a certain point at which a great molecular change takes place, and perfect hardness can only be obtained by quenching at this critical point. This would lie between 1300 and 1450 degrees F. When steel is cooled, whether slowly or not, it bears in its structure a condition representative of the highest temperature to which it was last subjected. From this it will be quite clear that in casehardening, as in all methods of hardening, the steel must be quenched on a rising heat. Steel which is overheated previous to the final quenching, is very brittle and liable to fracture easily, and although quenched and subsequently hardened, the metal has little or no cohesion, and rapidly wears away. Steel so hardened breaks with a very coarse crystalline fracture, in which the limits of the case are badly defined. If quenching takes place below the critical point previously mentioned, the steel is not sufficiently hard. If above, though full hardness may be obtained, strength and tenacity are lost, in part or completely, according to the degree of heat by which the critical temperature is exceeded.

It may be asked why it is not sufficient, when the pieces are heated at the first re-heating to about 1500 degrees F., to place them in another furnace and reduce to the critical temperature and quench, instead of quenching twice. The answer is that the high temperature has already created a coarse crystalline condition in the steel, and that, until it has been cooled down below the critical point, and re-heated to the critical temperature, a suitable molecular condition cannot be obtained.

As a further means of illustrating what is meant by the critical point, Fig. 9 shows a curve plotted from results obtained by a recording pyrometer, in which the decalescent and recalescent, or critical points are shown. From this it will be seen that the absorption of heat occurred at about 1375 degrees F. on the rising temperature; and the evolution of heat at 1250 degrees F. on the falling temperature which was allowed to fall slowly. The relation of these critical points to hardening is that it cannot take place unless a temperature sufficient to produce the first action is reached in order to change the pearlite carbon to hardening carbon; and also unless it is cooled with sufficient rapidity to eliminate the second action. The temperature would, of course, be gaged with a pyrometer.

Sandblasting

The sandblasting, which serves to scour off any roughness or stains which have been left on the surface during the heat-treatment, etc., is best conducted in a building separated from the remainder of the shop. The sand should be kept in a bin in one corner, and sucked up by a centrifugal blower and forced by air pressure through a blow pipe which terminates in a nozzle. The sand being forced by the air at a high velocity, may be directed at all parts of the piece to be cleaned. This is one of the most efficient methods of polishing and cleaning the gears, and does not injure the hard surface in any way.

Hardness Testing

The gears should now be tested for hardness. The scleroscope appears to be the best instrument for doing this. If a gear shows a considerable drop in hardness, a file should be used to determine whether the cause is due to the piece not being hard, or to crystalization. If the parts can be scratched with a file, it shows that it is not hard enough. If, however, the file will not bite on the spot where the scleroscope reads low, then it is positively known that it has been overheated and is crystalized. A good method of testing the teeth is the drop test. By this method a ten-pound weight with a 56-inch drop is directed at one tooth. The number of blows necessary to break the tooth should be noted. This test would only be applied occasionally, say, on one out of each batch of gears. A gear which has given satisfaction should be tested, and the result used as a standard for future comparison.

Final Turning Operations–Grinding

The metal left for supporting the gears while undergoing heat-treatment is now removed. This operation should be carried out with the gear held in a collet-chuck, and care should be taken that the outside diameter runs true before starting. The hole having been bored after carbonizing, is now soft. The metal can be turned out on both sides, or on one side, as the case may be, leaving 0.005 inch on the face of the web for grinding. This operation should come next, and is most essential in order to get a true running gear when in position. The castellated gears which were finish-bored with an allowance of 0.015 inch before carbonizing are now hard, this being necessary as they have to be a sliding fit on the shaft. The part of the bore which bears against the lands of the castellated shaft is all that can be ground. Unfortunately no method has yet been devised for grinding the castellations themselves, and these, therefore, have to be lapped separately by hand—which is most unsatisfactory. While grinding the bore, the gear should be held in a collet-chuck from the top diameter—hence the truing of the top diameter with the pitch line in the gear-cutting process. Gears ground in this way should be perfectly true, and are now ready to be tested for center distance and true running.

The Drilling

It should be clearly understood that the web of the gear shown in Fig. 1 is now soft. This brings us to the final machining operation, that is, the drilling. There are many advantages gained in leaving this operation until the last. The bore is now the correct size, this being essential for locating the drilling jig. Furthermore, in the grinding operation, the bore is totally ignored, the top diameter being the most important. The hole has been ground true with the latter, so that if the holes had been drilled previous to the hardening, they would not be concentric with the bore, and would not match with the gear or center to which it has to be bolted. Another advantage is that the holes are now soft and can be reamed with the piece to which the gear is to be bolted, it being understood that these would also be left soft in the parts in which the holes are required. All these are important points, and this is the reason for leaving the drilling until last.

The "Running-in"

The gears should now be bolted to their respective parts and finally "run in" before being placed in the car. This should

be performed in a special case, and the "running-in" done under belt power. The bearings, in these special cases, are set at the proper center distance, so as to accommodate the various gears of a train, thus wearing in the gears so that all those for similar parts are absolutely interchangeable. The case is made oil-tight, and a mixture of finely powdered emery and lubricating oil is forced through an opening in the top, so that this grinding material will come in contact with all the teeth in mesh in the train. The grinding is continued until each tooth has been worn perfectly smooth, and to an accurate fit with the teeth of the other gears with which it comes into mesh. As a further means of thoroughly running in the gears of the transmission to a perfect fit, the motor, transmission and driving shaft are installed in the chassis, and the motor is run while the various speeds of the transmission are thrown into mesh. During this run an electric dynamoter, by means of which a variable load may be applied, is connected to the end of the driving shaft. The gears should now be as perfect as, with the best practice yet known, it is possible to get them.

It may be objected here that the leaving of extra metal for heat-treatment is rather costly. This is a question upon which there is room for a considerable difference of opinion. The author is of the opinion that if the method of leaving extra metal is used with discretion, and only in the case of very intricate gears, the most satisfactory results should be produced.

* * *

VANADIUM IN HIGH-SPEED STEEL

When high-speed steel was first alloyed with vanadium the vanadium was used in no greater amounts than 0.2 to 0.3 per cent, but it has been found that greater percentages produce better results, and as much as 0.75 to 1 per cent is now generally used. The efficiency of a tool may be measured either by the cutting speed at which the tool will last for a specified time, or by the length of time it will last under the same speed and general conditions without resharpening. Tests have shown that a tool steel containing 0.3 per cent of vanadium will stand up under a ten per cent increase in speed as compared with the same steel containing no vanadium. If 0.6 per cent of vanadium is added, an increase of twenty per cent in the speed is possible, and with 0.9 per cent of vanadium the speed may be increased thirty per cent. As regards the effect on the time between grindings, the speed and other conditions being the same, 0.3 per cent vanadium in the steel doubles the time between grindings, 0.6 per cent quadruples the time, and 0.9 per cent octuples it, eight times as much metal being removed between grindings, if the same speed and feed are used as would be efficient with the same steel containing no vanadium. These figures are given in a recent publication issued by the American Vanadium Co., Pittsburg, Pa.

TOO MANY SPEED CHANGES NOT AN ADVANTAGE

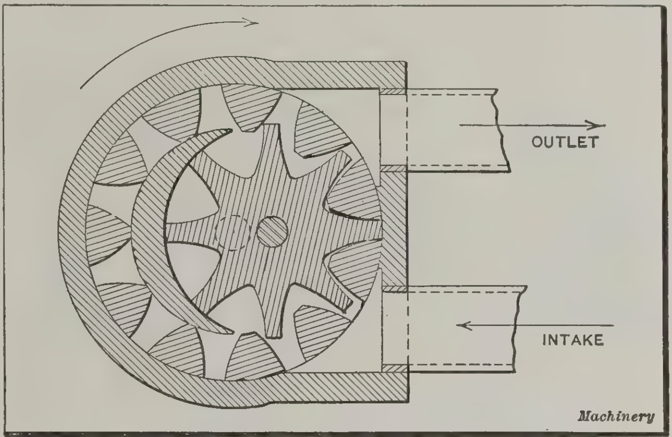
In an article on "Rational Machine Tool Design," by Prof. J. T. Nicolson, published in the *Machine Tool Engineer*, a supplement to the *Practical Engineer* (London), the author states with great emphasis that "the modern craze for large numbers of spindle speeds is not warranted by considerations of commercial economy; and it is to be distinctly condemned from the point of view of technical efficiency. The fewer the number of speeds, the broader, stronger, and more durable can be the gears, the smaller will be the power wasted in friction and the more compact and handy may be the headstock" of a machine tool. He says, further, that there is no money for the user, in a headstock with a large number of spindle speeds, and, even if there were, it is very doubtful whether the operator would use the speed changes intelligently. The added complication is a source of trouble in the working of the machine. A simple headstock with from eight to ten speeds, is, according to Prof. Nicolson, the best for every requirement. The great secret of economical cutting is not a complex headstock with many spindle speeds, but a lathe of moderately simple design which is kept constantly at work.

THE VIKING ROTARY PUMP

The accompanying illustration shows the principles of an interesting rotary pump, invented by Mr. Jens Nielsen of Cedar Falls, Iowa, which has recently been tested at the Engineering Experiment Station of the Iowa State College, and is described in the April number of the *Iowa Engineer*.

As will be seen in the illustration, the pump has but two moving parts—an outside annular gear, and an inside spur gear. The large gear has a shaft at the back which extends through the pump casing and carries the driving pulley. The spur gear is mounted on a stud extending from the opposite side of the casing, which also has a crescent shaped projection on one side, dividing the space between the two gears as shown. While, in the illustration, the lower pipe is shown as the intake pipe and the upper pipe as the outlet, either may be used for the intake, depending upon the direction of rotation. The action of the pump is evident. After the water enters the pump, it is carried around the pockets formed by the teeth in the large gear and the crescent-shaped projection. When the gears come into mesh on the upper side, all water is forced into the outlet port.

Tests have been made with heads varying from 30 to 150 feet of water and at speeds from 200 to 450 R. P. M. At 215 R. P. M., the efficiency was 48.6 per cent. At 400 R. P. M.,



Diagrammatical Section of the Viking Rotary Pump

the efficiency was 76.3 per cent. The average efficiency of all the tests was 64.8 per cent, the average speed being 360 R. P. M. At high velocities, the average efficiency was practically 70 per cent.

The comparatively positive action of the pump is shown by the discharge per revolution. At the lowest efficiency this discharge was 0.209 gallon, and at the highest, 0.235 gallon, which shows that even at the lowest efficiency the leakage was slight. The volume of water discharged per revolution, if there were no leakage, would be 0.259 gallon.

One advantage of the pump is that only one moving part requires packing—the main shaft where it enters through the back casing. The inventor has used one of these pumps in a stone quarry since 1906 pumping water mixed with mud and fine gravel. This pump is still working satisfactorily.

* * *

An interesting departure in advertising has been made by the American Woodworking Machinery Co., Rochester, N. Y., in a recent issue of *Vocational Education*. This firm offers to give, free, with a stereopticon, a series of slides showing in detail the construction of its No. 77 fast feed planer and matcher, from the foundry to the testing floor. The details which accompany each slide enable a teacher to prepare a talk before his class in connection with the exhibition of the views. What better method is there to acquaint a class in machine shop practice, for instance, with the mechanism and process of construction of a machine, than by showing the actual work? This, of course, can best be seen in the shops but if that is not practicable, the next best method is to show pictures of the operations. These few slides will convey more information on woodworking machinery to a class than pages of written matter or hours of unillustrated oral explanation. The value to the advertiser who thus makes known his tools is obvious.

Entered at the Post-Office in New York City as Second-Class Mail Matter

MACHINERY

RAILWAY EDITION

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS

49-55 LAFAYETTE STREET, NEW YORK CITY

27, CHANCERY LANE, LONDON, W. C., ENGLAND

Cable Address, Machinery New York

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit contributions from practical men on subjects pertaining to machine shop practice and machine design. All contributed matter published exclusively in MACHINERY is paid for at our regular space rates unless other terms are agreed on.

JULY, 1912

PAID CIRCULATION FOR JUNE, 1912, 24,674 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 700 reading pages. The Engineering Edition—$2.00 a year, coated paper, $2.50—contains all the matter in the Shop Edition, about 300 pages a year of additional matter and forty-eight 6 x 9 Data Sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. The Railway Edition, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of Data Sheets.

NOVELTY IN PATENTS

The communication from Mr. Shaw in another part of this number regarding an application of ball bearings to machine tools, raises an interesting question as to what constitutes novelty in patents. The requirements of construction for a drilling machine spindle as regards bearings are that thrust in the direction of the spindle shall be supported as well as the lateral thrusts due to belt pull and other forces acting against the sides of the spindle. This means that in the simplest form of spindle bearing, as ordinarily made, there shall be two radial bearings and two thrust bearings. Two thrust bearings must be provided, one to take the thrust of drilling, and the other to carry the weight of the spindle when not at work.

The designer of the drilling machine referred to by Mr. Shaw, took up the problem from a new point of view, however, and succeeded in providing a successful ball bearing construction consisting of two radial bearings only. The novelty lies in the elimination of separate thrust bearings by following a perfectly logical assumption. Radial bearings of the well-known annular types are rated as having a thrust bearing capacity of twenty-five per cent of the allowable radial load. Hence the requirements of drilling machine spindle bearings are perfectly satisfied by providing two radial bearings, one of which has a radial bearing capacity of at least four times the thrust bearing requirement. Suppose the maximum thrust to be provided for is 1000 pounds, then a bearing capable of carrying a radial load of 4000 pounds will safely carry the thrust load and, of course, be far above the lateral thrust requirements.

The question is: Does this design, embodying a simple construction found in hundreds of other machines not required to provide for endway thrusts on shafts but which in this case provides for thrusts by greatly increasing the radial bearing factor, constitute novelty? We believe that it does, and that the lucky discoverer of the principle is entitled to all the protection provided under patent laws. The best ideas are generally the simplest, and in this case machine construction has doubtless been improved and simplified at one stroke. This is the height of machine design accomplishment.

* * *

VALUE IN A GOOD NAME

A bill has been introduced in Congress providing that all products intended for interstate or foreign trade shall be stamped with the name and address of the makers. The penalty provided for violation of the proposed statute is a fine of one thousand dollars or imprisonment for six months, or both. The same penalty is provided for erasing or changing the stamp.

It is practically impossible to frame any drastic law that will not work hardship or injustice to a few, and probably this proposed legislation is no exception; but we believe that in the end it would confer material benefits on both manufacturers and consumers. A great step forward would be made for honesty in manufacturing and selling, and dishonest competition would be hard hit.

Every machine tool that carries the maker's name is not only a permanent advertisement for him, but an incentive to produce his best, and security that others shall not appropriate the prestige acquired through honest workmanship and effective design. There can be no objection to a dealer attaching his nameplates to machines sold; but we believe that the policy followed by some dealers of replacing the name of the manufacturer with their own is bad for the industry, because it relieves the maker of all responsibility for the character of his product and places a premium on poor workmanship. A good name and an established reputation are of the greatest help in selling machine tools, and the most successful dealers represent manufacturers who possess them. Their dealers can talk *quality*—the men who are selling tools without any reputation can only talk *price*.

* * *

FIXING RESALE PRICES

Many manufacturers fix the prices at which their products are sold by means of agreements as to resale prices, and by employing the principle of constructive infringement in the case of patented articles. Fixing resale prices has many advantages. The practice enables the manufacturer to advertise a product and the price, and to insure to the retailer a reasonable profit. It secures the retailer's position and prevents unfair competition so ruinous to the trade. Probably one of the most wholesome developments of the past twenty years of American trade has been the establishment of fair resale prices and the elimination of destructive competition.

But the principle of constructive patent infringement, of comparatively recent development, may be used for other purposes than the fixing of fair prices which insure reasonable profit to the retailer. Constructive patent infringement may be used as the means by which monopolistic control of manufactured products can be secured by groups of allied manufacturers. House bill 23417 has been drawn with the view of eliminating the danger arising from the power of the owners of patents to monopolize any manufacturing field, and this bill, it is hoped, will prevent patentees or owners of patents from attaching to the sale of goods unreasonable restrictions as to prices or methods of sale.

The matter of establishing resale prices presents many difficult and conflicting propositions. No one can deny that it is better for the manufacturer, jobber, retailer and consumer to have stable prices. Fluctuating prices mean uncertainty and demoralization. Fixed prices may insure a fair profit to all concerned in the distribution of the goods. The purchaser buys with the feeling that he is paying the market price and no more, and that he must pay the fixed price wherever he purchases the article. On the other hand fixed retail prices may enable groups of manufacturers to eliminate the law of supply and demand and impose monopolistic conditions which are intolerable.

We believe that whatever solution is found the result should not depend upon the provisions of the patent law, for that should not be used to enforce conditions of sale or use. The law should only secure to the inventor a reasonable reward for his ingenuity and labor.

WHAT TO STUDY

Sometimes we receive letters from young mechanics, saying, in substance: "I am a young man employed at the ——— Works, and I want you to recommend some books that I ought to study." The editor who must answer a question of that kind is in a worse plight than the doctor who is required to prescribe for a disease that he cannot diagnose; for the doctor can usually prescribe something harmless and "get away with it," but the editor cannot proceed along such easy lines. He is expected to give good, practical advice with but an indefinite knowledge of the needs of a young man whom he has never seen, and with whose previous education, ambitions and mental capacity, he is not familiar.

Some men should be advised to study anything and everything that would be useful to them in an executive position; while to others such advice, if followed, would mean simply disappointment and waste of time and effort. Some men do not possess the peculiar qualities that would enable them ever to rise to high executive positions; and those men should rather concentrate all their educational effort on practical study of the kind of work they are engaged on, so as to become proficient in that. Others, again, of a more energetic, more resourceful, or a more brilliant make-up, should pursue studies along entirely different lines—studies which may not benefit them within a year or two—perhaps not within five years; but which would ultimately prove useful to them when in positions of an entirely different character from those which they now occupy.

Fig. 1. One of the Drafting-rooms. All Work is designed here and Working Drawings are made for the Pattern and Machine Shop

What a man should study is largely a question which he must decide for himself. It is difficult for anybody else to decide it for him. A man should increase his knowledge of the work in which he is most interested—it will make both his work and study easier. For example, if he is interested in drawing, and has a natural ability for working out ideas or designs of his own, we advise him to study drafting, machine design, mechanics and mathematics, so as to utilize his natural inclinations. The young man whose sole interest is centered upon the practical operations in the shop, different methods of grinding tools to obtain the best results, short cuts for obtaining increased production, etc., we advise to pursue studies along shop practice lines, because for him the shop proper undoubtedly offers the greatest possibilities. If he is familiar with shop practice and has acquired a knowledge of the use of the various machine tools and shop systems, and, in addition, has a personality which makes him capable of handling men, there is no reason why he should not rise to be a foreman or superintendent.

In choosing a course for study, however, do not be misled by the idea that immediate benefit will be derived from it. Many a man who has risen to a prominent position in the industrial field has spent years in studying subjects which have been of no immediate advantage to him. It may have been five or perhaps ten years, before he has found a direct application for his knowledge; but he would have been unable to fill the higher position satisfactorily had he not acquired a fund of knowledge during the years when he had the opportunity.

THE WENTWORTH INSTITUTE*

A TRADE SCHOOL FOR TRAINING SHOP-FOREMEN AND SUPERIOR WORKMEN

By CHARLES L. HUBBARD†

A day spent at the Wentworth Institute, Boston's new school for industrial training, described in the October, 1911, number of MACHINERY, so impressed the writer with the value of the methods employed and the results obtained in training foremen and skilled mechanics, that he believes some of the enthusiasm absorbed from this group of busy men and boys should be passed along so that others may profit by it. What is so important to the efficiency of the shop as a whole, and to the advancement of workmen individually, as enthusiasm? Let the young man of average ability become sufficiently filled with love and respect for his chosen work and appreciation of the principles that underlie it, and the other requisites for success will follow naturally.

The Wentworth Institute is giving its students just this kind of a start, not by way of advice, but in a practical way, which not only makes a greater immediate impression, but is far more lasting. The object of this article is to describe briefly the general scheme followed in bringing about this result, in the hope that it may be developed in other schools of similar character, and also that it may awaken greater interest in practical industrial education, both among mechanics and among manufacturers and employers of skilled labor.

Fig. 2. Wood-working and Pattern Shop equipped with the Latest Machinery and Tools for this Class of Work

A casual inspection of the catalogue of this institution fails to show any particular difference from the methods followed in other trade schools, but as soon as one steps inside the building, he catches the air of the genuine earnestness, efficiency, and system noticeable in the business and engineering offices of the highly organized concerns of the present day. Furthermore, the impression is lasting as one passes through the different departments and notes the interest and industry of the students in their work, their businesslike, intelligent and skillful way of attacking their tasks and overcoming their difficulties, and the complete absence of any action which would tend to detract from the seriousness of the work in hand.

The average boy leaves school at fifteen or sixteen years of age. He enters a shop as an apprentice under the usual conditions, has little to encourage him during his hours of work, and too often little to look forward to in the future. He is placed at some task where he will be of most value to his employer, with scant regard to his own advantage in the way of learning his trade. A desire on his part to find

* The following articles on industrial schools, trade education and kindred subjects have previously been published in MACHINERY: "Features of Apprenticeship System at the General Electric Co.'s Lynn Works," April, 1912, engineering edition; "The Cincinnati Method of Industrial Education—A Friendly Criticism," March, 1912, engineering edition; "The Wentworth Institute," October, 1911; "T. R. Almond Mfg. Co.'s Evening School," July, 1911; "Training of Machinists in the Trade School," July, 1911, engineering edition. See also other information previously published, referred to in connection with the last-mentioned article.

† Address: 283 Central St., Auburndale, Mass.

out the reason for doing things is not encouraged, and those above him have not time for answering questions. It is not the fault of the foreman; he is held responsible for turning out the greatest possible quantity of work with the men in his charge. The fault is really with the system, and to remedy this fault, schools like the "Wentworth" are being established. Mr. Dodge, past president of the American Society of Mechanical Engineers, in speaking upon this subject, says: "The apprentice boy who picks up a trade, learning it chiefly by imitation and with little or no instruction, enters a machine or wood-working shop at sixteen and earns an average wage of $3.00 per week. At twenty-two years he may be earning $13.50, but at twenty-four years he has reached his highest earning capacity, getting $15.80 per week."

What is there to give a young man enthusiasm and draw out the best there is in him under such conditions? There may be a few special cases where young men have sufficient ability and endurance to win out under any condition, but the larger part usually drift from shop to shop, gradually losing hope of better things, and develop into "one-machine" men with practically no chance of further advancement. These statements are not intended to discourage men who are working under these conditions, but rather to encourage them by pointing out the opportunities that are open to them through the development of modern trade schools. Europe has long been aware of the advantages of this method of instruction, while America is only waking up to its possibilities. This is shown by an item which appeared in a recent number of the *Outlook*, and which states that in 1908 Prussia had 400,000 pupils, or nearly 14 per cent of its entire population, enrolled in its industrial schools, while only 2 per cent of the population of the United States were being trained in a similar manner. In some of the best shops, it is true, more care is taken in training apprentices than in others, and in certain cases private trade schools are now being carried on for the purpose of supplementing the training of the apprentices in the shop; but admirable as are some of these efforts to give the apprentice boys a chance, their number is still so small—and is certain to remain small in proportion to the demand—that there is genuine need for the public trade school in every industrial center.

Fig. 3. Foundry in which the Men are trained to become Skilled Workmen and Foremen

Fig. 4. Light and Spacious Core Department located on the Balcony in the Foundry

It has already been stated that one of the prime objects always kept in view in the training at the Wentworth Institute is to awaken in the student a thorough and lasting interest in his work. This is done, in a very simple and practical manner, largely by answering questions, both *asked* and *unasked*, and this really covers the whole field of teaching. Answering unasked questions gradually trains the student to ask them on his own account, and as his reasoning powers are developed, he reaches a point where he answers some of them himself. Now, when a man can both ask and answer his own questions he becomes original, and furthermore, an original man has ideas. Given a man with originality, and a training to properly discriminate between the practical and impractical, and he will neither lack interest in his work nor have a long wait for success. Such men are in demand in all the manufacturing plants of the country at wages that are only limited by their ability.

One or two illustrations will serve to show the general methods followed in accomplishing this result. For example,

Fig. 5. A Student engaged in Pattern Making, which forms a Part of the Shop Course in General Machine Construction

Fig. 6. A Student at Work in the Forge Shop, a Course in Forging also being included in the General Shop Course

Fig. 7. Work in the Milling Machine Department, illustrating the Character of the Work being done

a student is given a piece of work to be done on a lathe. His instruction is not confined to this piece of work alone, but he also makes a study of the lathe itself. Every part which goes to make up this machine is examined, and its use and the principle upon which it operates, are carefully explained. He is taught to make computations in gearing so that the necessary changes for screw cutting, etc., may be made without the use of tables. Tests are made upon the strength and friction of gears, belts, lubrication, etc., until

Fig. 8. General View in the Forge Shop

he has thoroughly mastered the machine itself, and has become proficient in its use. This same general scheme is carried out in a similar way upon all of the various machines in the shop. Thus the student not only becomes familiar with the use of machine tools, but is also able to detect and correct faults in their operation, and make proper adjustments. All of this forms a part of the necessary qualifica-

Fig. 9. General View in the Machine Shop

tions of a foreman, and adds greatly to the chances of future promotion.

Various methods are employed for awakening and holding the ambition of the student besides the regular routine work. One scheme is to incite a friendly spirit of competition in the several departments, which is illustrated by the following incident connected with the foundry practice. One feature of this course is to learn the art of shoveling sand properly, which, of itself, is not an especially interesting operation. To add zest to this exercise, and awaken a suitable amount of interest, and to test the mettle of the men, the class was divided into gangs working in competition, both as to speed and quality of work done. To avoid monotony, this work was carried on in connection with subjects requiring equal time in the class rooms, drawing rooms or laboratories, so that each type of work seemed by contrast a form of recreation when compared with the other. This was kept up every school day for nearly two weeks, at the end of which time the class had not only become proficient in the shoveling and tempering of sand without thinking of it as drudgery, but was also thoroughly drilled in team work. Each student had had opportunity to act as gang foreman and had learned how to take orders from his fellows, and had also learned from the records of successive days that there was a "science" even in shoveling sand. These are items of much value in the handling of men and are requisites in the training of a successful foreman. Compare this with the same work as done by the average apprentice, and note the difference in spirit and in the mental effect upon the two sets of boys. In like manner, time and efficiency tests are made in molding standard patterns, and records are established which every member of the class strives to excel. These methods of stimulation are only employed for first arousing an interest in the work, after which a natural desire for knowledge is developed which is sufficient to maintain the necessary degree of enthusiasm without artificial means.

Another important point in the general scheme of instruction is to make the men feel that they are doing *real work* with tools and machines of latest design, and that all knowledge gained is of actual practical value. This is well illustrated in the machine department, where, as elsewhere, work

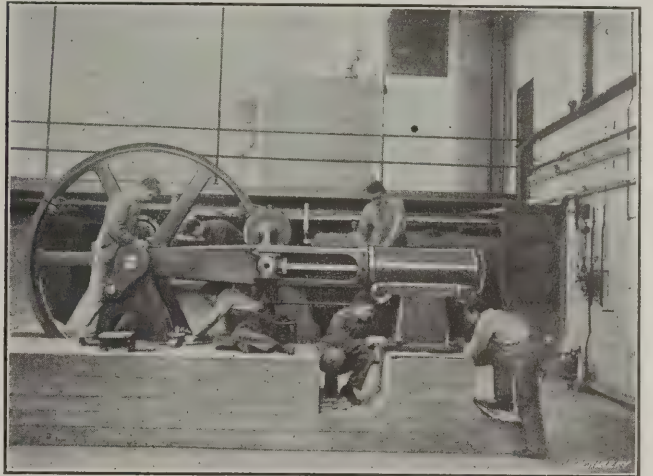


Fig. 10. Students assembling an Experimental Engine in the Steam Engine Laboratory. All Work of this Kind is done by the Students under the Direction of a Foreman

is carried through with the same order and system which would be employed in the most up-to-date shops. The article or machine to be built is first designed in the drafting-room, the patterns made in the pattern shop, and the castings in the foundry. The bench-work and machine-work are then given out to different men in the shop and the work is carried on to completion. In order to give a well balanced course, the men are shifted from machine to machine as fast as

Fig. 11. The Testing Laboratory where Materials entering into the Construction of Buildings and Machinery are tested for Strength

they become proficient in their use, and in this way they have an opportunity to work upon the different parts of any article or machine which is being built in the shop.

No man is held back in his work by another, promotion being dependent upon individual proficiency in each case. Nor is a man kept from using a valuable machine for fear he will damage it, as is often the case with an apprentice in a shop. He is given instruction in the use of each ma-

chine with an opportunity to put it in practice. Until he become thoroughly familiar with it, his work is kept simple. In this way the risk of damage is small.

Another feature of interest is the testing of work after it is finished, to see how it may be improved in design. For example, one of the exercises consisted of the design and construction of an arbor press. After completion, one of these was taken to the testing laboratory and each part tested to the breaking point under the kind of stress to which it would be subjected in actual use. The main casting was broken and the weakest section ascertained; the teeth on the rack of the ram were tested and compared with the teeth on the pinion and the maximum strength of the handle was

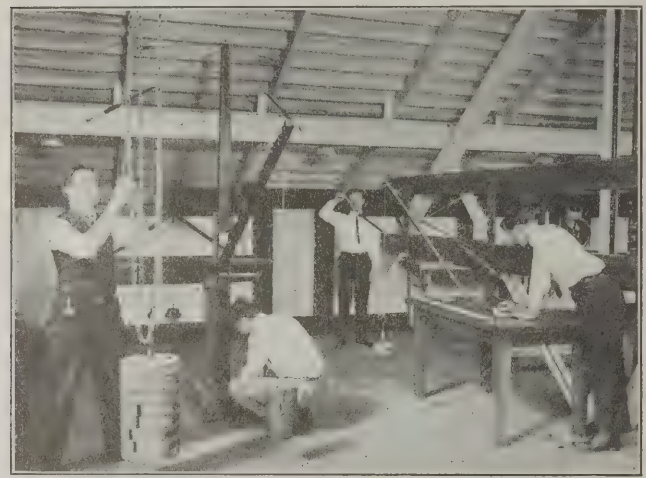

Fig. 12. Determining the Distribution of Load in Derricks and Cranes, using Specially Designed Apparatus

found. In this way the design of the machine may be revised, strengthening some parts and lightening others, to make the whole of uniform strength throughout. It is a noticeable fact that the men, as a rule, get a better grasp of theoretical problems of this kind when they can see their practical application to their particular line of work. The variety introduced into each day's work contributes greatly to its success. The school day is divided into four hours of drawing-room, class-room, laboratory or other theoretical work, and the same length of time is given to practical applications in shops or foundry.

In much that has been described there may appear to be a similarity with other trade schools, but the essential fact which seems to differentiate the Wentworth Institute from others with which the writer is familiar is the perfect blending of the spirit of investigation and open-mindedness of the best schools of science with the spirit of industry and production of the best commercial shops. In every course, theory and practice are carried on together in all the work, and theory is only taught so far as its practical application can be demonstrated.

The objection may be raised that this will have a narrowing effect upon the student, and that the instruction should be more general in its character. It must be remembered, however, that these young men are not university students to whom time and money are not of prime consideration, and who are simply laying a foundation for some special work later. The short length of the course is of the greatest importance to the type of men who enter the Wentworth Institute, and the sacrifice which they make for it is such that it must show practical results in higher wages as soon as it is finished. For these men, later success must come from practical experience obtained in passing upward through the different stages of their chosen trades, and not by passing over it, or dipping into it from the top, as a university student might do. The primary aim of the Wentworth Institute is to so equip its graduates, that with the later experience to be obtained in actual work, they may become superior workmen, foremen, and superintendents. The work done in the school is not intended to take the place of shop experience later on, but is expected to shorten this period at least one-third, and make advancement more rapid and more sure.

In addition to this, if a man develops superior ability as his work progresses, he can broaden his knowledge by further study to better advantage than at an earlier period. While a foundation, if sufficiently broad and deep, will support almost any structure, it is well in this short and busy life not to spend too large a share of it on the foundation alone, before finding out what it may be called upon to carry. The man who avails himself of the advantages of the Wentworth Institute, and subsequently works his way upward to better things, has constructed a foundation of sufficient depth to support almost anything he may wish to place upon it. If he desires to broaden this foundation, it is easily added to without tearing down that which he has already built. When a man has reached the point in his career above alluded to, he knows pretty accurately what his foundation is to support and can finish its construction without waste of time or material.

An advantage of the location of the school is its nearness to the manufacturing district of Roxbury, where various shops and factories are open to the students, thus permitting them to see in practical operation many of the machines and methods employed in the various courses of instruction at the school. A great number of courses are given, in order to meet the requirements of different classes of men. They are briefly outlined below. The one-year day courses include instruction in carpentry, electric wiring, plumbing, machine work, patternmaking, and foundry work. These one year courses are designed especially for apprentices, and aim to give a more thorough foundation than can be obtained in the commercial shop. It is not expected in this short time to turn out finished workmen, but to give the students a thorough understanding of the principles involved, together with sufficient manual skill, so as to enable them to gain a full mastery of their trade in a much shorter time than would otherwise be possible.

The two-year day courses have for their object the training of men to become superior workmen, foremen, and master mechanics. They include instruction in machine construction and tool design, and electrical construction and operation. The general methods of instruction are similar to those already outlined, except that the increased length of time makes it possible to teach the scientific principles in a more thorough manner. It also makes it possible for the student to obtain a greater degree of skill in the use of both hand and machine tools. Evening courses in seventeen practical trades are offered to young men who are employed in mechanical trades or industries during the day.

Fig. 13. Another View of the Mechanical Laboratory showing Students making Friction Tests on Pulleys and Gears

The directors have also inaugurated part-time courses in addition to those noted above. These require the students to attend their classes at the institute every other week, but give them an opportunity to work at some regular employment during the alternate weeks.

* * *

The ribs of a gear should never be made flush with the rim or hub, but should come from 1/8 to 1/4 inch below the rim or hub face; otherwise the rim and hub cannot be finished without making an unsightly appearance.

INDUSTRIAL ADMINISTRATION AND SCIENTIFIC MANAGEMENT*—1

WHAT CONSTITUTES SCIENTIFIC MANAGEMENT

By FORREST E. CARDULLO†

The work of the engineer may be divided into three great departments, since it has to do with the design of machinery, the methods of constructing and operating it, and the administration of the plants in which it is constructed and operated. The first two departments (namely the design of machinery, and its construction and operation) have received the careful attention of trained specialists for more than a century. Even at the beginning of the nineteenth century when engineers first began to apply the resources of modern science to their work, the arts of machine design and construction were in an advanced state, owing to the efforts of many generations of skilled mechanics. The third department of engineering work, however, has lagged far behind the other two, since comparatively little attention has been bestowed upon it. It is doubtful if any substantial advance in industrial administration was made in the thirty centuries preceding the year 1880, and even at the present time only a few men are devoting serious attention to the fundamental problems of management.

Importance of Industrial Administration

At the present time, industrial administration is the most important of the three departments of engineering work. It is not, of course, confined to purely engineering projects, but is an essential part of all commerce and manufacturing. Since the greater part of our working population is engaged in some kind of industrial work, the proper supervision of their efforts is a matter of prime importance to the well-being of the country. Most of the readers of MACHINERY are, or ought to be, interested in the proper administration of the mechanical industries. Hence, this series of articles will discuss more particularly the management of shops and factories engaged in the metal trades.

As has already been intimated, the art of industrial administration was stationary for a long period of time. In spite of tremendous changes in our social, economic and industrial systems, we have been content to adapt or modify methods which originated thousands of years ago. I may liken the system of administration which obtains in most industrial plants to one of those "old homesteads" which dot our New England landscape. They started as a log cabin, to which was successively added a lean-to, a barn, a shed, an ell, an upper story, and other "modern conveniences." As a result, they are roomy—and also inconvenient. The common system of industrial administration is constructed of the surviving remains of Greek slavery, Roman militarism, Saxon serfdom, the medieval guilds, and various other historical oddities, slightly altered to adapt them to the twentieth century conditions, and engrafted on one another in very much the same way as the additions to the old house. This system of management has been a growth in which each manager appropriated those developments of the past which appealed to him. Sometimes methods were adopted as a result of a carefully and properly conducted investigation, but nine times out of ten they were adopted because the manager "guessed" they were the best ones.

Conventional Management

We will designate the system of management described in the preceding paragraph as "conventional management."‡ It must not be inferred from the description the writer has given that conventional management is always and utterly objectionable. When the manager is a good guesser, he will usually choose good methods of work. If his lieutenants are able and energetic, these methods will be well carried out. Of course the system is not perfect, and in many cases it is not even satisfactory. Nevertheless conventional management can be made to work, and to work well, when it is in the hands of capable administrators. Different men will, of course, adopt different methods, and in different shops we will find that the work of administration is carried out in very different ways. In every case, however, the distinguishing feature of conventional management is the acceptance of something already in existence and the choosing, by guess, between methods which have been developed by someone else.

Systematic Management

Within the past thirty years, however, two other systems of management have arisen. One of these may be called "systematic management," while the other has been named by its originators, "scientific management." The systematic system of management is the development of the clerk and the bookkeeper. It aims at the keeping of careful records and the collecting and classification of information. It aims to proceed by continually bettering existing records. It aims to inform the management as to the preferable one of two alternative methods of work, each of which must be tried out in practice. Systematic management is, then, simply the keeping and comparison of records in order to determine the relative value of methods of work.

Scientific Management

Scientific management, on the other hand, has been developed by the engineer. Scientific management aims at the careful investigation of every problem of the industrial world in order to determine its best solution. It is not content to rely upon records, or upon the judgment of the most experienced workman. It brings to its aid all the resources of science. Every possible method of performing a piece of work is carefully analyzed and the best elements of all of the methods combined in order to form a new method. Having established the best methods of work, scientific management then instructs the workman how best to perform his task, and offers an incentive to do it in the prescribed manner. Scientific management is often called the "Taylor System" in honor of its foremost exponent.

Scientific management is not an invention but a discovery. It is the application of the scientific method of research to the problems of the industrial world. Insofar as it is concerned with the investigation of these problems, it is science and nothing else. Insofar as it is concerned with the proper application of the results of these investigations, it is management and nothing else. The combination is therefore correctly termed "scientific management."

Just as in the old days, certain types of machinery reached a very high state of development without the aid of the scientifically trained engineer, so in these days, the administration of certain of our industries has been very highly developed without the aid of scientific management. In some kinds of work, as for instance, watch making, the problems of administration are simple on account of the limited character of the product and the extensive use of automatic machinery. In industries of this class reasonable piece-rates have been established by a series of cuts and after prolonged labor troubles. Such industries have arrived at an efficient system of management by a very strenuous and unpleasant process, and the adoption of scientific management would not always bring notable advantages. On the other hand, most industries are not in this class. The character of the labor employed, the quantity and character of the output, the kind of machinery used, and the kind of material supplied, is continually changing. In the first class of industries a process of evolution extending over two or three generations has established the best methods of management. In the second class of industries the best methods are continually changing as conditions change.

In most industries, the introduction of scientific management promises to effect great gains, and to greatly increase the efficiency of our whole industrial system. Scientific management has been applied to many different kinds of work, and seems to be almost if not quite universal in its applica-

* For articles relating to scientific management previously published in MACHINERY, see "Scientific Management from a Social and Economic Standpoint," June, 1912; "Industrial Efficiency," May, 1912; "Helping a Man to find his Place," May, 1912; "The Efficiency Engineer," February, 1912; "Saving Time in Machine Work," February, 1912; "Scientific Management in the Seventies," January, 1912; "Scientific Management of Arsenals," December, 1911; "Task Work—The Basis of Proper Management," December, 1911; "Scientific Management of Railway Shops," September, 1911; "Scientific Management and Economic Problems," July, 1911; "The Art of Cutting Metals," August, 1907; "The Utilization of Labor," April, 1907; "One Thing at a Time," January, 1907, and the series, "On the Art of Cutting Metals," from January, 1907, to August, 1907.

† Address: Department of Mechanical Engineering, New Hampshire College of Agriculture and the Mechanic Arts, Durham, N. H.

‡ Mr. Gilbreth has designated this form by the term "traditional".

tion. It has brought to light many problems in connection with industrial administration of whose very existence we were previously ignorant. Every time it is applied to a new set of conditions, even in the same industry, new problems are presented. If, in the near future, it is extensively applied to all industries or even to any one industry, it will give rise to very serious political, social and economic problems as well as intensify a great many of the problems that are now pressing for a solution. It will be seen, then, that the application of scientific management in industrial administration is not only important to the factory owner, the superintendent, and the workman, but to the law maker, the citizen and, in fact, to every man, woman and child in the country. The field of industrial administration is a very great one, but we cannot appreciate the importance of a right understanding of the problems which will be raised by the extensive introduction of scientific management until we realize how this field is interrelated with our entire political and social system.

An Example of Efficient Management

It is a fact which cannot be controverted, that very few shops in this country produce more than sixty per cent of the work which it would be possible for them to produce with the same wage roll and the same physical equipment. A few of the best managed shops produce probably eighty per cent of the work which it would be possible for them to produce, and occasionally departments in well managed shops reach an efficiency of over ninety-five per cent. On the other hand, there are numerous shops in this country which, without any considerable change in their equipment or increase in their wage roll, could produce from three to five times as much work as they put out at present. This statement, extraordinary as it may seem, is not the result of a wild guess, but may easily be verified by any one who will make a study of conditions in these shops. Some two years ago, the writer made a trip through southern New England inspecting some of the representative industries. The most efficient department that I ever saw was the grinding department of the Norton Grinding Co., Worcester, Mass. I do not know that the engineer, Mr. Norton, made a conscious attempt to install the system developed by Mr. Taylor, but I do know that by a careful study of the work of this department he has raised the standard of efficiency so that every man that I saw was employed continuously in producing a very high class of work with a rapidity that was astonishing, and by methods which the average shop foreman would say were impossible. In conversation, Mr. Norton emphasized the necessity of a careful study of shop problems and stated that such problems were worthy of attention from the most highly trained engineers. Although he never once used the term "scientific," it was quite evident that his study was scientific in the best sense of that term, and that no single problem which had presented itself in his grinding department ever escaped a most thorough and searching investigation. I shall always remember this department of Mr. Norton's works as one of the finest examples I have ever seen of excellent management, and also I shall always remember the type of employe which I saw in that department as a representative of the very finest type of the American mechanic. Every man seemed to be a man of unusual intelligence and skill and seemed to be putting into his work that indefinable something, which for lack of a better term we designate as "brains."

A third matter which attracted my attention was the fact that Mr. Norton seemed to be personally acquainted with every man working in that department; seemed to know their especial abilities and the work for which they were best fitted, and seemed to take great interest in seeing that each man was doing the kind of work for which he could realize the highest pay. So far from adopting the attitude of the average employer, who is inclined to think it a matter of good business policy if he can drive a sharp bargain with his men, and obtain a day's work for a minimum wage, Mr. Norton spoke with pride of the unusual earnings of several of his men who were working under a premium system.

An Example of Inefficient Management

At another time I visited a concern in which it seemed to me that the majority of the men were doing absolutely nothing that was useful. This concern was one of the largest ship building yards of the Atlantic coast. I had no opportunity to talk with any of those responsible for its management and therefore cannot say what attitude they adopted toward various questions of administration. There did, however, seem to be a dearth of foremen, and as in the time of the Judges in Israel, "every man did that which was right in the sight of his own eyes." I remember seeing one man who was engaged in chipping a plate with a pneumatic hammer, and he had two assistants whose duty seemed to be to drag the air hose after them and carry his hammer as he went from place to place. At another place I saw a man measuring a plate and marking upon it an opening which was to be made in a bulkhead, with five or six workmen lounging around him doing nothing. Most of the work of the establishment seemed to be conducted in that manner, and altogether, it was the most disgusting exhibition of shiftless management that I have ever seen in my life. The matter was so apparent that several students who were with me at the time called my attention to it, although they were men unaccustomed to shop administration and most of them were men totally unfamiliar with methods of shop work.

Administration of Average American Shop

The administration of the average American shop is a mean between the slipshod methods of the shipyard and the careful and efficient methods of the Norton Grinding Co. In such a shop, such obvious inefficiency as I have described in the case of the shipyard, would be promptly squelched. On the other hand, in such a shop, careful investigation will usually show very great inefficiency in many departments although such inefficiency is not at first obvious. This inefficiency is due to a variety of causes. It may be that work is slack and the workmen are "nursing their jobs" in order to avoid discharge. It may be that they are prolonging an easy and agreeable task in order to avoid being assigned to a more difficult and disagreeable one. It may be that illness or unsanitary shop conditions have deprived the workman of a measure of his usual energy and ability. In many shops, inefficiency has nothing to do with the workmen, but is entirely chargeable to the management. All of the men appear to be busily employed and the work to be carefully conducted, but at the same time, the type of machines used, the sequence of operations employed, the conduct of the toolroom, or any one of a dozen different things for which the management is or should be directly responsible, greatly reduces the efficiency of the shop.

The writer was once employed by a firm that manufactured small steam engines for the oil trade. Each of these engines was equipped with two flywheels weighing about 600 pounds apiece and the only machine work done upon the wheels consisted in boring the hub, reaming it, and cutting the keyway. I was employed to bore the hubs, which was done upon a homemade machine having a stationary spindle and a revolving table. There was a crane which was used to place the wheels upon the table, but before the wheels could be lifted by the crane, they had to be brought about 500 feet from that part of the yard in which they were stored after being cast. I was instructed to get another apprentice who was named Gus, to help me roll them from the storage yard to a point under the crane. During this time, both my machine and Gus's machine were idle, since they were of a character which required constant attention. This job had to be done several times a day, and I doubt if those two machines were running more than half the time.

As I remember conditions in that shop, I can see that there were endless possibilities of increasing the output by improving the methods of management. Nevertheless, to one who is not in the habit of thinking about the possibilities in this line, the shop appeared to be busy and well managed. It was conducted by a foreman who had an excellent reputation and who was supposed to know "how to get out the work." He was a man of considerable experience and knew about how much time certain work would take when done by the average

machinist in the average way. Most shops would have considered him a valuable acquisition, and in a great many shops he would have introduced notable improvements. The ship building company I have already described would have been fortunate had he taken their affairs in hand, but any department managed by him would have made a sorry showing alongside of the grinding department of the Norton Grinding Co. He employed the usual methods of conventional management, that is, he allowed his men to choose their own methods of doing work, and then eliminated those men or those methods which were obviously incompetent or inefficient. He was not at all versed in the scientific plan of finding the methods of greatest efficiency, and of applying them in the administration of his department.

Misapprehension of Principles of Scientific Management

I have heard a good many men say, in regard to scientific management, that they have managed their affairs scientifically without knowing that they were scientific. However, when I have come to talk over the matter at length with them, I find that what they mean is that some of the inefficiencies not usually obvious had become apparent to them, and that they had adopted some of the methods of scientific management in attempting to eliminate the inefficiences which had come to their attention. This is a very different matter from installing a system of scientific management, although the efficiency of a good many plants has been greatly increased in this manner. However, the men of whom I speak do not understand what scientific management is. They think that scientific management is a collection of best methods, that it necessarily involves the use of certain kinds of blanks and records, or that it is a form of organization, a method of wage payment, or something of that kind. Of course such things are employed in scientific management, but they are only the tools which it uses, and just as a carpenter will change his tools for different kinds of work, so scientific management will adopt different methods, different forms, or different plans of organization, as conditions change.

A great deal of harm is likely to come from the unintelligent employment of some of the methods of scientific management by such men, even when they are acting in the best of faith. The introduction of some of the methods will often cause antagonism among workmen, and they will sometimes prove inefficient under new conditions. In either case scientific management is blamed for the failure, when, as a matter of fact, scientific management would probably have employed other methods under the given conditions. *Scientific management must not be confounded with its forms or its methods*, just as a man must not be confounded with his clothes, or a religious creed with its form of church organization.

Methods under Different Types of Management

It will help us in our consideration of different types of management, if we take a concrete example and note the differences of the several types, as they appear in the example. Let us suppose that a piece of lathe work is to be done, such, for instance, as the turning of a crankshaft. In the conventional type of management the foreman will assign such a job as this to the first man having a vacant machine in which it can be conveniently performed. Systematic management will usually do the same thing. Scientific management, on the other hand, will assign the piece of work to that machine in which it can best be performed.

Having received the work, under conventional management, the workman will determine the plan of procedure, will choose and grind his own tools, and will proceed to work, using those feeds, cuts, and speeds which he thinks will be the most satisfactory. In case the workman is receiving day wages, the pace of the work will depend upon the foreman. As the foreman goes about the shop, he will occasionally take notice of the condition of the work and the way in which it is being performed. If the workman is obviously incompetent or inefficient, the foreman will instruct, reprimand, or discharge him, as his judgment will warrant. On the other hand, if the work appears to the foreman to be going forward at a reasonable pace, nothing will be done.

In case the workman is being paid by some piece-work or premium plan, he will be anxious to earn as large a wage as possible and therefore will attempt to determine the best cuts, feeds, and speeds for the work in hand. There are two methods open to him for doing this. One is to guess at the best conditions and the other is to experiment until he has determined them. The first method, of course, leaves much to be desired. The second method is open to the objection that it takes a considerable number of experiments to determine the best conditions of work, even when the experiments are confined to the performance of a certain job on a certain machine. The workman is rarely, if ever, able to devote the necessary time to such experiments, and he has not the training which would enable him to properly perform and record them. With the facilities which he usually has at hand, it is impossible for the average workman to do any more than gradually improve his performance by careful attention to his methods of work.

Conventional management determines the time required to do a piece of work, or the piece-rate to be paid for it by one of two methods. The first method is for the foreman or some other experienced person to guess at the time required to do the work. The other is to put a capable and conscientious workman at the work and see how long it will take him to do it. Of course the guess of the foreman is about as good as the guess of the average drummer would be if he tried to estimate the population of a village while he was riding through it on a train. The other method of allowing a pace maker to determine the piece-rate is a better one. Since, however, the pace maker usually does not have the opportunity of making a careful study of the best methods of performing the work, his time allowance will usually be too large.

Systematic management, like conventional management, leaves the method of performing the work entirely to the workmen. It does not, however, leave the question of the proper pace to the foreman. The records of previous performances have established a pace and the management can readily determine whether or not the work is being conducted at the best pace of which there is previous record. If it is not, the foreman is notified and the workman is obliged to increase his pace. He may do this in one of two ways. He may experiment in order to determine the possibilities of the work, or he may go to someone who knows more about it than he does for assistance and instructions in regard to feed, cuts, speeds, and methods. In either case he is nagged into bringing up his pace to that of the previous man, and in this way the production is kept up to the best previous record.

Under scientific management, the sequence of operations, the cuts, feeds, and speeds, the tools and appliances, and the methods of work are determined by the management and not by the workman. Before the work is commenced, a specialist considers all the possible methods of doing the work and after carefully analyzing them determines which of these methods are the best. Having fixed upon the methods of work, a time allowance is then established for each operation. A typewritten or blueprinted instruction sheet is then prepared which informs the workman exactly what he must do, and how long it should take him to do it. Instead of grinding his own tools, he receives a supply of properly formed and ground tools. Instead of depending upon the foreman or upon previous records for establishing the pace of work, the time required to perform each of the several operations is exactly known. The whole series of operations has been subjected to a careful analysis, every possible variation has been considered, and the methods developed are not only good ones, but are the best possible ones, considering the limitations of that particular shop.

In order to accomplish the best results, not only must the workman receive an instruction sheet, but he must be shown how to perform many operations. One of the officers of administration is, therefore, the teaching foreman, who makes it his business to instruct the men in the proper ways of doing work and who is always ready to come to the aid of those men who are unable to perform their tasks in the allotted time.

In order to encourage the workman to follow the proper methods of work and to perform his task in the allotted time,

a piece-work, premium, or bonus plan is adopted for the payment of wages. The plan which seems to give the most satisfaction is known as the Gantt bonus plan. This consists in paying the man a certain definite percentage of his daily wages as a premium whenever he performs his task within the allotted time. If his task, for instance, consists of ten pieces a day, and he succeeds in making ten or more pieces, he will receive from twenty to sixty per cent additional wages as a premium. In case he produces less than ten pieces, he receives the regular day wages, but no premium. A man's earnings are computed each day and he knows on the morning of the following day whether or not he has earned the premium. If he has not, it is the duty of the teaching foreman to go over his work with him and instruct him in those points in which he may be deficient. In order to make sure that this teaching is thorough and effective the teacher receives as a bonus a fraction of the bonus earned by his workmen and in case all of his workmen earn bonuses, the teacher receives an extra bonus. It will readily be seen that with such a system of wage payment, thorough instruction and cooperation are the invariable order of the day, and that the foreman as well as the workmen are always on the lookout to see that the tools, machines and stock, are all in perfect condition.

Not only does the man receive adequate instructions, and a reward for obeying these instructions, but he is offered every reasonable facility for doing his work quickly and well. He does not have to spend his time hanging around the smithy or the toolroom getting the things that may be needed for his work. He spends no time repairing his machine, taking up the belts, or fixing the tools supplied to him. The management makes it its duty to see that nothing hinders him in his work so that his entire time and attention may be devoted to the performance of, and not to the preparation for, that work. This requires that certain assistants shall perform tasks which conventional management usually delegates to the workman himself.

Collecting Data Necessary for Scientific Management

It will be apparent from the foregoing, that instead of depending upon judgment, scientific management depends upon knowledge, in its task of administration. Judgment is the instinctive and subconscious association of impressions derived from previous experience. When a man's experiences are wide, his impressions of them are correct, and his memory is good, his judgment will be good. But even the best judgment falls far short of knowledge, and any system of administration based on judgment alone must fall short of scientific management. Judgment will always have its place in any system of administration for two reasons, firstly because knowledge cannot always be obtained, and secondly because it may sometimes cost more to obtain it than the knowledge is worth. In either case judgment is valuable, if not absolutely necessary. But at the best, judgment is only a guess and not to be relied upon if accurate information is available. Not only does scientific management depend upon knowledge, but this knowledge is carefully and systematically collected and the data so obtained are classified and digested until the knowledge is instantly available whenever a problem is presented to the management. Back of the form of organization is a knowledge of the needs and the work of the plant. Back of the plan of wage payment is a knowledge of psychology and sociology. Back of the instruction sheet is a knowledge of the sciences of cutting metals and of handling work. As examples of the way in which such knowledge is obtained, let us take the two subjects last mentioned, and see what scientific management has done to develop the sciences of cutting metals and of handling work.

Most readers of these articles are doubtless familiar with the paper of Mr. F. W. Taylor on the art of cutting metals, which was published in abstract in many of the technical magazines shortly after it was delivered, in 1906. The work described in this paper is probably the best example of the scientific study of methods of manufacture which has ever been made. Mr. Taylor and his associates at the Midvale and Bethlehem steel companies were engaged in the work for nearly twenty-six years, and during that time made many notable discoveries in the line of their work. One of the most important of these was the discovery of high-speed steel; which is, at a very conservative estimate, worth fifty million dollars per year to the machine industry of this country. Other no less important but less spectacular results were the discovery of the best forms for cutting tools, the invention of a slide-rule for the determination of proper cutting speeds, and the resulting developments in the form, rigidity, and power of machine tools.

In making this investigation suitable machines were prepared and after establishing certain standards in regard to the kind of material to be cut, the form and chemical composition of the cutting tools, and the length of time which the tools must run without regrinding, a very elaborate series of tests was made. The object of these tests was to determine the maximum permissible speed of cutting with different feeds, depths of cut, kinds of tool steel, forms of tools, classes of material, and conditions of work. There were in all twelve conditions affecting the cutting speed, each of which could be varied. Some of these could be varied over a very wide range, and every time one of the conditions was altered a large number of experiments was necessary in order to determine the permissible cutting speed. It is obvious that in such a complicated problem as this, thousands of experiments were necessary before it could be solved. As fast as experimental data were collected, the results were worked up in order to determine the mathematical laws governing the cutting of metals. Since these laws were found to be extremely complicated, and since, if the work was to be practical, quick and simple methods of solution had to be devised, a great deal of time and effort was spent in devising methods for determining the proper cutting speeds for any given conditions. Finally after many years of work, a slide-rule was invented which gave a quick and accurate solution of the problem.

This investigation was probably the most important investigation of the kind ever attempted. It was very thorough, requiring a period of twenty-six years for its completion. The total cost is stated to have been $800,000. The results, in which every metal working shop in the country has shared, are unquestionably worth one hundred million dollars a year. Hardly one manager out of one hundred, probably not one mechanic out of a thousand, realizes the immense value and scope of the improvements resulting from this investigation. They rank in importance with the development of the steam engine, the railroad and the printing press. There are equally great opportunities for a dozen, possible one hundred investigations of like character in other industries. It is to be hoped that they will be soon commenced and that they will be prosecuted with the same energy, tenacity and intelligence with which this investigation was so greatly marked.

Motion Study and Analysis

The method employed in determining the best way to handle work is known as "motion study." Motion study is almost a science in itself, and is really a branch of applied psychology. Motion study is not peculiar to scientific management, but has long been utilized by athletes in their endeavor to improve athletic records. A high jumper, for instance, will carefully train himself to do his work in a certain way, taking a certain number of steps in running up to the bar, throwing his limbs and body in a certain position as he jumps over the bar, and endeavoring in every way to develop that smoothness and machine-like precision of action which characterizes what he terms "form." The hurdler does the same thing, day after day making trial of different methods of running and jumping, timing himself by the stop watch, in order to achieve the most perfect form.

The same sort of study can be employed to advantage in training workmen to perform their tasks, when the tasks are repetitive in character. There is, however, one very great difference between motion study for the athlete and for the workman. Whereas the athlete strives to perform a task which taxes his strength and endurance to the limit, the workman strives to develop that form which will enable him to perform his task quickly and with a minimum of fatigue. In the case of the athlete, he is striving to excel for one supreme moment. The workman, on the other hand, must be

trained to repeat his task, day after day, month after month, year after year, without injury to his strength or his health, because only in that manner can the industry in which he is engaged reach its maximum prosperity. It takes a more carefully trained observer and a far better understanding of men and their physical capabilities to train a workman to do a task quickly and well without over-exertion, than it does to train an athlete to perform his task quickly and well, where the question of over-exertion does not come in.

Any one who has ever had anything to do with athletics understands how impossible it is for a man without training to compete with the trained athlete. Just as it would be impossible for the average healthy and vigorous man to enter an athletic contest and do creditable work in competition with trained athletes, so it is impossible for the average workman to go into a shop and accomplish a creditable amount of work, in competition with a workman who has been properly trained after a motion study has been made of his task. In the same way, just as it is impossible for the average man who likes to look at the stars, to predict the time of an eclipse or the future configuration of the heavens, so it is impossible for the average machinist to compete with the trained engineer who has at hand a slide-rule which will tell him exactly the cuts, feeds and speeds, which it is possible to employ with a given class of material and a given machine. We find it advisable to employ designing engineers who have spent years in studying the strength of materials and the sciences upon which engineering depends. It is equally advisable to employ another class of engineers who will study the principles of management, and methods of doing work.

So far we have only touched on two points in regard to the turning of our crankshaft, namely motion study and the science of cutting metals. There are a dozen other branches of science involved in the direction of the shop, all of which are used by scientific management in furthering administration. When we consider these things, it becomes apparent that in many industries the introduction of scientific management will completely revolutionize methods of work, methods of administration, and even methods of selling the product and of financing the industry.

It will be seen from what has just been said that scientific management is by no means a simple matter, that it requires forethought and care in its application, and that, above all things, it requires the scientific spirit in order to make it successful. It will also be apparent to every one, that while scientific management will very probably greatly increase the output per man or per machine, the staff which it requires for the planning of the work, for the conducting of experiments, and for keeping workmen supplied with material and tools, will be quite an expensive one. The question of whether or not scientific management is profitable, and therefore practicable, will hinge upon the question of whether the savings which scientific management will effect, will pay for the staff which it is necessary to maintain. In my opinion, the savings will usually be more than sufficient to pay for the extra cost of scientific management, although sometimes they will not. The application of all of the methods and machinery of scientific management to the pattern-shop, where every job is different and where the principal part of the work consists in planning rather than in executing, will not usually be a success. On the other hand, where scientific management is applied to repetitive work, there is no question but what the cost of maintaining the staff will be but a very small fraction of the savings which will result.

* * *

During the past year 29,353 applications for patents were filed in Great Britain. Of the foreign applications those from Germany and the United States were most numerous; 3304 applications were of German origin, while 2670 were received from residents of the United States. The United Kingdom, of course, contributed the largest number, or 19,579 applications. During the year, five applications were filed for the revocation of patents not worked to an adequate extent in the United Kingdom. Two of these applications were granted; in one case the application was dismissed; in one the patent expired during the proceedings; and the fifth case is pending.

A BALL RACE GAGE

The accompanying illustrations (Figs. 1 and 2) show a ball race gage, which is used in the works of the Cadillac Motor Car Co., Detroit, Mich., for gaging the diameter of the ball race in a ball retaining ring. Two of these rings form a thrust bearing to reduce the thrust on the main drive shaft of an automobile. As shown in Fig. 2, this gage consists of a cast-iron stand *A* in which a hardened and ground steel ring *B* is retained. The top portion of this ring is made a good fit for the inside diameter of the ball-retaining ring *C*, which when being gaged is simply slipped over the top portion of ring *B*. A stud *D* held to the base by a nut, as shown, is slotted to receive the gage frame *E*. Stud *D* is hardened and ground, and the plate *E* has a reinforced piece *F* held to it by rivets, the latter being hardened and ground and made a good fit in the slot in the stud. The fulcrum of the pointer or needle *G* is so disposed that any variation in the work is magnified twenty-five times at the point where the reading is taken. A knurled handle *H* is fastened to the gage for convenience in holding it.

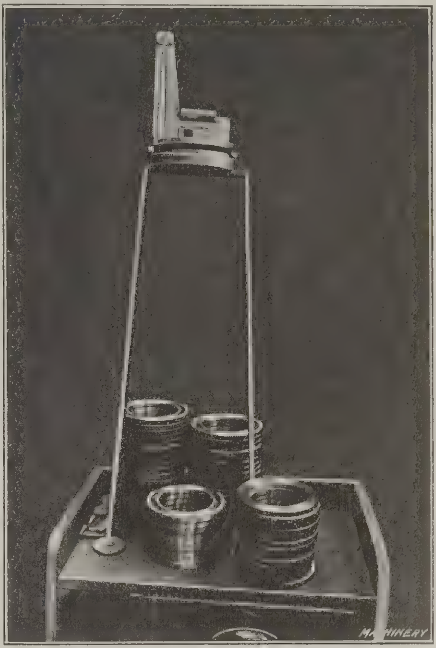

Fig. 1. Ball Race Gage in Use

In operation, the work is slipped over the ring *B* of the gage as shown in Fig. 2; then the gage frame *E* is placed in the slot in stud *D* and the gaging knife-edge rollers *I*, which in this case do not rotate but are held rigidly to the frame, are placed in the ball race. The position of the measuring point

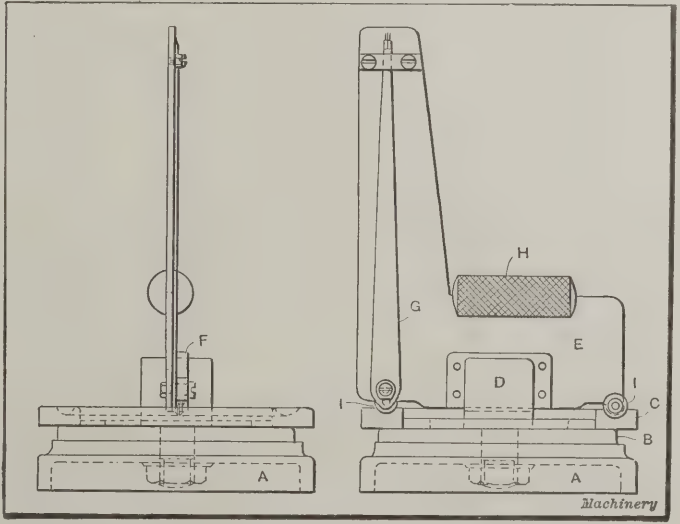

Fig. 2. Construction of the Ball Race Gage shown in Fig. 1

of the needle is then noted to see if the race is of the required diameter. A limit of 0.001 inch is allowed on the diameter of the ball race, the latter being 4.125 inches in diameter. The race is ground on a Brown & Sharpe generating grinder. As shown in Fig. 1, the base of the gage is fastened to a frame which is of sufficient height to bring the ring to be gaged in line with the operator's vision.

Bolts, cap-screws, or nuts, when used in connection with cored holes, should be supplied with washers for providing sufficient bearing surface for the nut or head.

THE EXTRUSION OF PLASTIC METALS*†

Although it had been found possible as early as 1850 to extrude such metals as lead and tin and thus form pipes and bars, the extrusion process had not, at that time, been successfully applied to the shaping, by means of extrusion, of such metals as copper, delta-metal, etc. It was when Alexander Dick, the inventor of the delta-metal, made some experiments with this material under high pressure and at high temperature, during the latter part of the eighties, that it was first shown that this material could be extruded in a heated state. There were, however, several difficulties to overcome. The extrusion process, as is well known, consists of hot plastic metal being pressed through a form or die at high pressure, so that a continuous bar or pipe of the cross-section of the die or form is produced. Lead and tin can be extruded at comparatively low temperatures (250 degrees F.), but copper and similar metals require temperatures all the way up to 1750 or 1800 degrees F.

The main difficulties to be overcome are to maintain the high temperature and plasticity of the metals during the extrusion, and to make press cylinders and dies which will be able to withstand the effect of the high temperatures and pressures. The first condition was met by Dick by filling

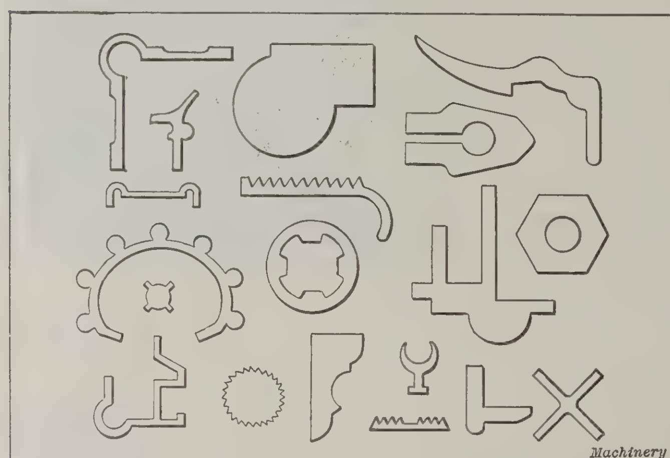

Fig. 1. Some Interesting German Products of the Extrusion Press

the press cylinder with molten metal and by surrounding it with heat insulating material, such as ground granite. In order to prevent the heated metal from forcing itself between the plunger and the cylinder, when the pressure was applied, a spherical steel piston was employed which spread when the pressure was applied, and in this way effectively closed the cylinder behind the metal.

The advantages of the extrusion process, as compared with the ordinary rolling and drawing process, soon became apparent. The extrusion process permitted parts of unusual cross-section to be produced in great quantities. In fact, sections could be extruded which could not be rolled under any circumstances. In Fig. 1 is shown a number of special sections which have been produced by extrusion. On account of the high pressure under which the metal is extruded it becomes more compact and its strength is increased. The extruded shapes, therefore, possess those qualities which make them especially useful in machine design. The surfaces are smooth, and free from flaws and other defects. The dimensions of the extruded shapes can be gaged with great accuracy, so that they may be used either directly or with very little additional finishing. After the advantages of the new method had become known, it was soon adopted and further developed by many different individuals and concerns.

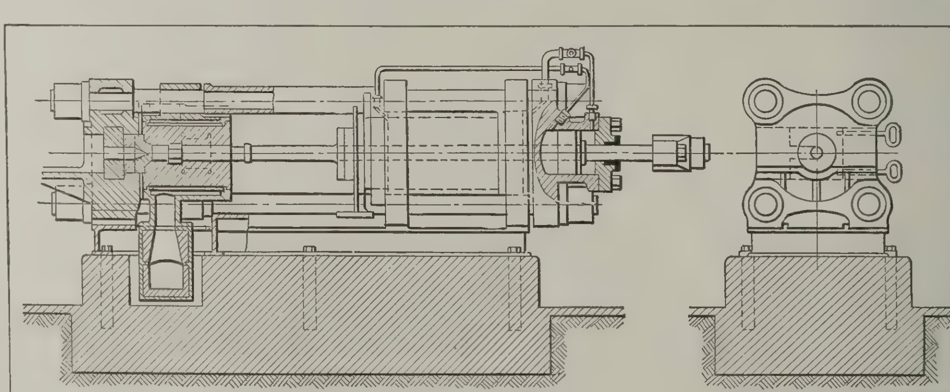

Fig. 3. General Arrangement of Krupp Extrusion Press

Instead of pouring the molten metal into the press cylinder, it was found to be better to have it cast into blocks which were heated to a white heat and inserted in the press. In this way the time required for the setting of the metal in the press cylinder was saved, and the efficiency of the machine considerably increased. Further developments resulted in the perfecting of the press, and the metals used for the cylinders

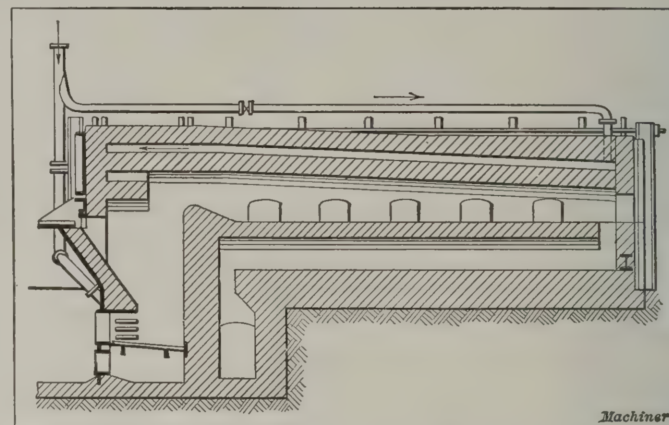

Fig. 2. Section through the Heating Furnace

and the dies. In order to retain the heat within the cylinder it was surrounded by a jacket and heated by special means. Several new presses were brought out, and besides the Dick press, those best known in Germany were built by the firm of Friedr. Krupp A.G., Grusonwerk in Magdeburg-Buckau. The object of this article is to describe the methods and processes used in connection with the machine. The complete installation consists of a foundry for producing the metal blocks, a heating furnace, and a hydraulic press and pumping arrangement.

The Casting of the Metal Blocks

The metal blocks are cast in long sections and are afterwards cut up into pieces of suitable size for the presses. The blocks are cast in permanent molds, and in order that as smooth a surface as possible may be obtained, it is necessary that the inside of the mold be of a close-grained metal, free from flaws. In order to still further insure against blow-holes or porous parts in the cast blocks, the molds are covered on the inside with a preparation, the same as is done in the casting of copper and brass in general.

After the blocks are cast and cut into parts, they are inspected for defects, and any burrs or fins that may be present are removed by chisels or scraping. Special care must be used in producing hollow parts for pipe. In this case, it is especially important that the core be central with the outside, in order that homogeneous walls of uniform thickness may be obtained in the extruded pipe.

Heating the Metal Blocks

The metal blocks are heated in a special furnace which should be placed close to the extrusion press. The important feature about the heating is that the block must be heated clear through to the center, and not be brought to the press when merely the surface has been brought to the required temperature. A furnace used for heating the blocks is illustrated in Fig. 2. The blocks are inserted at the end opposite

* Abstract from an article by Friedr. W. Siepke, of Magdeburg, Germany, in *Werkstattstechnik*, April 15, 1912.
† See also "An Experiment in Extrusion," MACHINERY, June, 1912, engineering edition, and other articles there referred to.

the grate, and roll by gravity down the somewhat inclined surface toward the fire-box. When the required temperature is obtained, they are pulled out through an opening at the side. In order that good results may be obtained in the extrusion process, it is important that the blocks do not come in contact with the brickwork of the furnace. The surface on which the blocks rest is, therefore, covered with a cast-iron plate. The length of the furnace is made to suit the capacity and speed of the action of the press. The width is usually made about three feet. The heated blocks are most conveniently transferred from the furnace to the press by means of an overhead trolley.

The Hydraulic Extrusion Press

The hydraulic extrusion press shown in Fig. 3 is of the horizontal type. The press consists mainly of the hydraulic cylinder, the dies, the pressure chamber or extrusion cylinder, and a head which holds the dies. Four heavy connecting bars tie this head to the hydraulic cylinder. The pressure chamber is located between the head and the hydraulic cylinder and moves on four guide bars.

These presses are built in two sizes, the main dimensions of which are given in Table I. The output of the presses varies according to the size and form of the cross-section of the different extruded shapes. With trained operators and simple cross-sectional shapes, it is possible to extrude about 20,000 pounds of metal in ten hours in the small-size press and 35,000 pounds in the larger press. This output cannot be obtained, however, when tubing of difficult sections is being extruded. The figures given above correspond to two hundred press operations in ten hours. In order to be able to maintain this efficiency the press chamber must be sufficiently heated at the beginning of the work and there must be no interruption in the operation. For the complete installation required for one press, four men are necessary, one of whom works at the furnace.

Details of the Hydraulic Press

The hydraulic cylinder is made of steel casting and lined on the inside with a copper bushing. The pressure chamber is made of so-called "Krupp special" steel which even when heated has a high tensional strength. This chamber or cylinder is forged and is provided with a jacket of steel casting. Between the pressure chamber and jacket an open space is provided through which the heated gases from the fire-place arranged beneath the pressure chamber can pass. By this means the chamber is heated to the required temperature, the gases from the combustion escaping through a pipe

TABLE I. GENERAL DIMENSIONS OF EXTRUSION PRESSES

Dimensions	Smaller Size	Larger Size
Total pressure, pounds	1,430,000	2,200,000
Maximum pressure, pounds per sq. in.	3770	4125
Diam. of hydraulic cyl., inches	22	26
Stroke, inches	$27\frac{1}{2}$	$31\frac{1}{2}$
Diam. of extrusion cyl., inches	$4\frac{5}{8}$	$5\frac{1}{2}$
Max. diam. of extruded bars, inches	2	$2\frac{1}{4}$
Required horsepower	100–150	175–225

above the pressure chamber into the chimney. The required temperature to which the pressure chamber should be heated by external means is about 600 degrees F. This heat is required so that the metal blocks which are heated to some 1650 or 1800 degrees F. may not be suddenly cooled. Should sudden cooling take place, the surface of the metal block may lose its plasticity and the extrusion may either be unduly delayed or be made entirely impossible. The high temperature of the walls of the pressure chamber, while the extrusion takes place, requires an especially high quality of metal, and it has been proved in a number of instances that forged Krupp special steel answers the requirements better than any other known material.

In order to prevent too high a pressure in the hydraulic cylinder, a safety valve is provided on the pump which opens at a pressure of about 4500 pounds per square inch. In order to instantly relieve the pressure in the hydraulic cylinder, a releasing valve is inserted between the pump and the controlling valve on the machine.

The dies containing the shape for the extruded form are held in the head. This latter takes the pressure during the extrusion process. One of the greatest difficulties in the past with machines of this type has been to remove the remainder of the metal block in the pressure chamber when operations are suspended or when practically all the metal has been extruded. Part of the metal would usually be pressed in between the joints, solidify and make the removal of the various parts difficult. In the Krupp press this difficulty is taken care of as follows: As already mentioned the pressure chamber is placed between the head and the hydraulic cylinder, but is movable on four guide rods. A tapered hole is provided in the pressure chamber in the end towards the head, and the dies are formed with a corresponding taper. An auxiliary hydraulic cylinder is provided at the right-hand end of the press in Fig. 3, and the pressure chamber is connected with

TABLE II. INFLUENCE OF THE EXTRUSION PROCESS ON THE PROPERTIES OF METALS

Metal	Cast		Extruded	
	Tensile Strength, Pounds per Square Inch	Elongation, Per Cent	Tensile Strength, Pounds per Square Inch	Elongation, Per Cent
Copper	28,500	35	34,000	38–40
Zinc	27,000*	12	35,000	38
Magnalium	43,000–64,000	5	53,000–71,000	10
Aluminum	14,000–17,000	3	33,000–38,000	4.3
Delta-metal	83,000	11	98,000	21.8
Durana-metal	58,000–74,000	35	60,000–81,000	38

[* The tensile strength of cast zinc is given by several authorities at about 3500 pounds per square inch, and that of rolled zinc at about 16,000 pounds. The strength of cast zinc given in the table is 70 per cent greater than for rolled zinc, which seems to be a very high and doubtful value.—EDITOR.]

the piston of the auxiliary cylinder by means of a cross-head and two connecting-rods. By this means the pressure chamber can be operated. Before the beginning of the extrusion, the pressure chamber is forced against the die by means of this auxiliary cylinder, and due to the tapered hole and the tapered end of the die a very close-fitting joint is provided, so that the metal, during the extrusion process, cannot enter between the two surfaces. At the end of the extrusion, the auxiliary cylinder operates the pressure chamber in the opposite direction, thus opening up a space between the die and the pressure chamber and making it possible to easily remove the remaining metal from the top of the die.

The press can be operated with considerable rapidity. For simple shapes, it is possible to go through the complete cycle of operations for one metal block in three minutes, this time being divided as follows: Putting the metal block into the pressure chamber, 1 minute 25 seconds; extrusion, 50 seconds; opening up the space between the pressure chamber and die, 10 seconds; removing the remaining metal, 15 seconds; and returning to the original position, 20 seconds. The effect of the extrusion process on the tensile strength of various metals is indicated by Table II.

* * *

Franklin H. Wentworth, secretary of the National Fire Protection Association, stated at the meeting of the New England Foundrymen's Association, April 10, that out of more than 11,000 fires under automatic sprinklers, of which the association had records during the past fifteen years, there was not a single instance where the automatic sprinkler, when of standard approved make and installation, had failed to put out or hold in check a fire under it, except in cases where the system had been tampered with, or crippled by an explosion.

* * *

Undoubtedly many (accident) prevention appliances in use in Germany might well be adopted here, but the real and important difference is not in the prevention apparatus—it is in the prevention spirit. In Europe, and especially in Germany, accident prevention is kept constantly before the public, before the legislatures, before the employers, and before the workers.—*F. C. Schwedtman in "Accident Prevention and Relief."*

DETAILING CRANE GIRDERS WITH CURVED LOWER CHORDS*†

By CHARLES B. GILBERT‡

The detailing of crane girders with curved lower chords—that is, of the fish-belly type—sometimes involves considerable labor. The tables given in the accompanying Data Sheet Supplement were, therefore, compiled by the writer about three years ago, and have been used by the structural detailers of the Niles Crane Works, of Philadelphia, Pa. The tables have been carefully checked and have been in use so long that it is assumed that all errors have been eliminated. The tables have proved of great value as time savers when figuring the depth of curved girders, half the span being divided, for convenience, into five or ten equal spaces for spans of different lengths. A glance at the accompanying engraving Fig. 1, will explain the use of the tables, a crane girder having a span of 61 feet 3 inches having been assumed as an example. The curved part has a span of 60 feet; one-half of this distance, or 30 feet, is divided for the convenience of the templet makers into ten spaces of 3 feet each. The end ordinate, assumed here to be 1 foot, will be found at the extreme left of the tables under the heading *H*. The lengths of the remaining nine ordinates follow in order.

For short spans, say about 30 feet, it is most convenient to divide the base of the curve into five spaces, as it is the usual practice to give ordinates about every 3 feet. In this case we would use only every other ordinate in the tables, or, beginning with the left-hand column, the ordinates would be as found in the columns headed *H*, 8, 6, 4, and 2.

The construction of the parabolic curve, while familiar to every student of geometry, may be of interest in this connection. In Fig. 2, divide the base *BO* and the height *H* into the same number of equal parts (ten in the illustration); draw straight lines from *O* to points 1, 2, 3, etc., on line *AB;* then draw vertical lines from points 1, 2, 3, etc., on line *BO*. The points of intersection between the lines 1 and 1, 2 and 2, etc., are points on the curve of the parabola. When the curve is slight, as is frequently the case in plain girder design, it is sufficient, on the drawing, to join the points by straight lines.

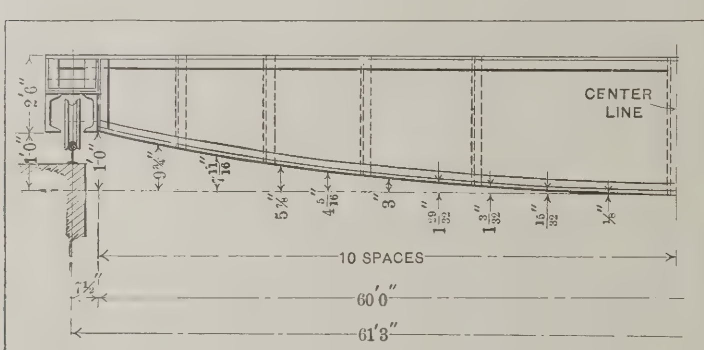

Fig. 1. General Lay-out of Typical Crane Girder

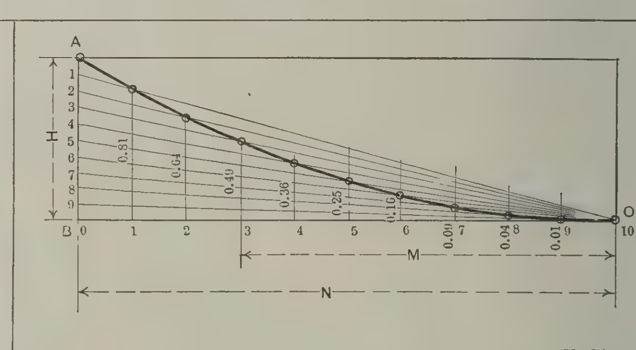

Fig. 2. Lay-out of Parabolic Curve, and Method of Calculating Tables

The tables in the Data Sheet Supplement are calculated as follows. In Fig. 2, let

H = end ordinate,
X = required ordinate,
N = number of equal spaces into which base *BO* is divided,
M = number of spaces from *O* to required ordinate.

Then,

$$X = H \times \frac{M^2}{N^2}$$

When $N = 10$, as in the case for which the tables are calculated, $N^2 = 100$, and

$$X = H \times 0.01\, M^2$$

Hence, ordinate No. 2 equals $H \times 0.01 \times 64 = 0.64\,H$. Ordinate No. 6 equals $H \times 0.01 \times 16 = 0.16\,H$, and so forth.

MAKING THE "UNIVERSAL" HACK-SAW BLADE

By CHESTER L. LUCAS*

The steel from which hack-saw blades are made is almost invariably a special grade of crucible steel, each maker having a preference for his own particular brand, the content of which he considers best for hack-saw blades. In making the "Universal" hack-saw blade at the West Haven Mfg. Co., New Haven, Conn., the steel comes to the factory in large sheets, and the first operation consists in cutting these sheets to smaller sections, each of which is wide enough to be cut

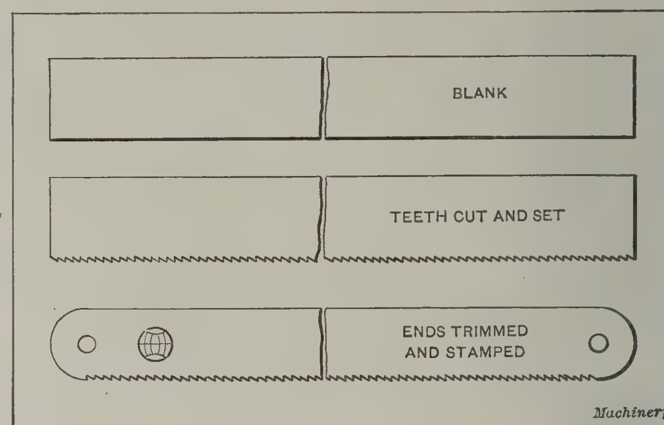

Fig. 1. Order of Operations in Hack-saw Blade Making

into blades of standard lengths, eight, ten or twelve inches. These sections are then cut into blanks for the individual saw-blades. The thickness of the stock and the width of the blank vary, of course, with the different lengths of blades being made. All of this cutting is done on square shears and it is essential that the shear-blades be kept in excellent condition so that the edges of the blanks will be square and free from burrs.

Cutting the Teeth

The blanks for the hack-saw blades are now in the condition shown in the upper view of Fig. 1, being merely blocked to size. Next in order comes the operation of cutting the teeth. Among hack-saw blades makers there are two distinct methods of cutting the teeth; by punching and by milling. The milled tooth is superior to the punched tooth, because milling leaves the sides and faces of the teeth perfectly sharp, while punching rounds one side of the tooth, thus impairing its cutting qualities.

Fig. 2 shows the operation of milling the teeth of "Universal" hack-saw blades. The work is done in plain milling machines, fitted with special vises for holding the thin blades, having "hold-downs" for the front jaws. The vise on the machine shown at the right is but partly filled with blanks, while the one at the left is completely full, and a cut is being taken across the work. The mirror-like appearance of the work is caused by the flooding of the oil over the work. The gang cutters used are made of high-speed steel, and it requires twelve or fourteen of them to make up the width necessary for the average cut. It will be noticed that in

* Associate Editor of MACHINERY.

mounting the cutters on the arbor, they are set one a little ahead of the preceding one, thus effecting a helical arrangement of the faces, the object being to distribute the cut.

These cutters are, of course, made for milling the various sizes of teeth. The number of teeth per inch varies from 14 to 32. Blades intended for cutting solids in iron and steel

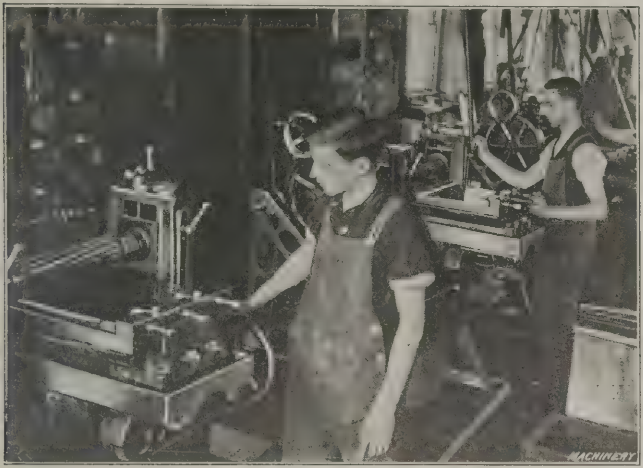

Fig. 2. Milling the Teeth

are usually cut with from 14 to 16 teeth; for general all-around work it is considered advisable to use 20 teeth. For soft brass, 24 teeth has been found better than a smaller number per inch, because there is less tendency to "hog in" and for thin tubing and sheet metal 32 teeth per inch is very satisfactory.

Setting the Teeth

The semi-completed hack-saw blade now appears as shown in the middle view of Fig. 1, and in this condition is ready

Fig. 3. Setting the Teeth

for the setting operation. There are two recognized methods of setting the teeth of hack-saw blades: one is by flat dies having a reciprocating motion, and the other, by rolls having a rotary motion. The machine shown in Fig. 3 is of the rotary type, and as the blades pass between the rolls, projections press the teeth alternately slightly upward and downward, thus giving the teeth the required "set." From the setting machines, the blades are passed to presses that clip the ends, punch the holes, and imprint the trademark upon one end. One of these presses may be seen in the foreground of Fig. 4, and in the background of the same illustration may be seen a battery of the milling machines that cut the teeth.

Hardening and Tempering

The hardening department of the West Haven Mfg Co. is located in a brick addition to the main factory and is exceptionally light and roomy for a department of this kind. The blades are treated by a special process that leaves them as hard as glass, and of extremely uniform hardness throughout.

In order to give them the required toughness, the blades are next tempered by immersing them in hot oil. Previous to this, however, they are packed loosely in an iron frame, similar to the vise used in milling the teeth. This frame has set-screws for applying pressure to the blades, against both the sides and edges. After placing the blades in the frame, and immersing frame and blades in the oil, they are allowed to remain there until the mass of blades has been brought to the temperature of the oil. After this, the screws of the frame are tightened upon the blades, thus bringing any that are bent or warped back into shape. It should be

Fig. 4. Milling and Punching Operations

remembered that this is done while the blades are very hot and still dripping with oil, in which condition they yield readily to the pressure from the clamping screws. The hack-saw blades are allowed to remain in the frame until they are cold, at which time those that were warped will have regained their original straight condition.

In order to reduce the brittleness of the pierced ends of the blades, the ends are dipped into a pot of molten lead. The lead in the pot is of the right depth so that when the bottom is touched, the ends of the blades will be immersed to the right distance. After this operation, the blades are cleaned and brushed free from scale and dirt, at which time they are ready for inspecting and packing.

Inspecting and Packing

Fig. 6 gives a general idea of the way in which "Universal" hack-saw blades are inspected and packed. The in-

Fig. 5. The Testing Room

spectors sit at well-lighted benches and successively try each saw for temper, at the same time inspecting them for poorly cut teeth and for soft spots that may be present. They are then wrapped in packages of twelve each, labeled and boxed for shipment.

From time to time, blades are selected at random from the different lots and tested for cutting qualities, after the manner shown in Fig. 5. They are tested for duration, for speed in cutting and for performances on various hard metals. The

Fig. 6. Inspecting and Packing

results of these tests are carefully recorded and thus the high standard aimed at in making "Universal" hack-saw blades is maintained.

INDUSTRIAL ADVANTAGES OF THE UNITED STATES

In the United States—a young, growing country—there has been, and still is, an unlimited demand for more highly developed industries. New manufacturing establishments are constantly under construction, and are usually equipped in the most modern manner. In Europe it is, with few exceptions, merely a case of remodeling old establishments. It is very easily understood that an old remodeled factory can never come up to the same standard or offer the same possibilities for manufacturing, as an establishment which from the beginning is planned after modern ideas. The familiarity with old established ways also tends to make difficult departing from old ideas and moving into new fields. The expense account is also a very important factor and should not be overlooked. Whereas a new shop will cost almost as much with an equipment partly copied after old ideas, as it would equipped in the most modern way, the old shop, modernized to the same extent, would have to stand the expense not only of the modern equipment, but of the old superseded one also. New buildings would in most cases have to precede the new equipment, as the facilities offered by old buildings are often so inferior as to make only half a success of the new departure.

The extent and population of the country makes the home market offered in the United States very large, as compared with the market available to the manufacturer in an average European country. This, in turn, makes possible a greater sub-division of labor. Even the smallest article can be manufactured on a large scale without looking for a market outside of the boundaries of the home country. In Europe, on the other hand, most firms of any importance have been, at least until a very recent date, compelled to go into a number of different lines of manufacture, as each line alone has an insufficient market to make the business pay the desired returns. This is a consideration of more than ordinary importance. Not only can an establishment manufacturing one article or one line of articles, secure a greater prestige in this certain line, and enable its responsible heads to gain a much greater experience in the particular line of work they have to direct, but a systematic arrangement of the work can be established, which is not possible in an establishment manufacturing many varied articles. This sub-division of labor, in the whole industrial field, as well as in the individual shops, has been the great cause of the systematic organization peculiar to American factories. This systematic arrangement, again, has made it possible for American shops to turn out, with the same number of men, a much greater amount of work in a given time than is usually turned out by the average European shop.—*From an address by Mr. A. L. Valentine, of Hartford, Conn., before the American Society of Swedish Engineers, Brooklyn, N. Y.*

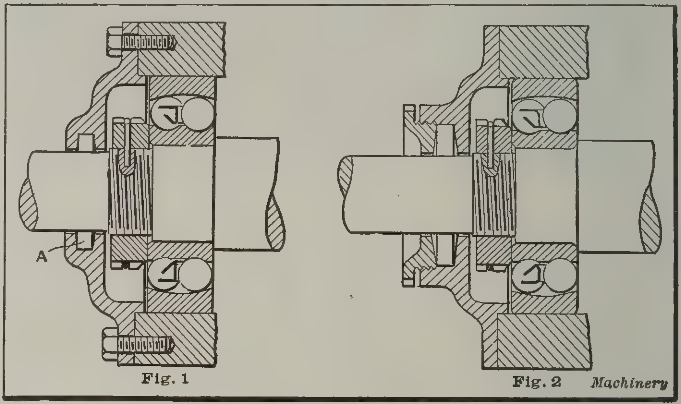
There is a distinction that makes a big difference between a smooth cutting file and a slick one.

THE MOUNTING OF BALL BEARINGS*

By F. H. POOR†

The method used for housing a ball bearing depends largely upon the nature of the machine to which the bearing is applied and the load and speed under which it is operated. One essential should always be kept in mind—ball bearings should in every case be kept clean, in order to give the best service. The selection of bearing caps for any given machine, therefore resolves itself practically into providing for sufficient protection of the bearings against grit or liquids which may be injurious to the bearing, and preventing the escape of the lubricant. The forms of end caps illustrated in the accompanying engravings have been designed for use in connection with the S. K. F. radial ball bearings and have been found satisfactory for general application.

The use of a single groove at *A*, as shown in Fig. 1, is generally sufficient. The grooves are cored to a depth of not less



Figs. 1 and 2. Cap Designs for Ball Bearings with Single Groove

than 3/8 inch and the edges of the lips are bored approximately 1/64 inch larger than the shaft. The width of the grooves and the lips must be determined with a view of providing sufficient strength and protection against abuse when installed. The use of a second groove in the end cap, as shown in Fig. 3, and sometimes a third groove, is recommended where machines are subjected to a great deal of dust, fine grit, moisture, etc. In this case it is customary to pack the outer groove with a felt washer or with a heavy grease, which will provide a frictionless packing. The groove for the felt

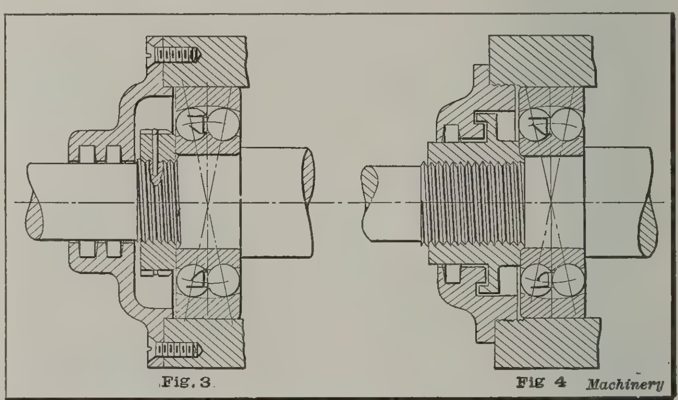


Fig. 3. Cap with Two Grooves. Fig. 4. Cap Design used where Bearing is exposed to Fine Dust

should be machine-finished. The groove adjacent to the bearing may be drained at the bottom to more effectually provide against leakage of the bearing lubricant. The return drain serves to keep the lubricant in circulation behind the sealing groove.

Caps of the type shown in Fig. 4 are too expensive to be considered except for extreme conditions, such as are found in high-speed grinders, cement machinery, etc., where protection against exceedingly fine dust is of importance. Fig. 2 shows a type of end cap, providing for a felt washer only, but

* For further information on ball bearings, see the following articles previously published in MACHINERY: "Some Notes on Ball Bearings," May, 1909, engineering edition, and also the articles there referred to. See also MACHINERY'S Reference Book No. 56, "Ball Bearings."

† Address: Care of SKF Ball Bearing Co., 50 Church St., New York.

having a tightening device to insure a tight fit of the washer on the shaft. This arrangement is applicable to low-speed bearings and is frequently used in automobile transmissions. In Fig. 5 is shown a plain end cap. Numerous means are used for securing the caps to the housings, and also for locking the retaining nut for the inner races. The G-shaped wire shown applied in the engravings, however, is generally considered the simplest form of locking device.

The fitting of bearings to shafts seldom presents any great difficulties. Inasmuch as the bearings are ground to very

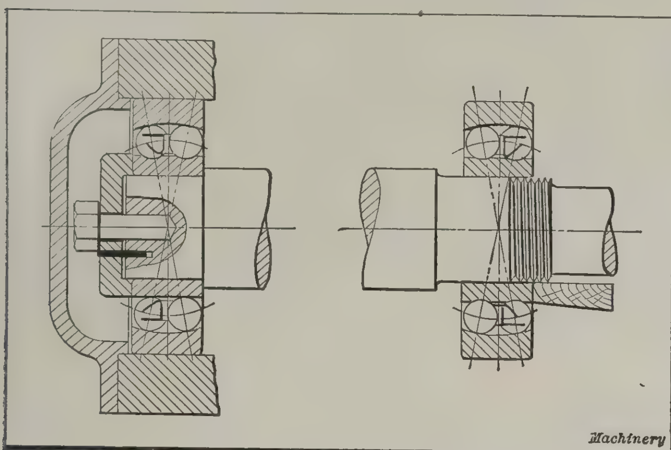

Fig. 5. Plain End Cap. Fig. 6. Using a Piece of Wood to drive Bearing into Place

close limits, the shafts to which they are to be fitted should also be accurately finished to present a smooth uniform seat for the bearing. The inner race should be a tight fit on the shaft and should be permanently seated in a fixed position against a shoulder on the shaft by means of a lock-nut or a distance piece. A driving fit alone should not be depended upon to properly retain the inner race in position, as the continued action of the load on the bearing will tend to peen down the shaft. A positive means for holding the inner race in position prevents creeping on the shaft and materially increases the actual bearing length on the shaft.

In order to obtain a proper light drive fit on the shaft, this should be finished slightly larger than the bore of the bearing, preferably within a maximum limit of 0.001 inch and a minimum limit of 0.0004 inch above the actual size of the hole in the bearing. If the shaft is made smaller, the bearing race will tend to creep and cut into the shaft, and if larger limits than indicated above are allowed, too great a force will be required to properly seat the bearing, with the added danger of cracking the inner race. It is easy to drive the race in place by heating it in oil to about 170 degrees F.

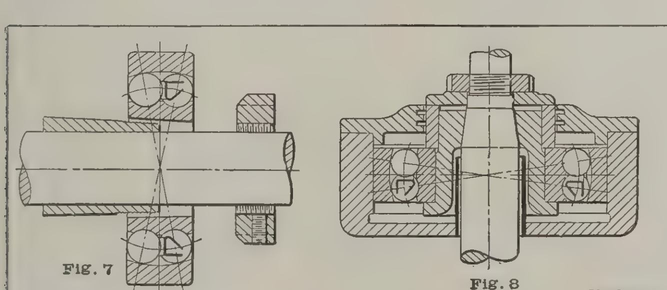

Fig. 7. Adapter Type of Bearing. Fig. 8. Method for Retaining Lubricant in Vertical Bearing Shaft

and driving it into position by light blows of a soft metal hammer. A piece of copper tubing, or a piece of wood in conjunction with an ordinary hammer can also be used for the same purpose, as indicated in Fig. 6. The outer race must under no circumstances be given a blow when fitting the bearing onto the shaft.

The outer race should have a very close sliding fit, but should never be securely fixed in the housing. A slow creeping of the race should at all times be possible under the vibration of the load. This slow intermittent creeping insures a proper distribution of the load over the whole surface of the outer race. Even when it is desired to prevent end motion of the shaft, a slight clearance of 0.010 inch should be provided on each side. Without this lateral clearance—*i. e.*, if the race is securely fixed in the housing—the load will always bear on one position in the race. When there are several radial bearings on the same shaft, one bearing only should be used to hold the shaft against end motion; the outer races of the other bearings should be free to locate themselves.

In cases where it is impossible to make the inner ball race a driving fit on the shaft or to secure it by means of a lock-nut or distance piece, the adapter type of bearing shown in Fig. 7 should be used. This bearing is provided with a conical split sleeve and lock-nut which clamps the bearing on the shaft in any desired position.

The shaft and housing should be turned as true as possible to insure concentric running of the races, and in case split housings are found desirable, great care should be taken to see that the housing sections do not bind the outer races and distort them. The application of radial bearings to vertical shafts occasionally makes lubrication difficult. A practical method of meeting these conditions—as they are sometimes to be found in the upper bearings of sugar centrifugals, vacuum cleaners, side cutters on wood planers, vertical pumps, etc.—is shown in Fig. 8, the retention of the lubricant being amply provided for by the tubular cup between the shaft and the seat for the inner race. This mounting is also made in a modified form with a lock-nut below the bearing, in which case the upper face of the inner race is held against a shoulder on the bearing support.

When it is necessary to use a thrust bearing to take the weight of a vertical shaft, a combination of radial and thrust bearings, as shown in Fig. 9, provides an ideal method of

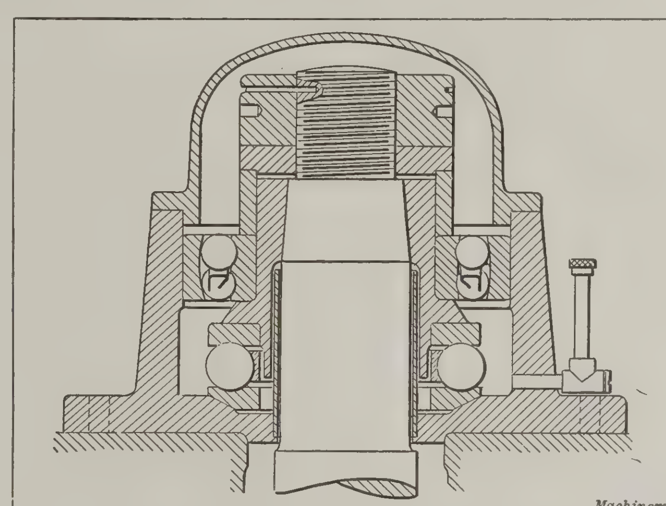

Fig. 9. Combined Radial and Thrust Bearing

mounting. The center of the radial bearing coincides here with the center of the spherical surface of the thrust disk. This provides a combination which is self-aligning about one point.

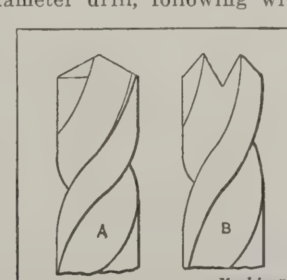
THE DRILLING OF MARBLE OR SLATE SLABS

Anyone who has had to drill marble or slate knows of the difficulties met with. Frequently holes are produced by drilling through with a small diameter drill, following with one of the full diameter of the hole required. A better method, says the *Practical Engineer* (London), is to mark out the center of the hole required and start it with an ordinary ¼ inch twist drill, as shown at *A* in the accompanying illustration, replacing this tool by a special tool, as shown at *B* (of the same diameter as that at *A*), as soon as the cavity is deep enough to permit of changing with safety. Then, to obtain the full diameter hole, a drill of the full size required is used as before. This method is more rapid than to drill a small hole right through the marble by an ordinary twist drill.



Drills for Marble or Slate

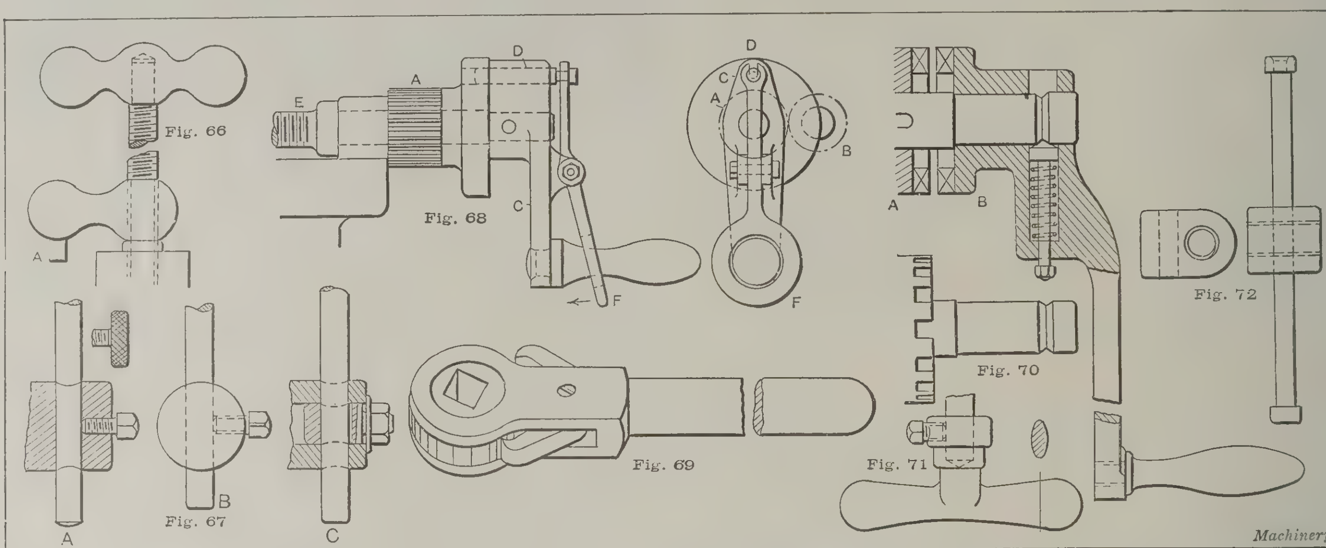
MACHINE HANDLES—2

A STUDY OF THE VARIOUS TYPES OF HANDLES AND HANDWHEELS USED ON MACHINE TOOLS

By FRED HORNER*

The handles and handwheels illustrated and described in the previous installment of this article were, in general, of a simple nature. In the present installment some of the handles and mechanisms described will be of a more complicated nature, including combinations of handles, handwheels, ratchets, indexes, and other similar mechanisms.

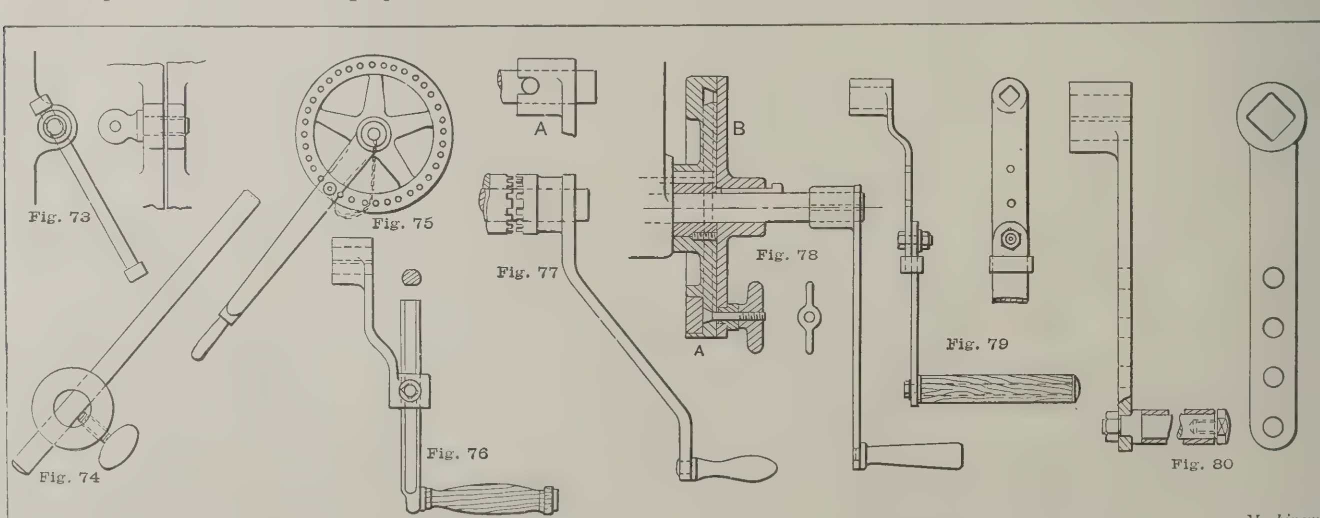
on the boss or hub of the handle and on the sleeve of the spindle, as shown in Fig. 77, thus permitting of disengagement when desired. Ratchet teeth are occasionally required. As an alternative design, a pin may be driven through the spindle and the hub of the handle may be provided with slots on either side as shown in the detail view at *A* in Fig. 77. Often the handle is kept out of engagement by a weak spring. A washer may be held on the end of the spindle by a set-screw to prevent the handle from falling off, while, in other instances, the washer is omitted in order that the handle may be slipped off and placed on another



Figs. 66 to 72. Types of Handles used in Machine Tool Construction

In Fig. 66 is shown an example of a handle combining the double and single types, one being used for adjusting the raising screw and the other for locking it. The latter has a small pin *A* which catches against the bearing cap and prevents the handle from swinging into contact with the revolving spur gears on the other side of the cap. A handle attached to the end of a spindle for operating a belt-shifting mechanism for a small countershaft, is shown in Fig. 71. This handle is made of cast iron.

In a few instances, it is not desirable or may be impracticable to permit the handle to project out on one side or adjacent screw or spindle. An example of this type of handle is shown in Fig. 70, where two screws or spindles on a boring mill are shown placed close together, and one handle serves for both. The clutch arrangement, in this case, differs somewhat from the ordinary type. The clutch *A* is double-ended, one end only being shown in the engraving, and slides along a feather key on the spindle. When moved to the left it engages with a power-driven clutch gear, but when moved to the right it meshes with the teeth of handle *B*, and the turning of the latter rotates the spindle when an adjustment is desired. The spring plunger in the handle engages with



Figs. 73 to 80. Types of Handles used in Machine Tool Construction

the other of its boss. In such a case, a sliding handle of the type shown in Fig. 73 is used; the same kind of handle, passing through a nut on one side of the threaded hole, is shown in Fig. 72. This example is taken from a brass finisher's lathe and is used for tightening the screw of the hand-rest underneath the bed.

Handles provided with clutches, apart from the friction devices already described in the previous installment, are sometimes required to prevent their being operated when the power feed is in and the shaft is rotating. Teeth are cut

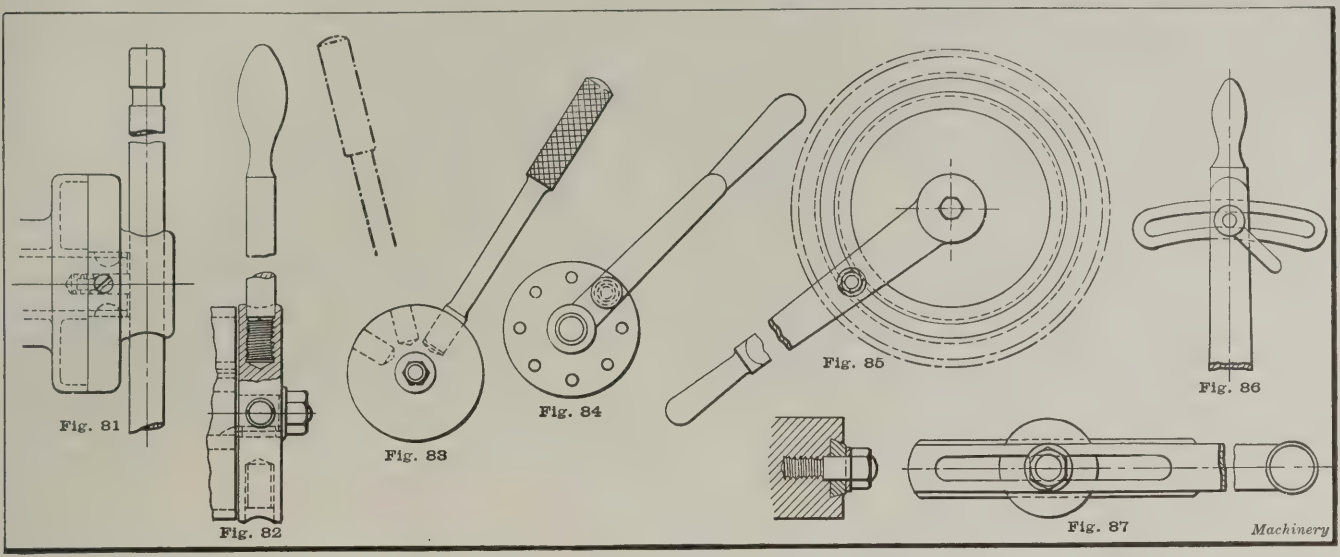
the V-groove in the spindle and prevents the handle from falling off endwise. The spring, however, is not strong enough to prevent the pulling off of the handle when it is desired to remove it.

Pilot or star handles, of the types shown in the previous installment, are generally so designed that they can be disconnected so that when the power feed is in action the star handle does not rotate. Some form of friction clutch is usually provided, or a spring plunger is fitted to the hub of the star wheel handle, the plunger passing through into a hole in the sleeve which rotates with the operating spindle

* Address: 13 Forester Ave., Bath. England.

or shaft. The friction-disk device is also a favored type of connecting medium for many mechanisms of this description. The Lang disk device was one of the first to be applied extensively in turret lathes. One of these applications is seen in Fig. 78, in which the power-driven plate A is coupled to the disk B on the shaft when the wing-nut is tightened. boring and drilling machines. The ratchet is usually double-acting, as shown in Fig. 69, so as to admit of adjustment in either direction without removing it from the square on the end of the screw or spindle.

Another class of handles is designed to enable two or more rates of speed to be obtained, this being accomplished by the

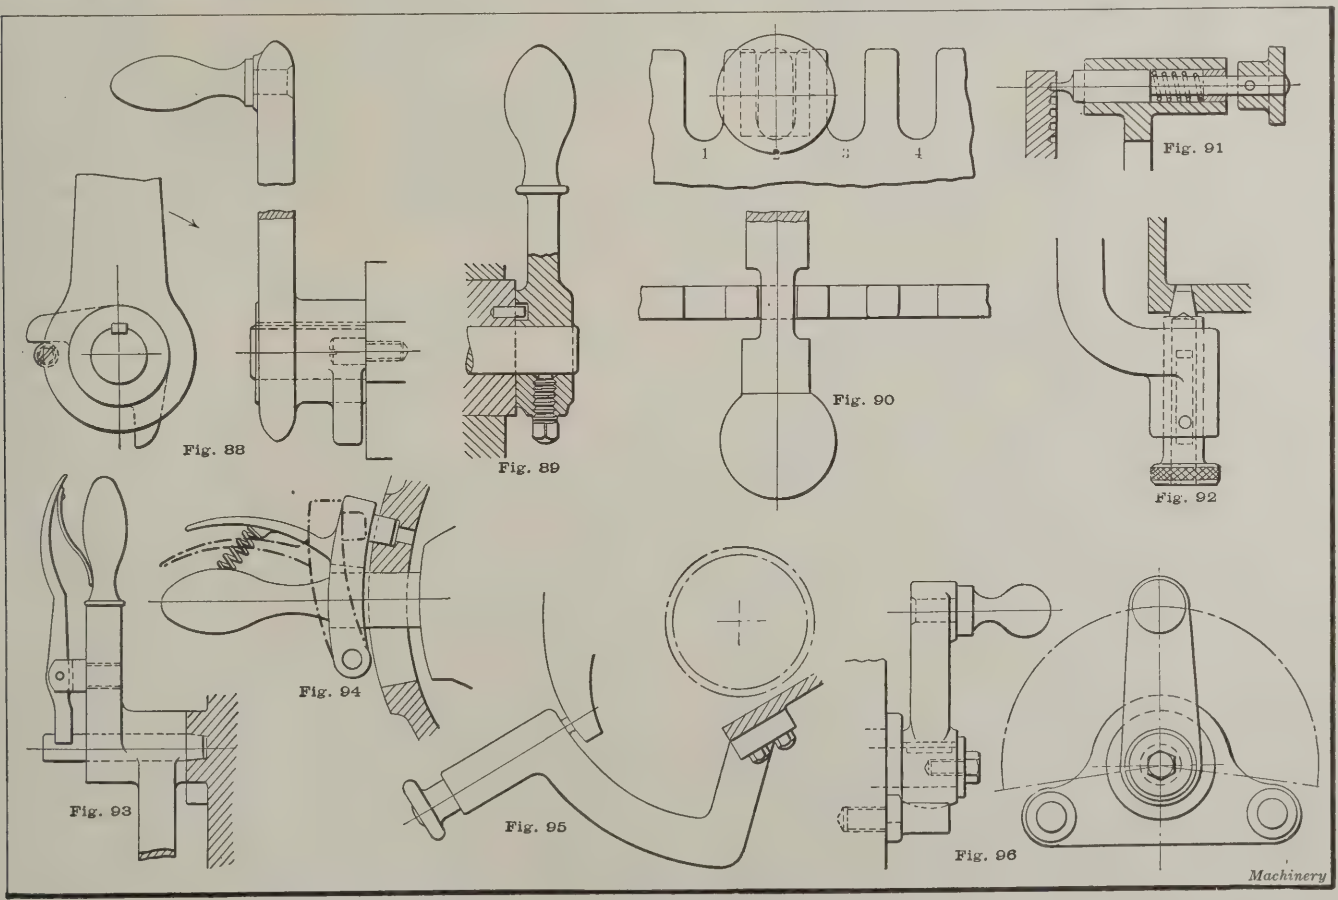


Figs. 81 to 87. Types of Handles used in Machine Tool Construction

Two of these nuts are used when the drive is heavy. Many variations in the details are found in different designs.

Ratchet handles are employed principally for two reasons: either because there is insufficient space for a complete turn of the handle, or because the power required cannot be conveniently applied by a full circular motion of the hand. Most cases of this kind relate to movements where only occasional adjustments are required, such as the adjustment

withdrawal of a pin or other means of coupling. Many feeds on drilling machines are constructed in this manner so that by a slight movement of a pivoted handle the rapid lever movement is changed into a slow one, by means of a worm or other mechanism for fine adjustment or feed. The application of this device is illustrated in Fig. 68, this being applied to a shaper and actuating the saddle screw. When the parts are in the position indicated, gear A, driven by



Figs. 88 to 96. Types of Handles used in Machine Tool Construction

of a slide at infrequent intervals, etc. Such cases occur when the setting lasts for a long period of machining, or when a power feed is usually applied, and the handle is required only to give a small adjustment for exact position. Heavy lathe carriages, for instances, are sometimes operated in this manner and also the saddles and slides for heavy

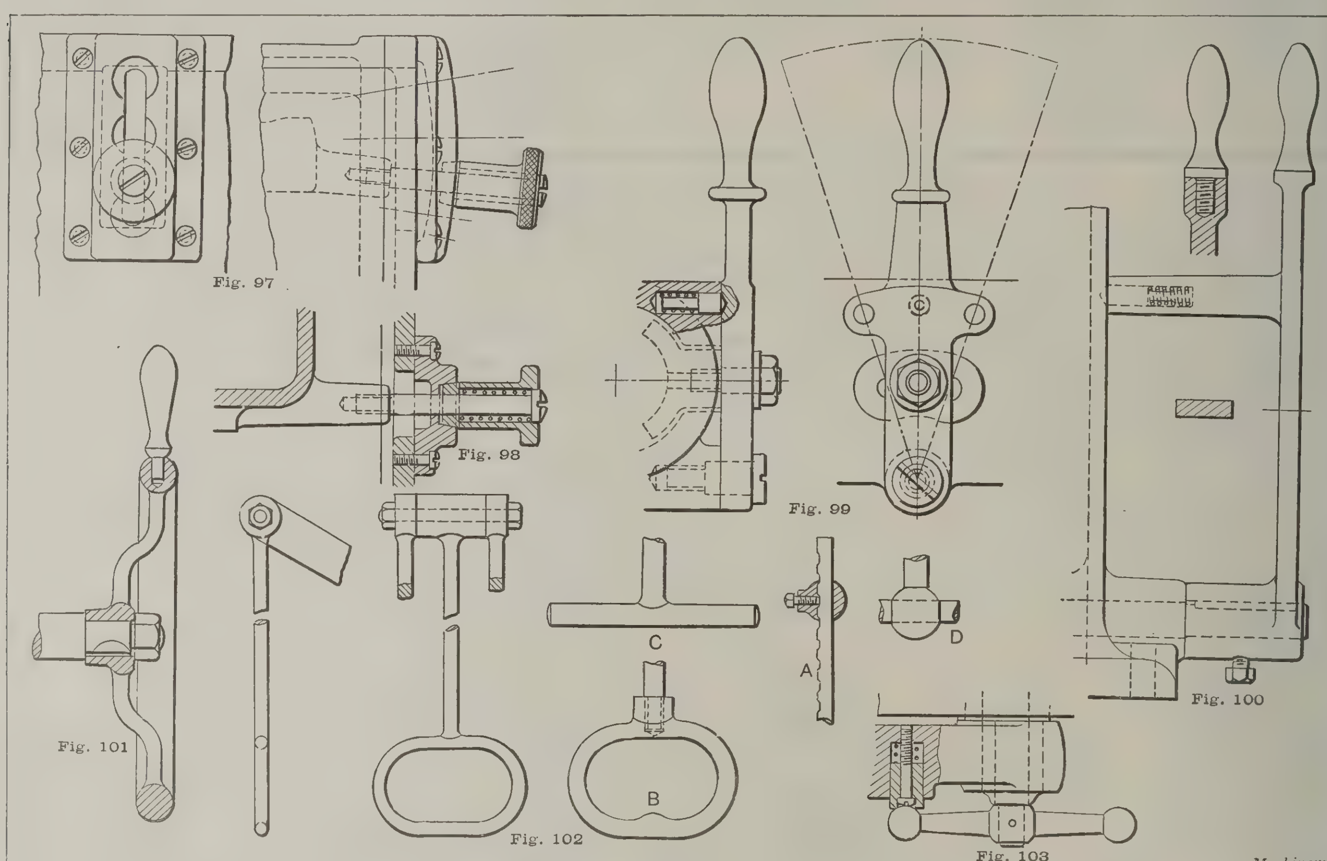
gear B, is coupled to the handle C by means of the plunger D, and screw E is rotated by power; but when the hand is applied to the handle, pushing the pivoted lever F in the direction of the arrow, the pin D is withdrawn and screw E may be revolved rapidly by hand.

Certain types of machines, especially for tapping, are pro-

vided with a simple means for obtaining two speeds, by having two squared spindles for receiving the operating handle. When the handle is applied to one, the drive is at a rapid rate, but when operating upon the other, the drive is through two spur gears at the slow speed. Then there is another common type, that adjustable for radius to suit different powers and speeds. Hand screw machines are very commonly provided with adjustable handles, and so are certain types of portable machines for drilling, planing, shaping, etc. Adjustment for radius is necessary in many handles for feed motions, principally in drilling machines, where a light pressure is more easily applied with a short handle, and a heavy pressure when the handle is drawn out to its full length. The lengths of handles are varied in different ways. A common method is to slide a loose handle through the socket portion which fits on the shaft, as indicated in Fig. 76. This loose portion is then tightened with a set-screw. Occasionally, a split hub is employed instead, and clamped with a set-screw. Another way is that shown in Fig. 79, where flat arms are used, provided with holes for the reception of a tightening bolt. The two parts are also kept together by a loop as indicated. Instead of the separate holes, a slot is sometimes made so that the readjustment may be effected without removing the bolt. In Fig. 87 is shown an instance of an adjustable handle applied to a keyway cutter of the portable type. The dovetail section of the lever prevents it from falling out when the nut is loosened. The handle in Fig. 80, from a portable cylinder boring machine, shows a case where the handle proper is adjusted along the web by a series of holes drilled at different radii. A continuous slot forms an alternative to the separate holes, if more rapid changes are desirable.

The handles for feeding spindles of small drilling machines, etc., are usually of plain bar section and can slide through the boss of the rack spindle. The method of clamping these handles and the means for adjustment are shown in Fig. 67. At *A* and *B* are shown arrangements with set-screws, with either square or knurled heads, and at *C* a grip-bolt design. A wing-screw, as shown in Fig. 74, is also often used. In some sensitive drilling machines the lever is self-locking in any position, through the medium of a spring plunger, as indicated in Fig. 81. The plunger presses against the handle with sufficient force to hold it by friction.

Another class of designs requires that a lever may be adjusted for radial direction so as to bring it in the most convenient angle for the operator's hand. Handles with split hubs, as already described, are used for this purpose in certain instances, but are not always desirable. A type suitable for small drills is that shown in Fig. 82, where the handle can be screwed into either one of three or four holes in the disk on the pinion spindle. Sometimes the handles fit into a tapered hole, as shown in Fig. 83. Among other methods for obtaining the same ends may be mentioned a circle of holes in a disk, into one of which the spring plunger of the pivoted handle can enter, as shown in Fig. 84. A similar method is adopted in the design shown in Fig. 75, where a large wheel is provided with holes for receiving the locking pin of the handle in any position which happens to be most convenient for feeding the spindle. This design is applied to a special vertical hole grinder. An alternative design is that in Fig. 85, where a T-groove is cut in a circular disk so that the handle can be locked in any position by means of a T-bolt and nut. This design is applied to a multi-spindle drilling machine in which each spindle is fed down independently with its own lever, or, if desired, simultaneously by a shaft (common to all) on one end of which is the wheel seen in Fig. 85. The ratchet lever is used on many drilling machines, the engagement of the pawl with any particular tooth governing the radial setting of the lever.



Figs. 97 to 103. Types of Handles used in Machine Tool Construction

In many cases it is important that means be provided for locking or retaining the handle in a certain position after the movement has been made, so as to keep the adjustment unaltered until a change is again made. This requirement is present in nearly all machine tools. Sometimes the range of movement of the lever is small, and, in such a case, the arrangement shown in Fig. 86 may be used, where the handle is clamped to a quadrant with a wing-nut after the handle is adjusted. A stop arrangement is shown in Fig. 96, where two stop-pins are used to arrest the motion of the small handle at each extreme of its movements. In Fig. 88 is shown another example of preventing a movement beyond a certain point. Here two lugs are provided which come in contact with the head of a screw. Still a different arrangement is shown in Fig. 89, where an annular groove is provided, fitting over the stop-pin, so that the latter arrests the motion of the handle at each end of the slot. Another means

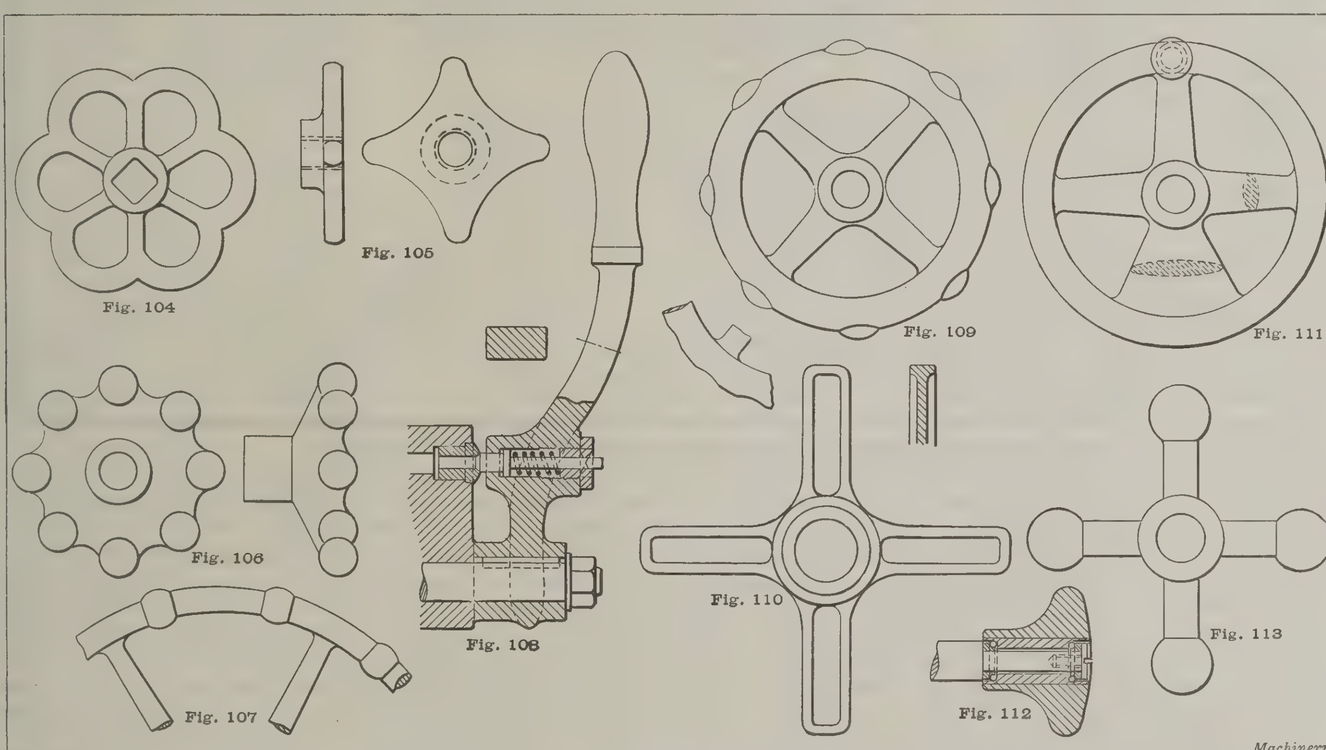
of control is indicated in Fig. 90, where the heavy knob end of a lever is raised, moved to one side and brought into the next notch of the disk.

By far the greater majority of locked handles, however, are retained by some form of spring catch. The spring is combined with a plunger which either acts automatically or is pulled out by hand when making changes, and which maintains the handle steadily in one place and eliminates the vibration which is liable to occur in a locking device without spring action. An example of a hand-operated plunger is shown in Fig. 91, this design being frequently met with on the indexing arm of milling machine dividing heads. Another example, from a milling machine gear-box, is shown in Fig. 92. Here the plunger has a tapered end dropping into a series of holes in the edge of the gear-box. A plunger is often withdrawn by a lever arrangement as shown in Fig. 93. A great many handles are also modeled after the steam-engine reversing lever, with a plunger fitting into notches on the rim of a quadrant or into ratchet teeth on the side of a disk. In Fig. 94 is shown an arrangement used for changing the gears in a gear-box, a pivoted clasp lever being used for withdrawing the plunger, and in Fig. 95 is another example of a handle used for operating gear-box change gears. In Figs. 97 and 98 are shown the elevation, end view and section, respectively, of a handle, the stem of which is screwed into the lug of a tumbler bracket carrying the change gears, and which is locked by the tapered end of the spring handle which enters into the counterbored recesses indicated. The same principle is applied to cases when gears have to be moved laterally, in which case the handles are attached to a forked piece embracing the gear.

The trouble of pulling back the plunger at each change is avoided in a great many handles, by making the plunger end of a pointed or slightly rounded shape, so that it will easily slide out of the countersink provided for it. In Fig. 99 an example of this kind is shown, where a handle can be locked in three positions by a spring plunger. A variation of the design, with the plunger placed in the handle, is shown in Fig. 108. The plunger here slides into a series of hardened steel bushings forced into the casting of the bed of the machine.

If two levers happen to come close to each other, as in the front of a drilling machine gear-box, it is often the practice to carry one handle out further than the other, in order to prevent the handle ends from interfering. The boss of one handle is then lengthened, as shown in Fig. 100, this requiring also the lengthening of the boss that receives the spring plunger. In some cases, the convenience of being able to machine the shaped handle portion separately prompts a design as illustrated in the detail in Fig. 100, where the handle is screwed into the main forged lever. Provision is sometimes incorporated for holding a spring plunger out of engagement with the locking holes, this being usually accomplished by a partial twist which engages a pin in a slot and prevents the forward movement of the plunger. A method of locking a handle in two positions is illustrated in Fig. 103. This method is applied to some milling machine back-gears. The ball ends of the handle are prevented from moving by the hollow spring plunger shown.

Mechanisms which cannot be easily reached by the attendant standing on the ground are either operated by long shafts or chains, or, if circumstances permit, a hanging pull-rod is used, the rod being provided with a loop or handle for the hand. Fig. 102 shows some details used on designs of this kind. The pull-rod is usually made with a boss fitting on the bolt or pin at the end of the levers to which it is attached, and is either of fixed length or adjustable, as indicated at *A*, in which the rod has a series of flats to receive the point of the clamping screw. The handle ends may be designed as shown at *B*, *C* and *D*. If there are two pull-rods close together they are often connected by a loose horizontal link to prevent their clashing with each other, and if a pull-rod comes close to a bearing or spindle, a light bracket is often carried out from the frame to embrace the rod and prevent it from coming into contact with the moving parts.



Figs. 104 to 113. Types of Handwheels and Handles used in Machine Tool Construction

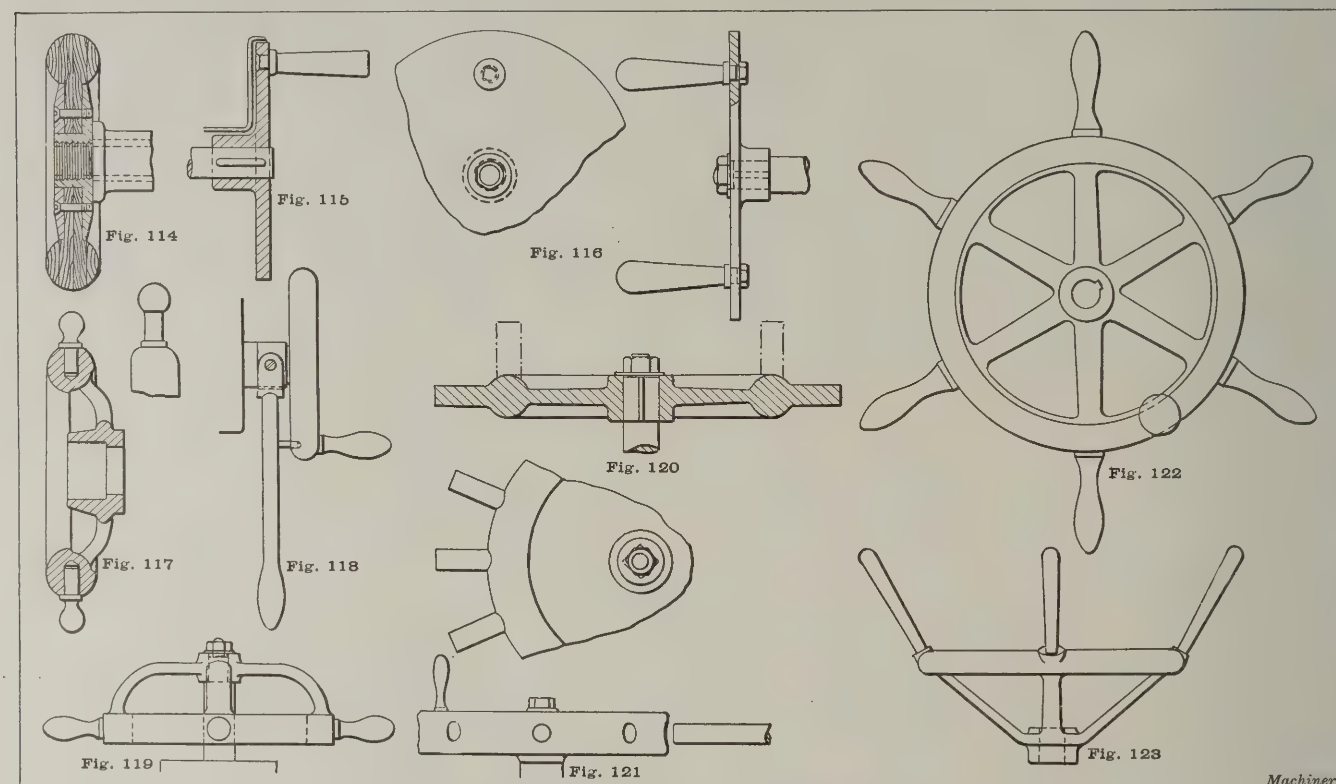
Handwheels

Handwheels are merely a special design of handles; on modern designs the use of handwheels is undoubtedly increasing. The continuous rim of the wheel possesses some advantages which are not present in handles even when made of the star or spider types. The continuous rim always presents something for the operator to grasp without feeling blindly for it in the air, as is often necessary when he has to keep his eye on the work or tools. It also permits of a more delicate feed motion. Micrometer graduations can be placed on a large diameter of the rim. The weight of the rim and its flywheel action are of great advantage when rapidly rotating the wheel for quick adjustments. It is well balanced and does not have a tendency to alter adjustments because of vibration. It can be provided with special fittings, such as dogs, ratchet teeth, feeding devices, and other details. The principal objection to a handwheel is that

it takes up more room than a handle and may, therefore, be in the way. In such cases, it either must be made removable or be discarded for some other design.

On the boundary line between star wheels and handwheels are a number of knobs, cross-handles or disks used chiefly for tightening or clamping where no great power is to be exerted. In Fig. 110 is shown a good example of a cross-handle, and in Fig. 113 another of the ball type. The plain star-shaped knob is often used as shown in Fig. 105, or

enable increased power to be exerted. An example of a wheel provided with a single handle is shown in Fig. 101. The accurate balancing of a handwheel with one handle is often neglected, but sometimes the arm opposite the handle is increased in size so as to balance the wheel properly, as shown in Fig. 111. Wheels of solid disk type, with one or two handles, as shown in Figs. 115 and 116, are easily manufactured and very convenient for certain applications; the edge is often graduated. An increase in the number of



Figs. 114 to 123. Types of Handwheels used in Machine Tool Construction

a small disk with a series of knobs on its periphery, to give a firm grasp, as shown in Fig. 106. The looped type of wheel shown in Fig. 104 is also very popular. Fig. 112 shows a special type of knob fitted with ball-bearings, its function being to control and feed endwise the grinding-wheel spindle of a small grinder. When it is desired to increase the grip of the hands on a handwheel, knobs or projections are often cast on it, as shown in Fig. 109, or the rim may be hollowed out with a series of transverse grooves, as in the small detail shown in the same illustration. Large

radial handles is often necessitated for reasons of convenience, because when provided with two or more handles, one will always be within easy reach. In Fig. 122 is shown a wheel with six radial handles, and one transverse handle on the rim. A peculiar specimen from a German turret lathe is shown in Fig. 124, in which a comparatively small handwheel has handles bolted into it and these handles again have lateral handles riveted to them.

A compromise between the radial and the transverse positions of the handles has sometimes been made, when the

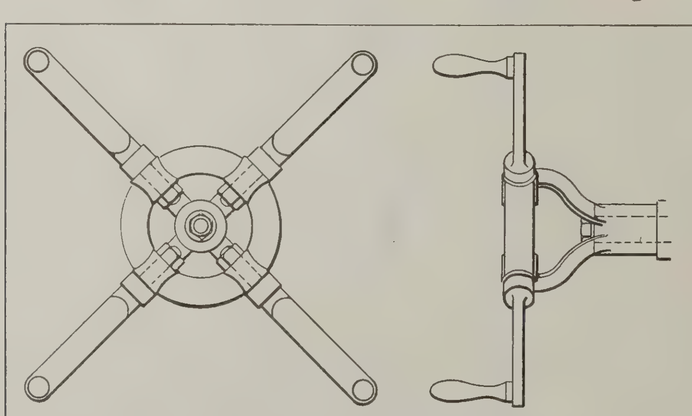


Fig. 124. Handwheel with Radial and Lateral Handles

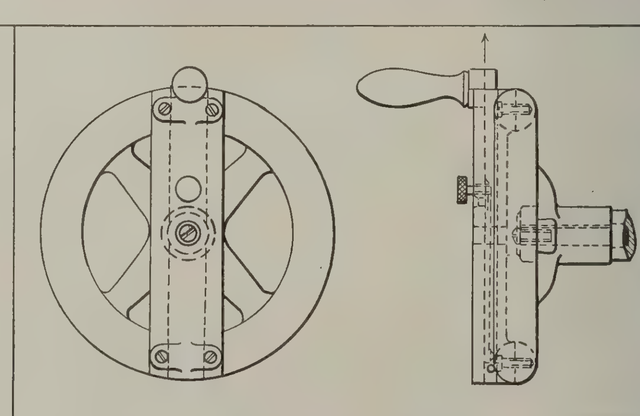

Fig. 125. Handwheel with Handle Adjustable Radially

handwheels are often cast with the rim as shown in Fig. 107. A wooden wheel made in segments as shown in Fig. 114 is very suitable for operating the draw-in chucks on bench and other small lathes.

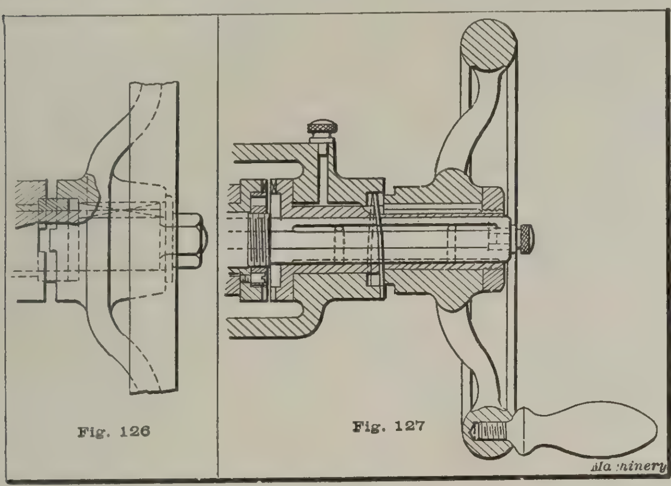
Handwheels are divisible into two main classes, those which are grasped by the rim only, and those that are fitted with one or more handles projecting either radially or laterally from them. The lateral extending handle is used for rapid rotation, and the radial handle chiefly to

conditions prevent a strictly radial setting. Fig. 123 shows an extreme case of this. This wheel is placed horizontally on the bed of a cold-sawing machine so that the operator would have to bend down to reach it. For this reason, the rim is carried upwards by the arms, and handles inserted into it in an angular direction. Another arrangement, with the rim and the handles in a different plane from the boss, is shown in Fig. 119, this being the operating wheel for a vertical forming-slide, where the inside of the wheel can

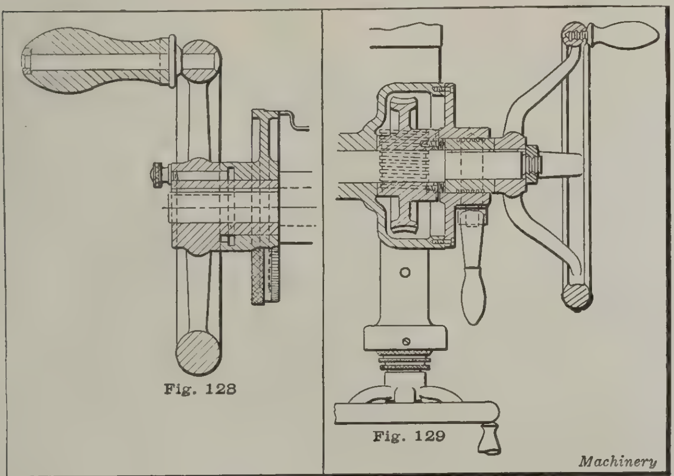
pass over the outside of the slide. Sometimes small knobs are fitted to the rim of the handwheel as shown in Fig. 117.

In some cases a considerable increase of power over that ordinarily required may be necessary at intervals. This condition is met in a German turret lathe by the arrangement shown in Fig. 118, where a lever pivoted on a boss adjacent to the hub on the handwheel is provided. This lever can be moved up against the handwheel so that a pin in it engages with the wheel, and a more powerful turning moment is thus obtained at the end of the lever than would be possible at the handle of the wheel.

Certain classes of handwheels made with solid webs instead of arms are provided with a set of holes around the periphery for the insertion of bars for turning them, as shown in Fig. 121. Another method of attaining the same object is to forge the wheel with a series of short pins or arms extending out from the rim and slip a piece of pipe on either of these for getting the increased leverage. A design of this kind is shown in Fig. 120. Sometimes the pins project out in the direction indicated by the dotted lines, in which case a bar can be laid across the wheel to engage with these pins. Fig. 125 illustrates a more complicated method of design for increasing the leverage of the handwheel, this being applied to certain milling machine table handwheels and cam-cutting attachments. The handle is formed with a sliding piece moving in ways screwed onto the wheel, and is pulled out when required.



Figs. 126 and 127. Handwheels with Clutch Arrangement



Figs. 128 and 129. Means for Connecting and Disconnecting Handwheels

A great number of devices for coupling and disconnecting handwheels have been designed. A plain clutch hub, as shown in Fig. 126, may have only a couple of teeth on opposite sides of the periphery, although it is more convenient if a greater number of teeth are used, so that the wheel may be slipped into engagement at almost any point. A spring may or may not be incorporated to keep the wheel out of mesh. In Fig. 127 the spring is placed in front of the boss and the resistance of this has to be overcome when the wheel is pushed forward to engage the teeth inside of the casing. Sometimes clutch teeth are provided in both faces of the hub so as to engage different mechanisms when moved toward the right or left.

Friction locks frequently are used in connection with micrometer dials when the dial must be released to turn it to the zero position for a new setting. This is accomplished, as shown in Fig. 128, by a bolt working in a circular T-slot by means of which the micrometer disk can be clamped to the wheel hub. Another method is to use a central threaded pin and let this force a transverse pin upward against the bore of the disk.

In the case of many handle mechanisms, it is necessary to provide for rapid and slow feeds or adjustments, which cannot be done by a single handle or handwheel. The most commonly used method is to use a worm and worm-wheel, the wheel being on the shaft of the rapid handwheel and the worm being turned by another handwheel at right angles to the first, as shown in Fig. 129. Some kind of clutch is incorporated to connect or disconnect the two movements. In the example shown, the rapid handwheel has a clutch moved along by a circular rack in order to engage the worm-wheel.

PATTERNS FOR THE FOUNDRY

In an address before the Superintendents' and Foremen's Club at Oakley, Cincinnati, Ohio, Mr. H. M. Ramp, superintendent of the Modern Foundry Co., called attention to the difficulties the foundryman has to meet because of the fact that patterns are poorly made or in poor condition. In the course of his address he said that many concerns have inspectors who check up every piece of work done in the factory; some have inspectors who check up every gage and templet at stated periods to discover errors and prevent mistakes; but he knew of no concern that employed an inspector to periodically check up the patterns to find out if they were true. Usually such checking is first done after a lot of castings have been rejected, and only then is the pattern found to be at fault. There seems to be a tendency today to save on pattern cost, although a great deal of money is spent for improved machinery in the machine shop to improve the quality and cheapen the cost of the finished product. The average patterns in the average foundry today are not made as well as they were ten years ago, and still there is a reason why the foundry ought to be supplied with better patterns than formerly. The trend of the times is to reduce the skill of the workers by putting more dependence on improved machinery; hence, the molders of today are not as skilled as they were years ago, and, for that reason, better patterns rather than poorer ought to be the rule.

Mr. Ramp also called attention to the lack of understanding of the requirements of the foundry on the part of many machine designers. The castings designed may be perfectly fitted for the purpose for which they are made, but the design is such that the molder cannot make a perfect casting on account of the excessive strains produced by the unequal proportions of the different parts, and it is impossible to prevent these castings from cracking or warping. It is easy enough to say that no more metal is required at this or that point; it may be very creditable to be able to design a machine with a maximum of utility and a minimum of weight, but, nevertheless, there are unalterable laws in the shrinkage or contraction of cast iron that the designer cannot be permitted to overlook. Many castings are designed with a view to saving metal, which, as a matter of fact, will have a higher ultimate cost than if no specific effort to save metal had been made. The extra labor cost in the foundry in such cases outweighs the saving in the cost of the metal.

* * *

Fernand Forest is credited in France as being the first mechanic to construct a multiple-cylinder explosion motor. Forest claims that he built the first four-cylinder motor in 1889, and the first gasoline launch in 1885. He developed magneto ignition in 1883, thirteen years before it was adopted by any automobile manufacturer. A movement is on foot in France to reward Forest for his inventions which are the foundation of the modern internal combustion motor, and for which he received little or no financial benefit.

RADII FOR TOOLS TO TURN SPHERICAL ENDS

BY WILLIAM W. JOHNSON*

The method of arriving at the results given in the accompanying table of radii may be of interest. The work was reduced to a minimum in the following manner. The general formula for r in terms of h and d is

$$r = \frac{1}{2}\left(\frac{d^2}{4h} + h\right) \qquad (1)$$

Let $d = \frac{m}{32}$, and $h = \frac{n}{64}$; where

m = the number of 32nds in d, and
n = the number of 64ths in h.

* Address: 10017 Ostend Ave., Cleveland, Ohio.

Then,

$$r = \frac{m^2 + n^2}{128\,n} \text{ or } r = \frac{n}{128} + \frac{1}{n}\left(\frac{m^2}{128}\right) \qquad (2)$$

By means of a table of 1/128ths of an inch, and a table of squares, each column of figures is calculated as follows:

Take for example the column for $\frac{3}{8}$ inch diameter.

$\frac{3}{8} = \frac{12}{32}$, then $m = 12$ and $m^2 = 144$.

Giving n the values 2, 3, 4, 5 and so on, in (2), we have

$$\frac{2}{128} + \frac{1}{2}\left(\frac{144}{128}\right) = \frac{74}{128} = \frac{37}{64} = r.$$

$$\frac{3}{128} + \frac{1}{3}\left(\frac{144}{128}\right) = \frac{51}{128} = 0.3985 = r.$$

$$\frac{4}{128} + \frac{1}{4}\left(\frac{144}{128}\right) = \frac{40}{128} = \frac{5}{16} = r.$$

$$\frac{5}{128} + \frac{1}{5}\left(\frac{144}{128}\right) = 0.0391 + \tfrac{1}{5}\,(1.1250) = 0.0391 + 0.2250 = 0.2641 = r$$

and so on, until $n = 11$.

Then $n = m$, $h = \frac{d}{2} = r$.

* * *

One good way to spend some of your stray thinking moments is in digesting the question of just exactly what it is you are aiming at in the world anyway.

ELECTRIC CONTROLLING DEVICES

By G. J. KIRCHGASSER*

Electric controlling devices for electric motors include such apparatus as starting rheostats, speed regulating or controlling rheostats (referred to as speed regulators and controllers), and such devices as compensator or auto-transformer types of motor starting apparatus, which are used for alternating current motors. Besides these, there are special types of switches, such as float and tank switches, magnetically operated switches, star-delta switches used with squirrel cage induction motors, and various other styles used for controlling the motor or the circuit to it. Automatically operated motor starters, regulators and controllers are also included under this heading.

The motor with its controlling device can be compared to the human body. The muscles, representing the power, correspond to the motor, and the brain which controls or regulates the working of the muscles, corresponds to the controlling device. Work done by the muscles can be disastrous unless properly controlled, and an electric motor supplied with power is also very apt to cause trouble unless provided with a controlling device of some kind. The wires connecting the controlling device and motor are comparable to the nerves emanating from the brain and passing to the muscles.

A motor of very small power can be started without the need of a starting rheostat, but for most motors used in manufacturing or industrial plants starting or regulating devices of some kind are required.

Action of Motors

Current is passed through the armature conductors of a motor (which are parallel to the shaft) at right angles to the magnetic lines which pass from the motor field poles. The electrical energy transmitted to a motor meets with several losses in changing to mechanical action. If the resistance of the armature conductors is high, there will be a correspondingly high loss in this part of the motor. As the motor armature revolves in a magnetic field, a current is set up in the armature conductors just as in the case of a dynamo. This flows in a direction opposite to the current being fed to the motor and is greater at full speed than at half speed, while at a standstill, of course, no counter current is generated, because the conductors are not moving through a magnetic field. Because of the absence of this counter current or counter electromotive force when a motor is being started, there is nothing to check the inrush of current.

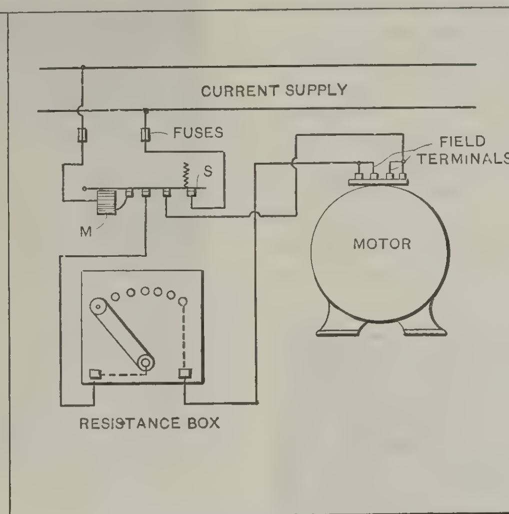

Fig. 2. Diagrammatic View of the Main Features of Shepardson's Patent Magnetically closed Main Line Switch

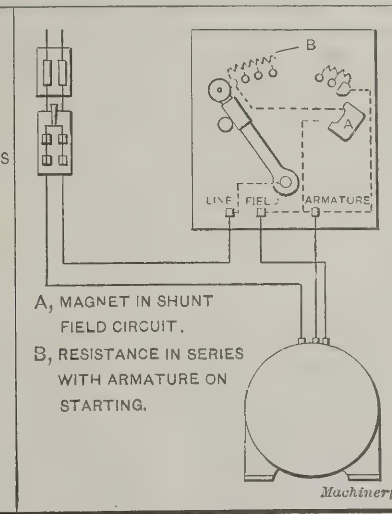

Fig. 3. Blades' Patent Controlling Device having Magnet incorporated with Starting Device and connected in Shunt-field Circuit

The necessity for controlling devices (of which the motor starter is the pioneer) for use with motors was recognized even before the first commercially efficient motors were put on the market for industrial purposes, which was about 1885. Early motors caused trouble, becasue it was found that when the switch connecting them to the line was closed, a very large current inrush took place. Controlling devices were not made then, so the armature was built with a high resistance, which served to retard the current inrush during starting; but as this high resistance was in circuit at all times, it resulted in the motor being very inefficient during normal running, and its speed varied considerably under varying load conditions.

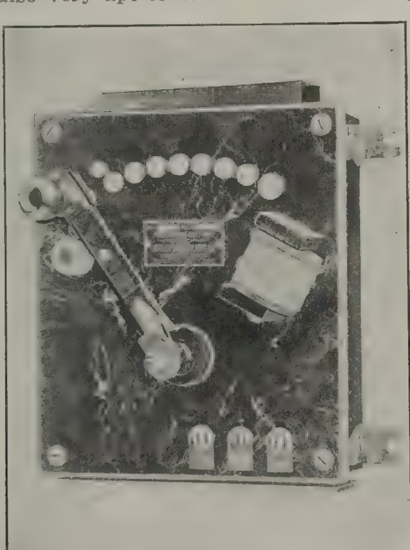

Fig. 4. Simple Hand-operated Motor Starting Rheostat with No-voltage Release

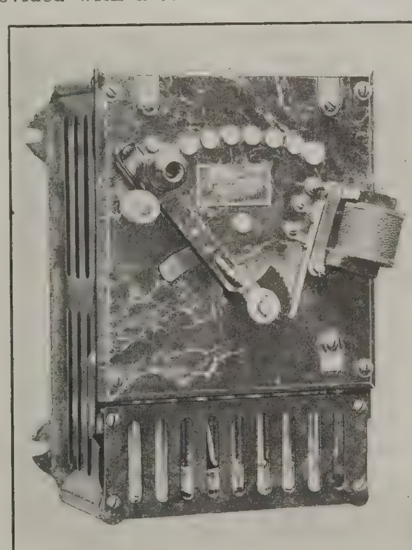

Fig. 5. Small Hand-operated Speed Regulator

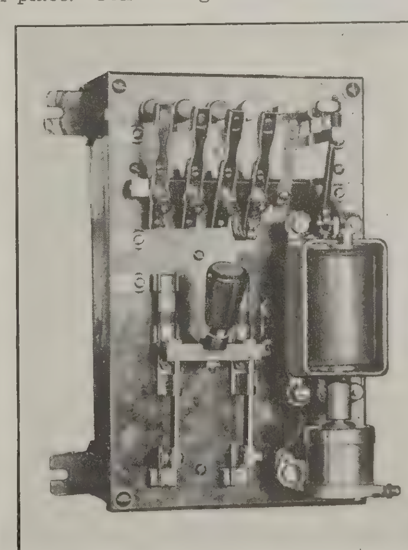

Fig. 6. Simple Automatic Motor Starter, Single Solenoid Type

One of the chief advantages of the shunt-wound motor is its ability to run at about constant speed even though it be driving two lathes or five, for instance, but the high resistance armature destroys this self-regulating feature, and, therefore, early electrical men tried to invent and design devices or methods for regulating the high resistance armature motor.

* Address: 3221 McKinley Boulevard, Milwaukee, Wis.

No commercially practicable results followed until the armature with low resistance was developed. To avoid the large inrush of current mentioned, a resistance connected so as to be inserted during the starting period and cut out when running was employed. This was set up outside of the motor itself and really was the first controlling device of any value. The low resistance armature motor runs at practically constant speed, and with the arrangement of an outside starting resistance for cutting down the current, it put the high resistance armature motor and the various regulating devices into the scrap heap at one sweep. The diagrammatic sketch, Fig. 1, illustrates the method of inserting the resistance by means of a now obsolete type of starting-box. The lever for cutting out the resistance or returning it to the "off" position had to be moved by hand.

Motor manufacturers began using the shunt motor and this starting-box in which the starting arm was moved from the "off" to the "on," and *vice versa*, by hand. This arrangement, which marked the highest type that the most capable men in the electrical industry at that time were able to devise and place on the market, involved several great dangers: first, due to accidental breaking of the shunt field circuit, resulting in running away and destruction of motor and excessive

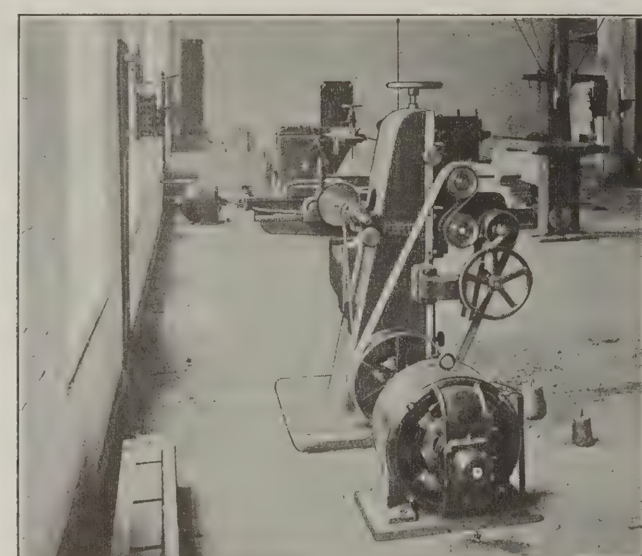

Fig. 7. Motor Starting-box, mounted on Wall for Starting Motor installed on Floor

current in the armature caused by the decreased counter electromotive force generated; second, due to the contact lever not being returned to the "off" position when shutting down, resulting in destructive current when the main switch was thrown in again and in sudden jerk instead of gradual acceleration (just as though no starting rheostat were installed); and third, due to leaving the contact arm on intermediate contacts, resulting in burning out the resistance of the starter.

Besides this, the blowing of the fuse, the cutting off of the current supply, the sudden drop of voltage—all left the motor unprotected, no starting resistance being in circuit when the current was again supplied. It meant that every motor would have to have an attendant to push the operating lever to the starting position when trouble arose, and it should be remembered that in the early days interruptions in current supply, drops in voltage, etc., were of more frequent occurrence than now. The dangers arising from the re-establishment of the current supply after the same had been cut off were a serious menace to the commercial operation of the electric motor. There was a crying need for a controlling device to overcome these dangers.

Shepardson's Main Line Magnetic Switch

Shepardson's main line magnetic switch was an effort to solve the problem, but it did not take care of all requirements. The switch lever *S*, Fig. 2, is held back by a spring so that when the current supply is cut off the magnet *M* is demagnetized, and the switch springs up and opens the circuit to the motor. The motor was not left connected to the line, but an attendant was just as necessary to push the starting lever back, and nothing prevented leaving the lever on an intermediate contact. Also, if the connection to the shunt field opened, there was no provision for opening the circuit automatically to prevent destruction of the motor.

Blades' Controlling Device

The device required, however, was finally invented. It marked the greatest step in the commercial application and operation of the electric motor. The invention, application for patent on which was filed Nov. 30, 1888, by Mr. Harry H. Blades, comprised a shunt motor connected to a constant po-

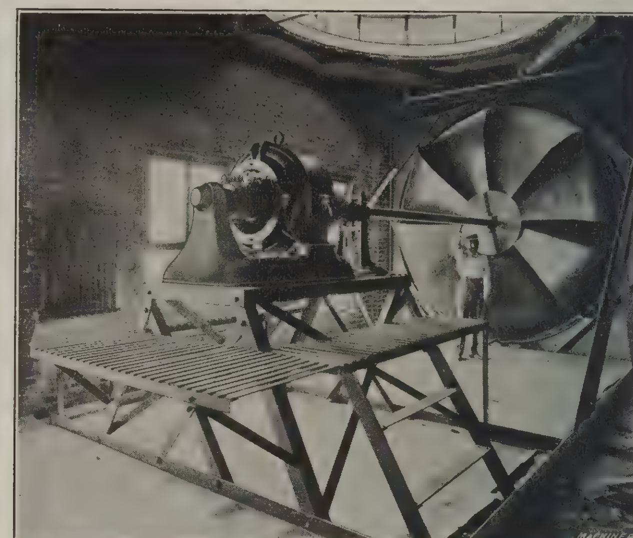

Fig. 8. Ten-foot Fan driven by a 25 H. P., C. & C. Direct-current Motor regulated by a Cutler-Hammer Speed Regulator

tential circuit; a starting-box consisting of a series of resistance steps; a contact arm adapted to be moved by hand over the terminals of the resistance associated with the motor, whereby the resistance may be included in series with the armature of the motor when the contact arm is in the "off"

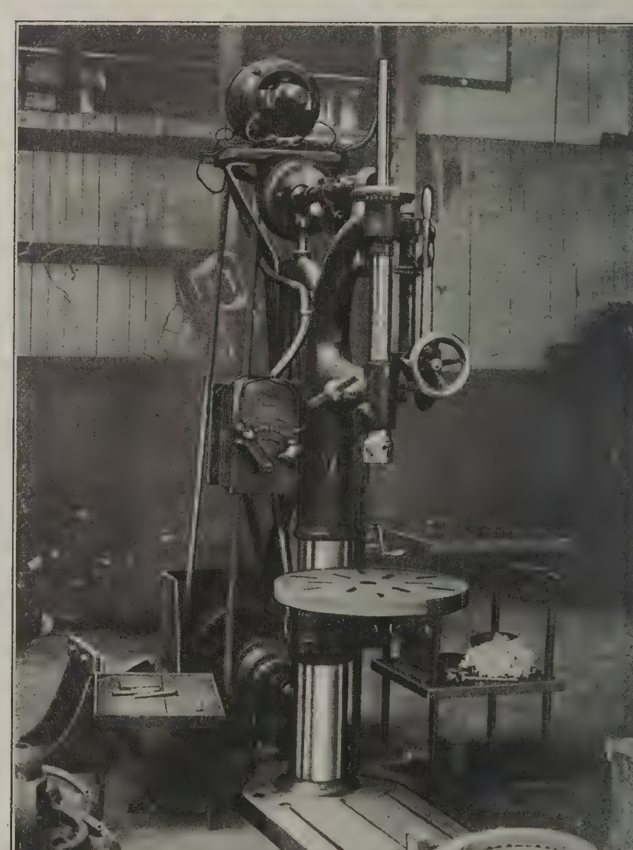

Fig. 8A. Drill Press equipped with Combination Starting and Regulating Rheostat

position, and may be removed entirely from the circuit when the contact arm is in the "on" position; and a magnet which is adapted to grasp and hold the contact arm in the "on" position after it has been moved to the "on" position by hand. This magnet is connected in the shunt field circuit so that it

will not be influenced by varying currents flowing through the armature, but will be influenced only by the current flowing through the shunt field circuit. Fig. 3 illustrates Blades' original structure, patent for which was issued January 7, 1890. Mr. Blades was at that time electrical engineer for the Detroit Motor Co., which company has long since been out of business.

Blades had produced a novel combination for overcoming the dangers incident to the employment of the shunt motor and hand starting-box. If the shunt field were broken, the current supply interrupted or the fuse blown, the motor would shut down with the lever of the starting-box in position for starting properly; if the voltage dropped a trifle and only temporarily, the motor would not be disconnected, but if the drop were prolonged, the motor would be shut down and the rheostat lever returned to the starting position automatically. As there are only two rest positions of the starting lever, "off" and "on," and a strong spring is provided, the danger incident to leaving the lever on an intermediate contact was obviated. About 1892 and 1893 the Blades patent began to be used to a great extent, and by 1896 the use of the automatic release of the operating lever was considered essential to the successful operation of motors.

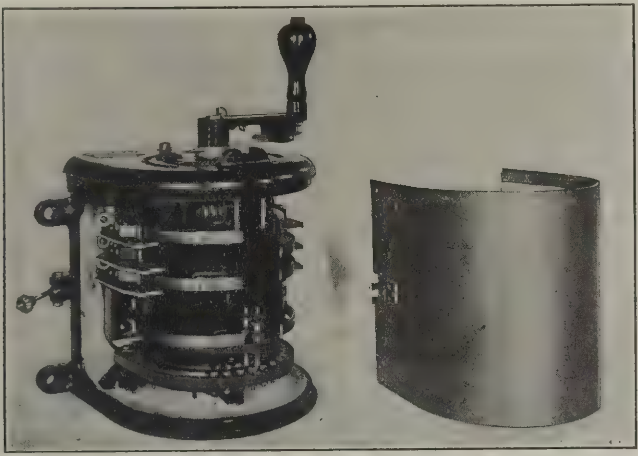

Fig. 9. Drum Type Machine Tool Controller

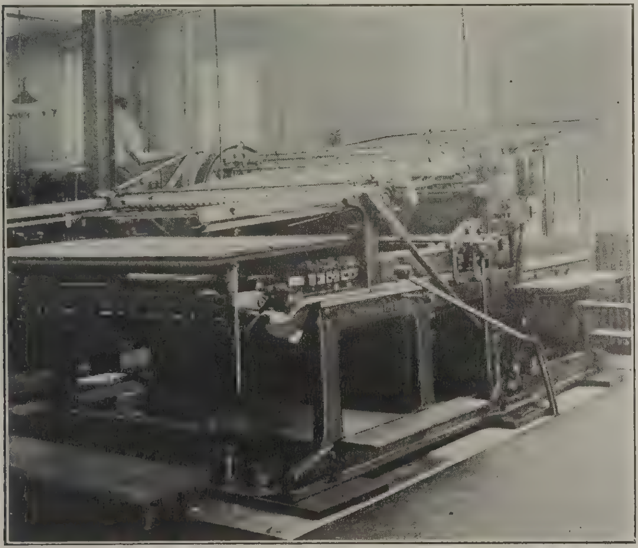

Fig. 10. Drum Controller installed for Controlling Motor-driven Printing Press

Modern Motor Starters

The present standard motor starter of the manually-operated type illustrated in Figs. 4 and 7 is built on the same principle as the first Blades structure. This device has, however, led to the development of innumerable kinds of motor controlling devices. The recognition of the value of the Blades patent by a Milwaukee electrical manufacturing company has been the means of the establishment of the largest plant devoted to the designing and building of motor controlling devices in the world.

Motor starters, starting rheostats, or "starting-boxes," as they are sometimes called, are used, as already stated, for starting an electric motor without excessive current inrush and bringing it gradually up to its normal speed. Some types of speed regulators are similar in appearance to starting rheostats, but the resistance employed is designed for carrying the full current constantly.

A starting rheostat used with the ordinary shunt or compound motor cuts out steps of resistance in succession as the lever is passed over the contacts. When the lever is held in contact with the magnet of the no-voltage release, no resistance is in circuit, but the current passes directly to the motor. Five to fifteen seconds is the usual period for starting a motor under ordinary load. Where the motor is driving a machine which requires very heavy starting torque, a starting rheostat having resistance designed for a longer starting period should be selected. A motor heavily loaded should be started slower, allowing the handle to rest for longer periods on successive contacts. This prevents large current inrushes and blowing of fuses, and takes from thirty seconds to one minute for the whole operation, depending upon the load.

Speed regulators for machine tool motors, fans, pumps, printing presses, controllers for hoists, cranes, elevators, etc., are made in types for every application, each providing special features, as required. In all cases the character of the drive and the motor data must be considered. For instance, a controller for a printing press must be differently proportioned from a controller for a lathe. With a printing press, the torque is about the same whether running with paper or without, and the vital requirement is to bring the motor up to speed smoothly and quickly.

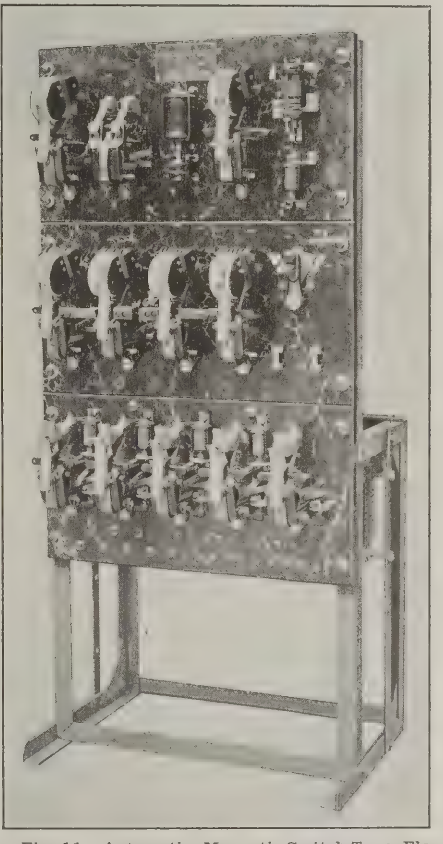

Fig. 11. Automatic, Magnetic Switch Type, Elevator Control Panel, for High-speed Electric Passenger Elevators, Multiple Solenoid Type

A motor speed regulator, such as used considerably for regulating ventilating fans, illustrated in Fig. 5, is practically a motor starter with resistance designed to be capable of being in circuit all the time the motor is in operation, instead of just five to ten seconds, as required in starters. The resistance must be ample to carry the full load motor current for long periods of time, so that the operating lever can be left on any contact segment. Fig. 8 shows a 10-foot fan driven by a 25 H. P. C. & C. direct current motor regulated by a Cutler-Hammer regulator mounted against the wall.

Speed regulation of shunt-wound and compound-wound motors may be effected by inserting resistance in the armature circuit of the motor, or by inserting resistance in the shunt-field circuit. The first method reduces the speed of the motor below its normal rated speed. The second method increases the speed of the motor above normal. Fig. 8A is an example of the latter type of control. The drill press shown is driven by a ½-horsepower Watson motor and a speed variation above normal is obtained by the combination starting and regulating rheostat within easy reach of the operator. By a combination of the two methods the speed of a motor may be both decreased below and increased above normal speed, thus affording a wide range of speed variation.

Speed regulation by armature resistance is open to two ob-

jections: first, the difficulty of maintaining constant speed under varying load conditions, and, second, the necessity of wasting energy to secure speed reduction. These objections are in part offset by the fact that speed reduction by armature resistance may be applied to any motor of standard design and requires nothing more than the simplest (and, therefore, least expensive) speed-regulating rheostat. In cases where the motor will be operated nearly always at full speed, and only occasionally at less than its normal speed, the difference in first cost of the installation may justify the use of the armature resistance method of control. When the speed is changed frequently regulation by shunt-field resistance is preferred.

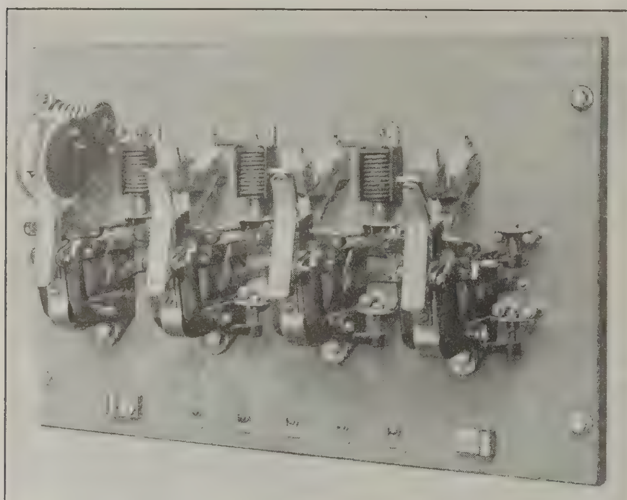

Fig. 12. Series Relay Multiple Solenoid Type Self-starter

One of the most common errors is that of selecting a regulating rheostat of insufficient capacity. If the current required to operate the motor at full speed with no resistance in circuit is greater than the rated capacity of the rheostat, overheating of the resistance will result. An increase in temperature even to a point where the hand cannot be held on the enclosing case need cause no apprehension, but should the resistance become red-hot, the regulator is being worked beyond its capacity and the load on the motor should be reduced or a regulator of greater capacity substituted. If the current required to operate the motor at full speed with no resistance in circuit is less than the rated capacity of the regulator no over-heating will occur, but it will not be possible to secure the full fifty per cent speed reduction which the rheostat is designed to give with all resistance in circuit.

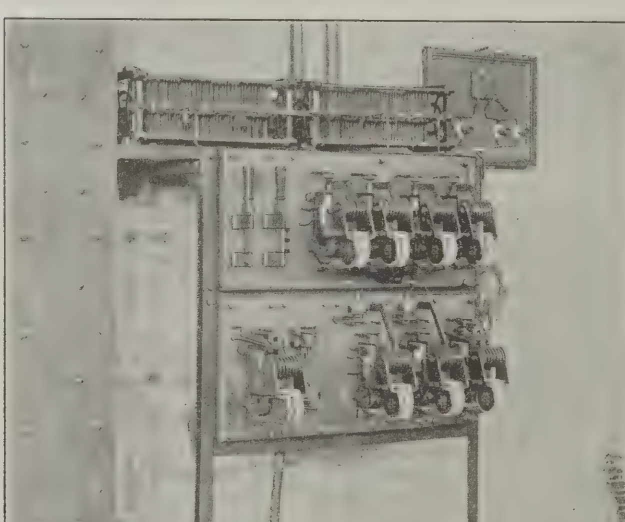

Fig. 13. Control Panel for Steel Mill Service. Magnetic Switches on the Panel are operated by Small Control Master Switch on Rolling Mill

The power required by some kinds of motor-driven machines when running at slow speed is less in proportion to the reduction in speed than in other classes of machines, some of which take almost as much current when operating at one-half speed as at full speed. Typical examples of the two classes of machines referred to are furnished by a ventilating fan and a hydraulic pump, the current required to operate the fan becoming less and less as the speed of the fan is diminished, while in the case of the pump practically the same amount of current is required to operate it at half speed as at full speed. In other classes of service, such, for instance, as the speed regulation of ice cream freezers, several ventilating fans driven by one motor, line-shafting subject to variable loads, etc., the current requirements can only be determined by tests made at various speeds.

Drum type controllers, such as are used for machine tools, printing presses, cranes, etc., operated by a revolving handle at the top, are built on the same principle. They vary the speed by inserting resistance in the armature circuit and in the shunt-field circuit, and provide several reverse speeds or full reverse operation of the motor, as desired. A revolving drum carries segments, as shown in Fig. 9, so arranged as to make contact in a predetermined order with contact fingers. By means of accurate control the output of a machine can be increased, because for the various operations the most efficient speed can be employed. The method of mounting a drum type controller is illustrated in Fig. 10, which shows a flat bed printing press.

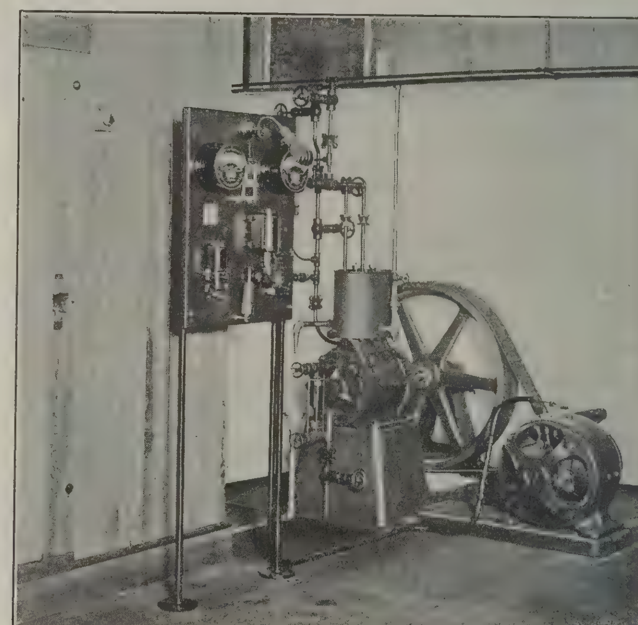

Fig. 14. Automatic or Remote-controlled Self-starters, used in Connection with Motors operating a Refrigeration System

On the simple regulator, Fig. 5, it may be noted that contact to cut in or out the various steps of resistance is made by moving a handle or lever by hand. On automatic starters, regulators or controllers, the cutting out of the resistance is accomplished by magnetically operated switches. The principle is exactly the same. A simple automatic starter is illustrated in Fig. 6. The solenoid at the right side, when energized, closes the fingers at the top in succession and starts the motor with which it is used in the same manner as if the operation were by hand. In the "off" position all resistance is in circuit so that on starting there will be no current inrush. As each finger closes, a step of resistance is cut out. The last finger cuts out all the resistance.

An automatic control panel for varying the speed may consist of a number of magnetically operated switches, the closing and opening of which may be accomplished by pushing buttons connected in the switch magnetic circuit. Assuming that a motor is running at its normal speed and that it is desired to increase this, a control button connected so as to magnetize a switch, the closing of which would connect a resistance in the shunt field, is one means. The button may be located at any location

remote from the motor and control panel. Several typical control panels are illustrated in Figs. 11, 12 and 13.

For some motor applications it is now desirable to have the starting-box automatically operated, or capable of being started by pushing a button or closing a switch at some remote point. The "self-starter" or automatic starting device is one of the most interesting devices employed in connection with motors. Unless one has been able to keep in close touch with the development of electrical apparatus in recent years, one is likely to be astonished at the results accomplished by the various applications of the solenoid. This coil of wire which "sucks" in its iron plunger or core when energized by the passage of current through it, is used in what is called the dashpot-controlled self-starter and in the multiple solenoid current relay type.

In some plants automatic motor starters are installed solely for the purpose of preventing careless employes from starting up the motors too suddenly, but the value of the self-starter consists chiefly in the fact that when combined with suitable energizing devices, such as float switches, pressure regulators, limit switches, or even a push button switch, it dispenses altogether with the need of employing someone to start and stop the motor at the proper time, or else enables the one charged with this duty to control the motor from a distance.

In connection with motor-driven pumps and air compressors the self-starter finds one of its widest fields of usefulness. By means of a switch operated by a copper float in the tank, the circuit to the motor is automatically opened and closed through the self-starter whenever the water in the tank reaches a predetermined high or low level. The same device may be used in sump pits or, indeed, wherever there is sufficient change in water level to operate a float switch. In compression tank systems, and when used with air compressors, a pressure gage is substituted for the float switch, the circuit being made and broken as the needle, or indicator, moves back and forth between two fixed points.

A good example of the advantage of remote control is found in mining work where (in mines employing manually-operated starting-boxes) it is oftentimes necessary to send a man down the shaft to start a motor. In mines where self-starters are installed, every motor can be controlled by switches located in the power house, or at any other convenient point. In connection with electrically operated elevators, hoists, etc., the self-starter insures a smooth start and gradual acceleration to full speed, since by means of the dash-pot referred to the starting period is predetermined and is not affected by carelessness on the part of the operator.

In connection with refrigeration systems, automatic motor starters are frequently used for various purposes. The panel shown in Fig. 14 carries a main line knife switch, fuses, voltmeter and ammeter at the top, with an automatic starting rheostat and pilot switch for the motor driving the brine pump. By running control wires to several points in the building it is possible to start or stop the motor as desired from any of these locations. The starting is accomplished in the same manner each time, and the time of acceleration can be regulated to suit each particular requirement.

In short, practically every motor installation requires a controlling device. The choice of control is equally as important as the choice of a motor. All conditions should be considered in selecting the controlling device. Will the ordinary type of hand-operated starter be most economical or convenient, or would an automatic starter be better in the long run? Is speed regulation required? Is the device to be located where dust, lint, etc., are present in excessive quantities? Is the motor to be reversed? Is the motor of direct-current—series, shunt or compound type? Or of alternating current—single phase, or, squirrel cage or slip ring polyphase type? What duty will the motor be required to do? These are all questions concerning which information is required when considering the installation of the controlling apparatus.

* * *

In all places where bolts, studs, cap-screws, etc., are used, care should be taken to allow enough room for the use of a standard wrench.

CASEHARDENING TEMPERATURES

In an article in *Le Genie Civil*, Dr. L. Guillet gives some interesting information relating to casehardening methods and temperatures to be used in casehardening processes. In general, the regular carbon steels should be carbonized at a temperature of about 1560 degrees F. After carbonizing, the objects should be permitted to cool to about 1100 degrees F. or lower. They are then again heated and quenched from a temperature of about 1875 degrees F. for refining the core, after which they are again heated and quenched from a temperature of 1380 degrees F. for the final hardening. The quenching in both cases is done in water.

The carbon contents in ordinary carbon steel for casehardening should, in general, be from 0.10 to 0.15 per cent, and in no case should it exceed 0.20 per cent. In alloy steels the carbon contents may be as high as 0.30 per cent. The manganese contents should not exceed 0.40 per cent if a single quenching only is employed, but can be somewhat higher if two quenchings are used. Silicon increases the brittleness in all cases, and should not exceed 0.30 per cent. Tungsten and molybdenum also increase the brittleness of the core.

Nickel steels are very suitable for casehardening, but have, however, both advantages and disadvantages. Among the latter are that nickel seems to retard the process somewhat and the hardness of the case is somewhat lower than that obtainable in ordinary carbon steels. On the other hand, nickel tends to oppose the crystallization of the steel at high temperatures and to eliminate the consequent brittleness. Because of this, the first quenching for refining the core is not always necessary, although it noticeably increases the tenacity of the core. With a 2 per cent nickel steel the following temperatures are recommended: The first quenching should be from a temperature of 1830 degrees F. The second heating should be to 1380 degrees F., after which the quenching should take place after the objects have cooled off to about 1290 degrees F. A single quenching from 1290 degrees F. gives the greatest hardness in the case but not the greatest tenacity in the core. Quenching from 1380 degrees F. gives a somewhat higher tenacity but a slightly lower hardness in the case. A 6 per cent nickel steel should be quenched in the first instance from 1560 degrees F., and after reheating from 1245 degrees F. Since this high nickel percentage almost completely prevents the brittleness of the core, one quenching from about 1290 degrees F. is in most cases sufficient.

Steels with from 1 to 1.2 per cent chromium are sometimes used when an especially hard case is required. This element, however, aids the crystallization of the core and the double quenching is, therefore, absolutely necessary. Chrome-nickel steels with a low chromium content require about the same heat treatment as pure nickel steels.

The author does not recommend charred leather for a casehardening mixture, as he considers that it works too actively, but, instead, believes that a mixture of 60 parts wood charcoal and 40 parts of barium carbonate is the best to use. It is easy to obtain, is not expensive, and can be used over again for a number of times.

* * *

A combination of the moving picture machine and the phonograph has been recently demonstrated in London. The invention is of French origin and its development has been under way for a couple of years. Two electric motors are used, one for the moving picture machine and one for the phonograph. These are kept in synchronism by a special arrangement which makes it possible to instantly remedy any defects in the relative speeds of the two instruments. The combination machine is called "chronophone." At the demonstration, prominent actors could be seen reciting monologues. The sounds and the movements on the screen were in perfect harmony. One remarkable picture was that of a lion tamer in the cage of the animals. The mixture of sounds—those of the man speaking, the crack of the whip, the thud of an iron bar falling on the floor of the cage, and the growls of the lions—harmonized perfectly with the pictures. As these are also shown in natural colors, the illusion seems perfect.

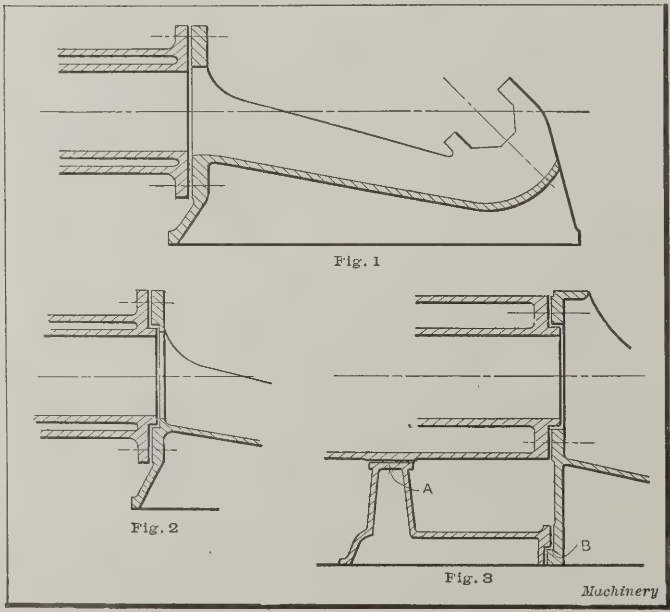
DESIRABLE IMPROVEMENTS IN AMERICAN GAS ENGINE DESIGN*

By C. F. HIRSHFELD†

The designer of gas engines has a double problem to solve. He must not only develop an apparatus which will function properly through a long life, but he must also, in general, design it in such a way that it can be built at a cost which will make it possible to meet competition. In criticizing commercial designs one must, therefore, bear in mind that manufacturing costs limit the refinement of design; but manufacturing costs do not excuse poor designs which a resourceful designer could improve without making the machine more expensive; nor do they excuse designs which make it difficult or impossible for an engine to function properly through a reasonably long life. Such design may give a manufacturer a temporary advantage, but it can never result in giving him a permanent share of the engine business. In the following paragraphs, some of the faulty constructions which are more or less common in small and medium sizes, will be pointed out, and better methods suggested.

One of the most glaring faults still found in many American gas engines of the horizontal type is the unsupported, overhung cylinder shown in Fig. 1. In very small sizes this construction would be justifiable if it were not more expensive than other and better designs which can be used for small engines; in medium and large sizes it is well-nigh inexcusable. The studs or bolts which hold the cylinder to the frame, and which often pass through unfinished, cored holes, cannot be depended on to keep the cylinder in proper alignment. These fastenings are, moreover, not well adapted for taking care of the normal pressure of the piston and of the weight of the cylinder and piston. In the case of large engines constructed in this way it is sometimes possible to notice a measurable deflection of the cylinder during the expansion stroke.

If this general type of design is deemed necessary because of the present investment in drawings, patterns, etc., it should at least be modified as shown in Fig. 2, so that a generous

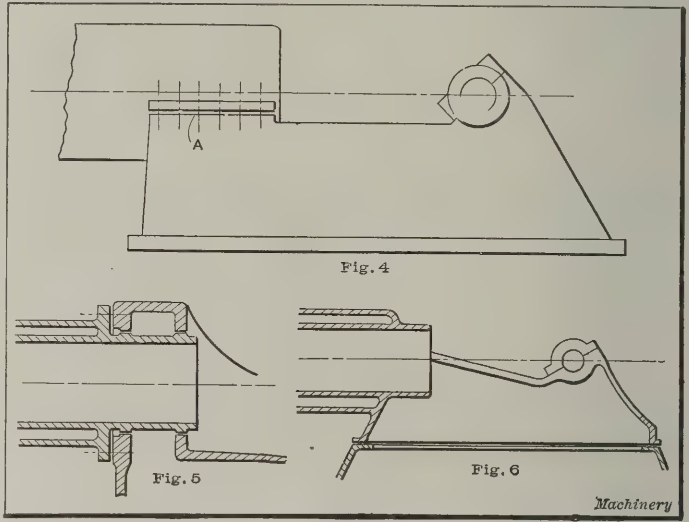


Figs. 1 to 3. Methods of Attaching and Supporting Cylinders

counterbore serves to locate the cylinder and to prevent motion of the crank-end with respect to the frame. The next simplest improvement is to slightly modify the patterns, using a support such as that shown in Fig. 3. This should be cast with, or bolted to, the frame, and should be so arranged that the cylinder can slide back and forth upon it at the point of support *A*. To secure accurate alignment when this auxiliary support is bolted to the frame, some kind of shoulder bearing, such as that shown at *B*, should be provided. Another solution, but a more expensive one, is to allow the cylinder barrel to extend into the frame for a considerable distance, as shown in Fig. 5.

One of the most satisfactory designs, so far as locating and supporting the cylinder is concerned, is that shown in Fig. 4. By making the bench at *A* short in the smaller sizes, the necessary support can be given the cylinder without necessitating the use of an excessive amount of metal in the frame. As the size of engine increases, this bench can be made relatively longer, thus giving the more perfect support required in higher powers. This design is particularly desirable from the manufacturing point of view, because the machine work is simple in character, and because, if properly designed, one frame can be used with several sizes of cylinders.

For very small single-cylinder engines some makers have developed designs similiar to those in Figs. 6 and 7, in which the working bore, jacket and frame are all cast in one. For small sizes this is a satisfactory solution; for larger engines



Figs. 4 to 6. Methods of Attaching Cylinders to the Frames

it should be so modified as to permit of the use of a separate cylinder liner, as shown in Fig. 8.

In tandem engines the front cylinder should be supported in much the same way as in the single-cylinder type. The rear cylinder should be located with respect to the front cylinder by counterbored flanges which are finished when the cylinders are bored. These flanges should not, however, be called upon to resist bending moments caused by the weight of the cylinder, the thrust of valve mechanisms, etc. This bending moment should be taken care of by a simple support. A modification of the support shown in Fig. 3 is adapted to this case. The use of a support entirely separated from the main frame, a common practice in tandem constructions, is not to be recommended. The accuracy of its location depends entirely upon the care exercised by the erector, and is beyond the control of the manufacturer.

There seems to be a difference of opinion as to the necessity of a crosshead in single-acting tandems. From the viewpoint of rational design, there can be no question: a crosshead should be used. A piston cannot perform the functions of a crosshead without impairing the perfection of its action as a piston. From the viewpoint of the designer, however, the case is different. However desirable a crosshead may be, financial considerations may not be neglected. Although the crosshead itself is not necessarily a very expensive piece, it involves the use of a piston-rod and guides; but many manufacturers increase the cost of crosshead constructions very considerably by using an unnecessarily complicated crosshead. With proper slipper surfaces, no wedge adjustment is required on this member. A simple construction so arranged that the lower slipper can be moved down by the insertion of shims, if it should become necessary, is all that is required. As a result of the balance between cost and desirability, trunk-piston designs are generally used in smaller sizes, and crossheads in larger engines. The split might well be made at about 100 horsepower per crank. The reboring and ultimate replacement of 50 horsepower cylinders will, in general, about

* For additional information on this and kindred subjects, see MACHINERY, February, 1912, engineering edition, "Points in the Design of Two-stroke Cycle Engines," and the articles there referred to.

† Professor, Gas Power Engineering, Sibley College, Cornell University, Ithaca, N. Y.

balance the interest on the additional investment involved in a crosshead engine.

The cylinders of single-acting engines of American design are often open to considerable criticism. One of the most common faults is the use of a working barrel and jacket of too nearly the same diameter, giving inadequate jacket space. Faults that generally accompany this are the entire omission of openings through which this space can be cleaned, or the use of openings so small and so distributed that they are of little practical use. Builders of what may be called "stock" engines can seldom be sure that their engines will not be used in places where the only available water is muddy or carries large quantities of mineral matter in solution. If designers would regard the jacket as a water heater as well as a cylinder cooler, fewer designs of the kind mentioned would appear. Openings into the jacket space should be of such size and number that all parts of the interior can be easily reached, so that mud and scale can be cleaned out.

It is not good practice to make provision for cleaning by combining the jackets of the cylinder and of a separate cylinder head, that is, making them continous, as shown in Fig. 9. Experience has shown that joints of this kind are very difficult to pack. Leakage of water into the cylinder is apt to occur, causing irregular operation, or, if this can be prevented, water is apt to leak to the outside of the engine. If such cored passages are deemed necessary by the designer for the support of cores or for simplicity of construction, the head should be made to fit into the end of the cylinder with a metal-to-metal contact at some point in the counterbore, in order that the gas pressure acting on the inner edge of the gasket may be reduced to a minimum. It is, however, far better to cast the abutting faces solid and to carry the water around from jacket to jacket by means of a U-shaped connection. Even in this case many troubles will be eliminated if the counterbored construction is adopted. This method of protecting the gasket against blowout is well worth while.

Vertical engines have many head joints which are difficult to properly care for in operation. Whenever valves are placed

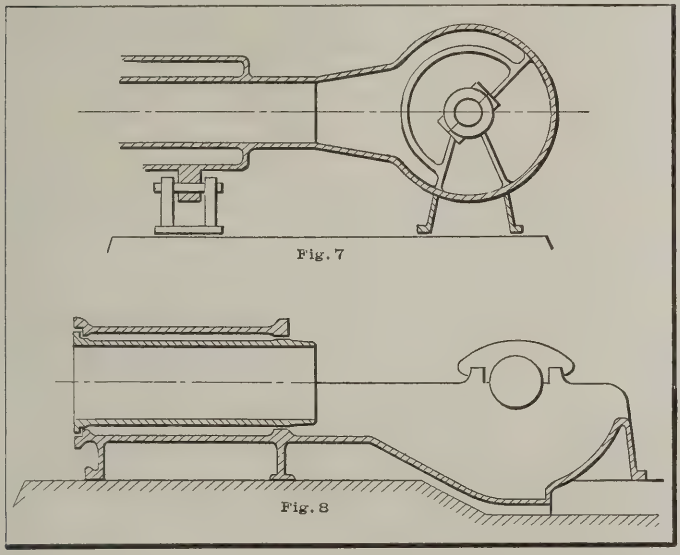


Fig. 7. Arrangement for Small Single-cylinder Engines. Fig. 8. Frame for Heavy Engine

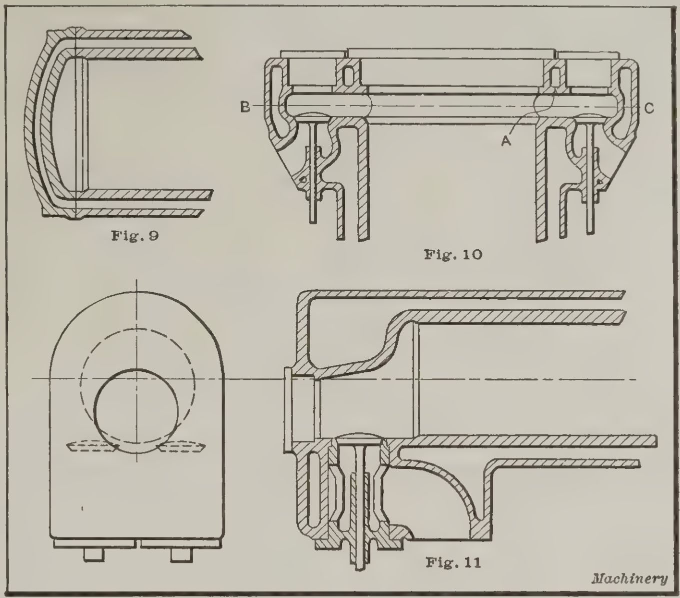
in side chambers or pockets in high-compression engines of this type, it becomes difficult to design proper covers for the cylinder and valve chambers. The ideal arrangement would be the use of circular covers for each part, with each cover fitting into a counterbore, as shown in Fig. 10. When high compression and large valve diameter are desired, it becomes necessary to decrease the distance between the center line of the cylinder and the center lines of the valves. This generally makes it impossible to leave enough metal at point *A* to make it feasible to use separate covers, and there is a tendency to split along the line *BC*, move the valve toward the cylinder, and use non-circular covers. Not only does this construction require non-circular gaskets and prevent the use of counterbores, but it also often makes it impossible to finish the abutting surfaces with circular cuts which do not run off the edge of the casting. The satisfactory packing of a joint of this kind is often a matter of great difficulty. If, in addition to the disadvantages already enumerated, the gasket is called upon to take care of a continuous jacket, such as that previously mentioned, it will require both skillful manufacture and attendance, to keep the engine in successful operation.

These considerations and others to follow form strong arguments in favor of the location of valves in the head in high-compression vertical engines, if not in all engines with a vertical center line. Other advantages are simple cylinder castings, better shape of combustion space, and general accessibility of valve operating mechanism. The advantages accruing from valves in the head are particularly noticeable in



Figs. 9 to 11. Cylinder and Valve Arrangements

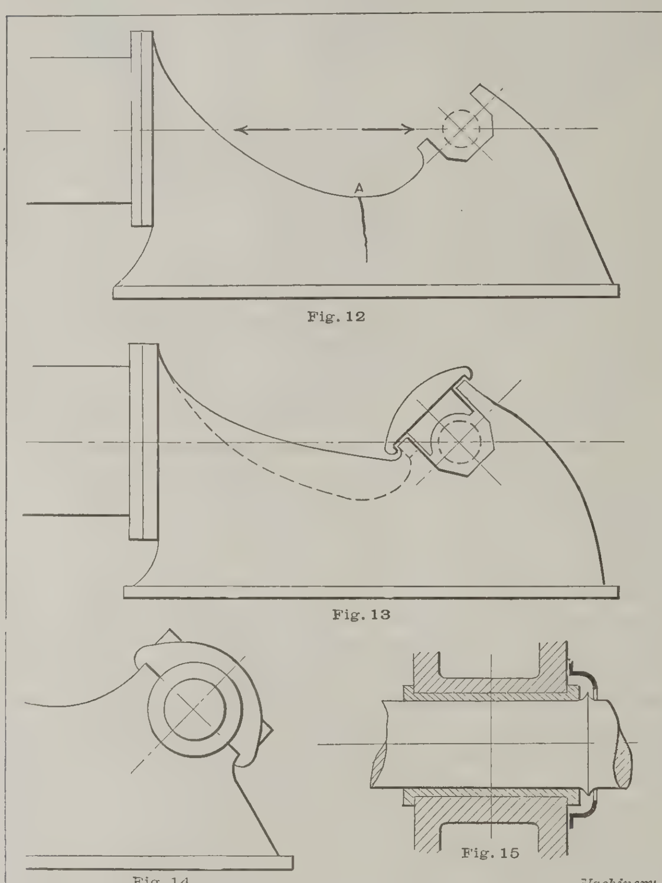
Diesel engines, which are almost universally constructed in this way.

While speaking of valves and valve gear, it will not be amiss to consider some of the designs used in horizontal constructions. There are still a large number of these engines constructed with horizontal valves, that is, valves with their longitudinal axis horizontal. It needs no theoretical discussion to prove that such an arrangement is incorrect; the engines themselves prove that. Such valves are bound to wear their guides and seats out of round at a comparatively rapid rate. It is no more expensive to use vertical valves, and it is no more difficult to devise the operating mechanism for such valves.

In small types of horizontal engines with vertical valves, these members are located at the top and bottom in the cylinder or head, in chambers at the side or sides, and side by side in the bottom of the combustion space. The last-named location is generally preferable on the grounds of cheap construction and simple operating mechanism. An arrangement of this kind is shown in Fig. 11. This design is open to the objection that the volumetric efficiency of the cylinder is decreased by the heating of the incoming charge, which must pass in close proximity to the hot exhaust valve. The thermal efficiency is also apt to be slightly decreased by the loss of unburned mixture, if any considerable overlap of valve events is permitted. For small engines, however, these considerations are insignificant in comparison with the advantages to be gained by this construction.

Valves in pockets cast or bolted to the walls of the cylinder are open to criticism because of the poor shape of the combustion space, the complication of the cylinder end and its jackets, and the more complicated mechanism generally found necessary; but these pockets have the advantage of making it possible to remove the valves through plugged openings, so that valve cages are not necessary. In this sense the construction is cheaper than that just recommended; but on the other hand the advantages of valve cages are so great and the difference in cost so small, that cost can hardly be urged as a justification for valves in pockets.

Such seemingly simple things as frames are often incorrectly designed, particularly in the smaller sizes of horizontal engines. It is evident that the end of the frame to which the cylinder is fastened and the end which supports the bearings tend to separate during each combustion and expansion. To prevent this they are tied together by the metal in the frame. The most effective way to tie two pieces together against the action of separating forces is to put the tie member in such a position that its gravity axis coincides with the line of action of these forces. If this is not done there must be a bending moment on the binding member. A common type of frame is shown in Fig. 12. The two arrows in the center line show the line of action and the directions of the separating forces. It is evident that the upper surface of the frame will tend to separate at some such point as *A*. The result will be a crack extending downward. The trouble can be remedied by raising the upper lines of the frame as shown in Fig. 13, in which the dotted lines indicate the construction of Fig. 12. This results in bringing the gravity axis of the frame section nearer to the center line of the engine and thus reduces the bending moment.



Figs. 12 to 15. Frame and Bearing Design

Many designers deem it desirable to use a bearing split at an angle as shown in Fig. 13, in order to take up the maximum thrust with the strong, cantilever-like piece which backs up the bearing. With this design it is difficult, although not impossible, to carry the top line of the frame as high as desirable, and as a result many of the engines now built in this way have abnormally strong bearings in proportion to the strength of their frames. In all but the smaller sizes it is better to use a design such as that shown in Fig. 8; it gives more nearly the same strength in different parts of the frame. Some makers are still using the type of bearing shown in Fig. 14. For this type there can be no justification. The maximum thrust must be taken largely by the cap and transmitted to the frame through the studs which hold that cap in place.

Another fault in some frames as now built in this country is to be found in the footings or surfaces on the lower side of the frame which are to rest on the foundation. In large engines, which may reasonably be expected to receive proper care in erection, it is good practice, when necessary, to use transverse footings within the walls of the frame, as shown in Fig. 8. In small engines there is no need for such supporting surfaces. The support furnished by the feet on the walls at side and end, is amply sufficient, and bearing surfaces inside of the walls may do more harm than good in the hands of a careless erector.

The downwardly projecting crank-case is a weak point in many engines of the smaller type. In large engines it is often necessary, if the shaft is to be at a convenient height above the floor, but this argument does not hold for the smaller sizes. Where small engines are designed as stock types, it is far better to protect the bulge of the crank-case with slightly deeper frame walls.

Many designers have not yet realized the desirability of an oil groove or channel on the outside of the frame at the bottom. Such a groove adds little to the molding cost, but adds materially to the ease with which the engine and foundation can be kept clean and free from oil. The channel should be properly sloped to insure drainage, and a drain provided at the lowest point, preferably at the front of the engine. It should also be noted that oil channels which are broken up into several undrained or imperfectly drained parts by bosses for foundation bolts are little better than no channels at all.

In the same class with these oil channels are oil guards over the crank-case in horizontal engines, and oil drains at the lowest point of the crank-case in all types. Unfortunately these are often ignored through ignorance, or as a foolish means of cutting down costs. Many of the larger engines in which oil channels, crank-case guards and oil drains are provided as a matter of course, are still faulty in that no provision is made for taking care of the oil which works out of the bearings and along the shaft. Splash rings and guards, such as those shown in Fig. 15, are not very expensive, and they materially assist in maintaining cleanliness.

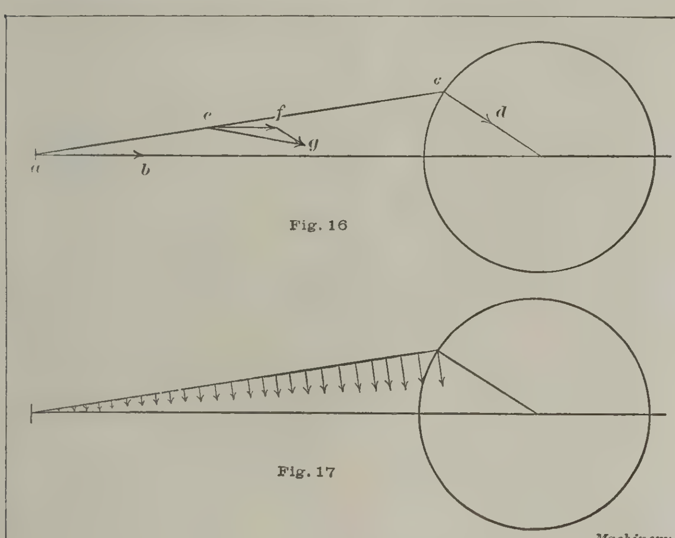
A very weak point, characteristic of American design, is the exposed or partly exposed gear. When possible, cam shaft and similar gearing should run in an oil bath and be entirely enclosed. There are, however, many types in which such an arrangement would be very expensive, but this should not be used as an excuse for leaving these gears poorly protected or not protected at all. Danger of injuring the attendant is not the only thing to guard against; it is also necessary to prevent accidental damage to the gears. There are many engines now on the market in which the gears are so protected that it would be practically impossible for an attendant to get caught in them, but which have the guards arranged in such a way that tools can easily be dropped onto or between the meshing teeth. Several engines which were temporarily disabled in just this way within a few weeks after installation have recently come to the attention of the writer.

Another weak point in American design, which fortunately is now being rapidly eliminated, is the use of a malleable iron connecting-rod. It is generally conceded that the proper material for connecting-rods is steel, forged or cast in the smaller sizes, and forged in the larger. It is true that malleable rods are used only on single-acting engines, in which the maximum load puts the rod in compression, but these rods are too weak and are liable to fracture. The compression loading is only part of the story. Every connecting-rod, in operation, is also loaded like a beam, and iron is notably not the proper material for use in a beam. This beam loading is illustrated in Figs. 16 and 17. The acceleration at the wrist-pin end of the rod is shown in Fig. 16 by the arrow *ab*, and the normal acceleration at the crankpin end by *cd*. Any point between these two is subject to an acceleration which may be regarded as made up of two components, one parallel to and smaller than *ab*, the other parallel to and smaller than *cd*. These components and their resultant are shown for one point in the length of the rod by *ef*, *fg* and *eg*. If the normal accelerations of all the points be found, they will be about as represented in Fig. 17. Since there can be no acceleration without an accelerating force, there must be forces acting along the length of the rod in the same general way as do the accelerations in the illustration. It will be observed that these forces load the rod as a beam. The existence of these forces also shows the folly of using an H-section as is done by some makers. An I-section is rigid in the plane of rotation and

is well able to care for the beam loading; an H-section is not sufficiently rigid in this direction.

While on the subject of connecting-rods, it would be well to speak of the methods provided for taking up wear at the two ends. In normal operation the wear at the crankpin end will be far in excess of that at the wrist-pin. The design of adjustments which will leave the distance between the pins the same is, therefore, practically impossible. The designer must decide whether the rod is to grow shorter with age, giving decreasing compression and efficiency, or whether it is to grow longer with the opposite results, and with the possibility of causing preignitions because of high pressures. The former is generally preferable as being safer, although the kind of fuel, the compression pressure for which the engine is designed, the kind of attendance which may reasonably be assumed, and a number of other considerations should also be given due weight in arriving at a conclusion. One case has come to the writer's attention which is interesting as illustrating what extreme conditions may be attained in practice. Wear was taken up in such a way as to lengthen the rod to such an extent that the first piston ring was driven into the counterbore of the cylinder and effectually locked the piston. This is, of course, a most exceptional case, but serves to show what is possible with some engines in some hands.

It has become recognized as desirable to provide means for adjusting the time of ignition while the engine is in operation. There are still many engines built in which such adjustment cannot be made. It may surprise some, but it is nevertheless a fact, that several large engines which are commonly recognized as "standard designs" have no such provision. The convenience of being able to adjust the time of ignition during operation can hardly be questioned, and it is absolutely necessary with producer gas engines.



Figs. 16 and 17. Forces acting on Connecting-rod

Another weak point in many ignition systems is the lack of proper provision for taking up wear. The parts are of necessity rather small, and rub across one another millions of times per year. Adequate lubrication is difficult, and wear is certain. Such systems should always be so arranged that the effect of wear upon the timing can be compensated for in a simple manner, and that considerable wear can occur before it is necessary to replace parts of the apparatus. It is rather remarkable that more manufacturers have not deemed it advisable to adopt the high-tension system which has proved its worth under the severe operating conditions pertaining in automobile practice. This type combined with careful construction can be relied upon to give most satisfactory results.

* * *

The methods of Russian high finance are startling, if we can accept the report current in regard to the use of certain die-casting machines recently bought. It is alleged that ten die-casting machines were lately bought by the Russian Government from a New England concern, for making certain Russian coins. The price was the mere bagatelle of $40,000 each.

THE INFLUENCE OF HEAT ON HARDENED TOOL STEELS*

By testing various samples of carbon steel in the tool steel testing machine designed by the author, it was found that carbon tool steels have a very low durability at a low cutting speed; that there is an increase of durability as the cutting speed increases; and that a maximum durability of cutting speed is obtained at about 50 to 80 feet per minute. There is then a decline of durability to a very low value if the cutting speed is further increased. These general characteristics are common to all tool steels that have been tested, whether of the carbon or high-speed steel type (tungsten or tungsten-vanadium varieties). All of these give, when the durability is recorded in diagrammatic form, a single- or double-peaked curve, according to the heat-treatment they have received. All show a low durability at low cutting speed, this characteristic being especially marked in the case of some high-speed steels, which latter often retain their durability at very high speeds.

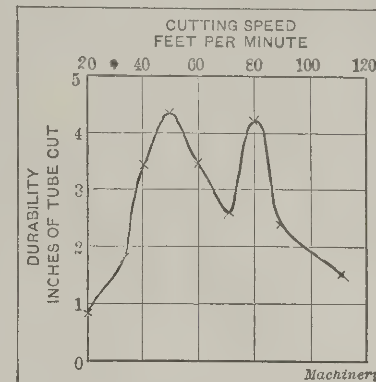


Fig. 1. Example of Double-peaked Durability Curve

The author, at a previous occasion, has pointed out that the observed changes in the durability of cutting tools are mainly caused by the changes in the temperature of the cutting edge, due to the heat generated at different cutting speeds. This heat theory has been confirmed by experiments showing that changes of durability corresponding to those which occur under varying cutting speeds can be produced by varying the temperature of the tool in other ways, while the cutting speed remains constant—for instance, by varying the temperature of the water with which the tool is flooded, or by varying the depth of the cut (a heavy cut generating more heat than a light one), or by dispensing entirely with the cooling water.

The various problems that were dealt with in the experiments were as follows:

1.—It has been found by experiments on the tool steel testing machine that all tool steels, without exception, have a very low durability, and are very quickly blunted when cutting under water at low speeds and fine cuts, that is, under conditions which preclude any considerable heating of the cutting edge; and it has been found that any alteration in the cutting conditions which tends to increase the temperature of the cutting edge results in an increased durability of the tool. What, if any, are then the correlative changes in the physical properties (strength, hardness, toughness, etc.) of hardened steel which occur when it is raised from a low to a higher temperature?

2.—All varieties of tool steel have been found to be capable when suitably hardened, of producing double-peaked speed-durability curves (see Fig. 1), the characteristics of such steels being that at a certain speed they are less durable than at either a higher or lower speed. Is it possible to correlate this low durability at a certain speed with a particular physical condition at a certain temperature?

3.—All tool steels are found to lose their durability when the cutting speed is raised above a certain limit. Is there any corresponding change in their physical properties when they are heated above a certain temperature?

4.—Assuming that each cutting speed corresponds to a definite temperature of the cutting edge (the weight of cut and all other conditions remaining constant), what are the actual temperatures of the cutting edge corresponding to the various cutting speeds, and corresponding to the various changes in the durability and physical properties of the steel?

Before dealing with these problems, it is necessary briefly to consider the nature of the actions tending to wear or blunt a cutting tool, and the correlative physical properties constituting durability, which the tool must possess in order to withstand these actions. The principal action to which a tool is subjected in cutting is one of friction under heavy pressure. This tends to rub away the surface of the steel, by causing

* Abstract of a paper read by Mr. Edward G. Herbert before the Iron and Steel Institute, Great Britain, at the May, 1912, meeting.

the particles of steel to slide over one another. To resist blunting by this action a tool must possess hardness. But the stress on the tool point is not constant: as the chip is detached it breaks up into a series of short segments (more or less completely separated), and this process subjects the tool to a succession of changes of pressure, amounting almost to blows, and tending to chip off portions of the cutting edge. To withstand this action the tool must possess toughness.

If we make a tool of glass and another of copper, and use them to turn a cylinder of soft material such as lead in the lathe, we shall find that both are very soon blunted, but from totally different causes. The glass tool, though extremely hard, is brittle, and is blunted by the chipping away of minute particles of the cutting edge. The copper tool, though very tough, is soft, and is blunted by the rubbing away of the cutting edge. If now we imagine that by some subtle alchemy we can gradually change the tool of glass into one of copper, it will probably pass through some intermediate stages where it will retain some of the hardness of glass without all its brittleness, and will have attained some of the toughness of copper without all its softness. The tool in this intermediate state will probably keep its sharp cutting edge much better than either the glass or the copper tool.

In order then to measure, throughout a range of temperatures, those physical properties of steel which constitute its durability, it is necessary to test it at each temperature for hardness and for toughness. Experiments with suitable apparatus were, therefore, carried out for measuring the hardness and toughness at various temperatures, taking into consideration such factors as different methods of grinding the tools, etc. The experiments made it possible to answer the questions propounded above, as follows:

1.—The low durability of all tool steels, cutting under water at low speeds and light cuts, seems to be completely explained by the low values of hardness and toughness which always occur at cutting temperatures of 50 to 100 degrees C. (122 to 212 degrees F.). The breaking tests have shown in every case the product, hardness times toughness, increases in value as the temperature is raised above 100 degrees C. The cutting tests have shown in every case that the durability increases when the cutting speed is raised above 20 feet per minute. These cutting tests have also shown that the durability always increases when a tool working at 20 feet per minute is allowed to cut dry instead of with water, or with hot water instead of cold. It is impossible to doubt that these are different manifestations of the same physical change in the steel.

A clear recognition of this phenomenon is of great practical importance. A great deal of the metal cutting in every machine shop consists in taking fine finishing cuts, often with water on the tool. If such cuts are taken at a slow speed, the temperature of the cutting edge may not rise above 100 degrees C., in which case the tool will be quickly blunted. Its durability can be increased by increasing the speed or by cutting dry. Many cases are known to have occurred in ordinary workshop practice, where an increase in cutting speed has actually resulted in increased durability of the tool. Low durability at low cutting temperatures (on, for example, finishing cuts) is a familiar characteristic of high-speed steels, and is most marked in tools which have been suitably hardened for very high temperature work. High-speed steel can be so hardened as to retain its durability at fairly low temperatures, and there are now on the market tungsten steels specially adapted for low temperature work, such as finishing very heavy forgings; but every description of steel known to the author loses its durability if the cutting temperature is low enough. It should be noted that a low cutting temperature can only occur when there is a combination of low speed with light cut. A heavy or moderate cut raises the temperature of the cutting edge above 100 degrees C., even at very slow speeds.

2.—The phenomenon of the double-peaked curve is not completely elucidated, though the evidence goes some way to explain it. The variations of hardness and toughness with temperature are of a complicated character, and the cleft between the two peaks of a durability curve appears to be caused by the conjunction of depressions in the hardness and toughness curves at a particular temperature. The relative heights of the two peaks are found to vary with the conditions of cutting, and this variation may be due to a change in the relative importance of the hardness and toughness factors, according to the quality of the material cut, or the shape of the tool.

3.—The decline in durability which takes place when a certain limiting speed is exceeded, is evidently caused by an actual softening of the cutting edge by the heat generated in cutting. This softening, which is extremely local, takes place even when the tool and the work are practically immersed in running water. The speeds and temperatures at which the softening occurs depend largely on the particular hardening process which has been applied to the tool, and are generally highest in high-speed steel.

4.—It is not yet possible to establish an exact scale of cutting temperatures corresponding to the scale of cutting speeds, but a comparison of the temperature-durability tests with the speed-durability tests enables us to make an approximation, as in Fig. 2.

To establish the relation between the speeds of cutting with and without water, a comparison was made between the various results obtained in the tests, from which it appears that the effect of using water is approximately to double the cutting speed; in other words, the edge of a tool flooded with water attains about the same temperature as the edge of a tool cutting dry at half the speed. This must not be taken as a general statement applicable to all cutting operations. The dry cutting temperature depends largely on the volume of metal operated upon. The tube used in the tool steel testing machine is small in diameter and light in section; it becomes considerably heated under a dry cut. In machining a large forging, the body of metal absorbs a great deal of heat, with only a slight rise in temperature, and the use of water has less effect on the cutting speed.

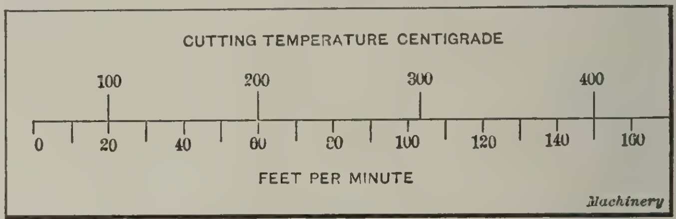

Fig. 2. Approximate Scale of Cutting Temperatures and Cutting Speeds, when Testing in Tool Steel Testing Machine

Considerable interest attaches to a comparison of the durabilities of carbon and high-speed steels. It appears that the high-speed steel has two distinct features of superiority. The speeds at which it attains its maximum durability are not very different from those at which carbon steel is most durable, but the high-speed steel is several times as durable at these speeds. Quite distinct from its superior durability at moderate cutting temperatures is the property possessed by high-speed steel of retaining some durability at temperatures high enough to soften carbon steel, but its actual durability under such conditions is much less than under conditions which do not unduly heat it. In other words, its abrasive quality appears to be more important than its heat-resisting quality.

ERRORS IN JUNE DATA SHEET

We have been advised by the Society of Automobile Engineers that a few errors appear in the specifications for heat-treatment of carbon and nickel alloy steels reported by its Iron and Steel Division, January, 1912. The data of this report which was condensed into the June Data Sheet also contains the errors which are as follows: In Table I, reduction in area for annealed 0.10 carbon steel should be 55 to 65 per cent instead of 60 per cent; elongation of 0.50 heat-treated carbon steel should be 5 to 20 per cent instead of 0 to 20 per cent. In Table III, elongation of 0.40 carbon high nickel-chromium steel should be 2 to 15 per cent instead of 0 to 15 per cent; same for 0.45 carbon high nickel-chromium steel; and 150,000 to 225,000 pounds elastic limit for heat-treated 0.50 carbon chromium-vanadium steel instead of 150,000 to 200,000 pounds.

* * *

A few years ago engineers considered that 8, 10 or 12 square feet of heat transmitting surface per boiler horsepower was good practice, but improvements in the circulation system of steam boilers have made possible great increases in efficiency and now the ratios have been cut down to 4, 5 or 6 square feet per boiler horsepower.

THE RIVETT INTERNAL GRINDING MACHINE IN THE AUTOMOBILE FACTORY*

By CHESTER L. LUCAS†

The manufacture of automobiles has done much to develop general machine shop practice, and the necessity for mechanisms requiring hardened and ground parts has created a demand for the best that can be produced in grinding machinery. In internal grinding of the smaller variety, considerable trouble was met with at first in securing a suitable quill-spindle that would maintain its accurate adjustment and still run at the high speeds required in the grinding of holes of small diameter. A second difficulty was encountered in grinding holes perfectly straight, without tapering or "bell-mouthing." Grinding machine builders soon recognized the fact that before internal grinding could become of great value as an accurate machining operation, these two primary troubles must be overcome.

One of the first persons to recognize the possibilities of internal grinding, as well as the limitations of the machines in

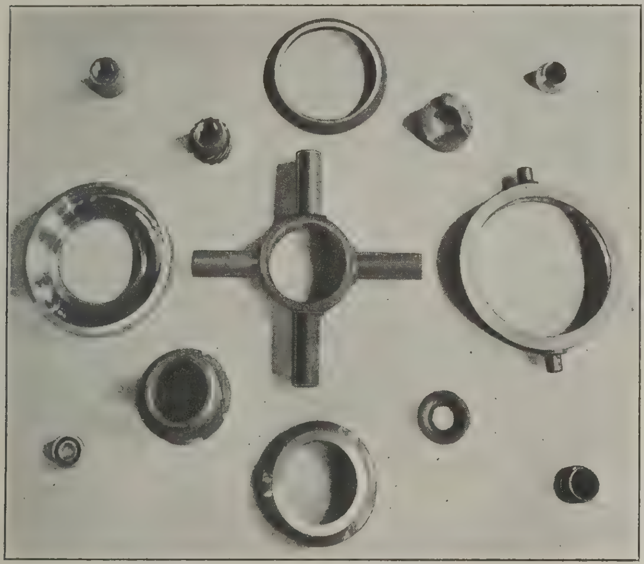

Fig. 1. Some of the Automobile Parts ground on Rivett Grinding Machine at the Stevens-Duryea Co.'s Factory

use, was Mr. Edward Rivett of the Rivett Lathe Mfg. Co., Boston, Mass., who, in 1900, took out a patent on an improved form of grinding machine quill-spindle. This spindle was designed to run at the high speed required for internal grinding and was designed particularly to overcome the end shake of the spindle, as well as to insure the proper fit of the spindle in the bearings. Essentially, this spindle consists of a centrally located shaft upon which is a fixed collar. Against this collar, sleeves are fitted which may be adjusted laterally

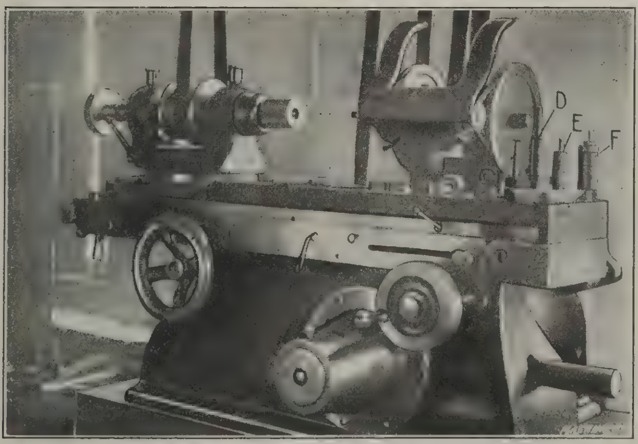

Fig. 2. Grinding the Bores of Tappet Rolls

against suitable washers which bear against the sides of the collar, thus effectively taking up the end thrust. The spindle itself runs in two split bushings, one on each side of the collar. These bushings are adjusted to the spindle by means of two sets of tapered wedges fitted in holders placed about these bushings. With this spindle, which is driven by belts passing from pulleys at both ends of the quill-spindle, speeds as high as 100,000 revolutions per minute can be obtained, although the usual speed employed is far less.

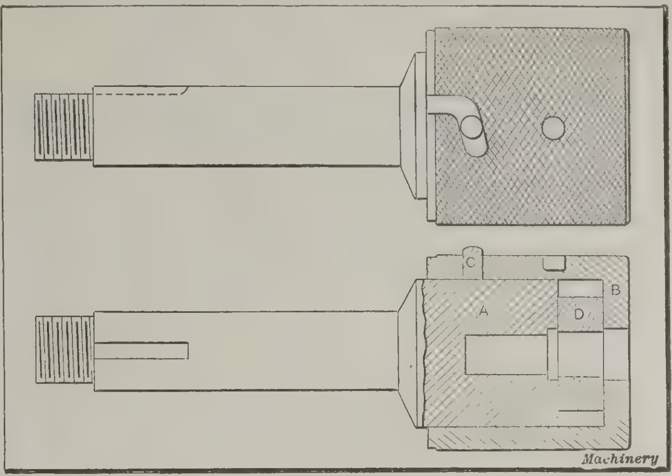

Fig. 3. Method of holding Tappet Rolls for Grinding

This style of spindle was used successfully for several years, until in 1907 Mr. Rivett brought out the new high-speed ball bearing spindle, which has superseded the former one. This spindle has specially designed ball races, made of a high grade of steel, and ground and lapped on Rivett ball grinding machines, which makes it a most rigid and durable type. The adjustment of these spindles is very simple, as there is but one screw, which governs both the end and side shake simultaneously.

In meeting the second obstacle in the path of successful internal grinding, that is eliminating the tendency toward grinding tapering or bell-mouthing, an important problem was solved. It was generally conceded that this tendency toward

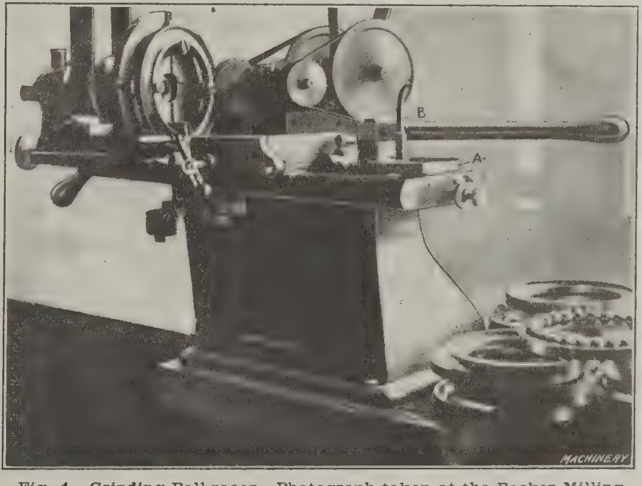

Fig. 4. Grinding Ball-races. Photograph taken at the Becker Milling Machine Co.'s Shops, Hyde Park, Mass.

bell-mouthing in internal grinding was due to the fact that in reciprocating the table of the grinding machine in the ordinary way, the table moved with varying speed throughout the whole distance of travel. Thus, at the extreme ends of the stroke the table was moving more slowly than at the central portion; consequently more stock was removed from the ends of the hole than from the central portion, as the wheel was in contact with the work longer at these sections. In 1904, Mr. Rivett patented a mechanism for changing rotary into reciprocating motion, and applied the principle to his grinding machines. In brief, this mechanism consists of a lever mounted on the base of the grinding machine and fulcrumed near its central point. The upper end of this lever is connected to the table by means of a link, and the lower end carries a roller whose position is adjustable in relation to the fulcrum. This roll serves as a means of contact with a conical heart-shaped cam.

The object of this special table traversing motion is to pro-

* For additional information on this and kindred subjects, see the following articles previously published in MACHINERY: "Holding Work for Grinding," March, 1912; and "Internal Grinding Practice in the Hardinge Bros. Shop," May, 1912.

† Associate Editor of MACHINERY.

vide a slight retardation at the middle of the stroke. The gradually accelerated traverse of the table towards the ends of the stroke gives less cutting time on the ends than at the center, thereby producing a hole which is about one ten-thousandth of an inch larger in the center than at the ends. In order to provide for the traversing of the table on long and short strokes, the heart-shaped cylinder cam is made conical, and by moving the roll upon the lever to a suitable position along the cam, the stroke can be reduced to any desired length.

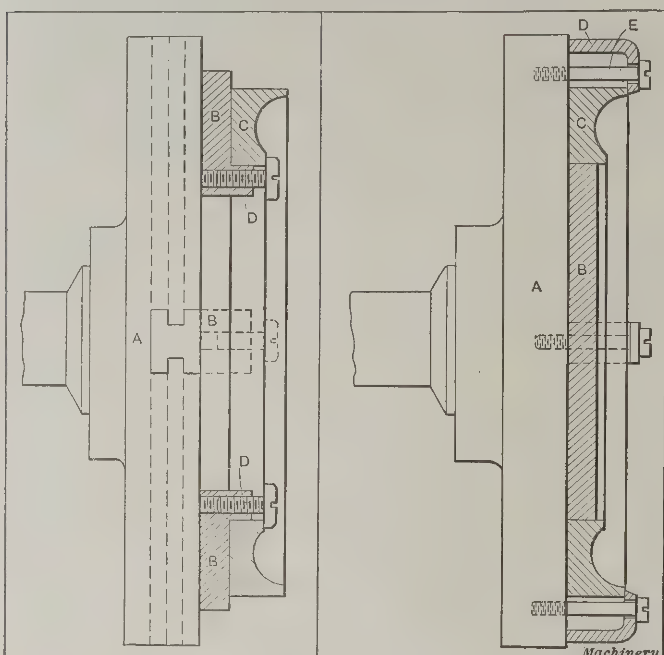

Fig. 5. Special Chuck used for the Grinding Operation shown in Fig. 4   Fig. 6. Another Method of holding this Class of Work

By thus securing an even table travel, an important improvement in internal grinding was made which enables these machines to grind internally without tapering or bell-mouthing.

Special Grinding Operations and Chucking Devices

In order to illustrate some of the possibilities of internal grinding and to show some of the chucking devices used in performing these operations, the accompanying illustrations and descriptions of modern internal grinding operations have been secured from leading automobile factories. Fig. 1 shows various automobile parts that are regularly ground in the Stevens-Duryea Co.'s factory in Chicopee Falls, Mass.

Grinding Tappet Rolls

Small tappet rolls like those shown on the end of the table of the grinding machine in Fig. 2, one of which is also shown in Fig. 1, are ground in an interesting manner on the Rivett No. 3 grinding machine. These rolls are used on the ends of the tappet rods and, when in use, are in constant contact with

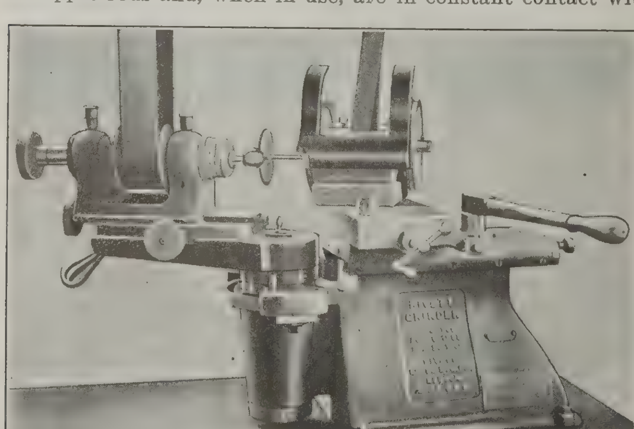

Fig. 7. Ball-grinding on the Rivett No. 5 Grinding Machine

the cams on the camshaft that operate the valves. In order to obtain satisfactory action of the valves it is necessary that the holes in these rolls be ground true with the end-faces. The rolls are first ground on these faces on ordinary surface grinding machines, and come to the Rivett grinding machines with their faces ground true and parallel.

By means of the special chucking fixture shown in Fig. 3, the rolls are chucked for the grinding of the bores, being held by their faces. This chucking device consists of a central shank *A* which fits into the spindle of a grinding machine after the manner of an ordinary draw-in collet. Over this shank, a sleeve *B* is fitted. A hole is bored in the end of this sleeve slightly larger than the hole in the tappet roll. By means of an inclined slot in the wall of the sleeve, acting in conjunction with a pin *C* driven into the shank, it is possible to hold the tappet rolls securely by the faces. This method of clamping is of the bayonet-lock order. Previous to clamping the tappet rolls in position, however, they are centrally located by means of a locating plug shown on the end of the table of the grinding machine at *D*, Fig. 2. The end of this plug is fitted to a central hole in the shank *A* of the chuck, and being a close fit for the hole in the tappet roll, the latter is thus located in a central position ready to be clamped and ground.

In grinding these holes, the grinding wheels used are of Norton make, J grade and No. 38 grit. The wheel spindle is operated at a speed of 17,500 revolutions per minute and the work spindle travels at the rate of 200 revolutions per minute. Limit gages are used for testing the work; these are shown at *E* and *F* on the end of the table of the grinding machine. The holes in these rolls are 0.4375 inch diameter and limits of but 0.0005 inch above or below are allowed. The thickness of the rolls is 7/16 inch. It will be noticed that the table and slides of the grinding machine are protected with

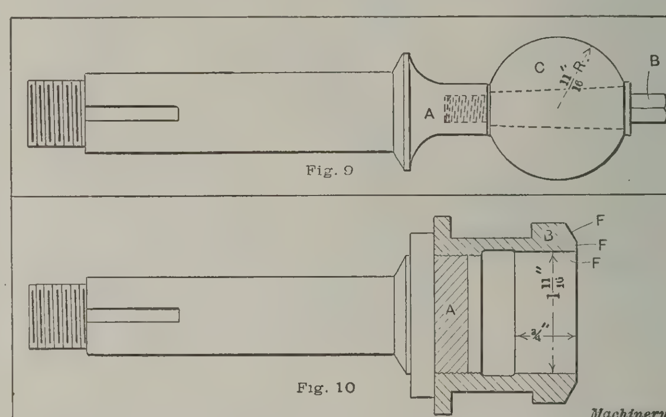

Fig. 9. How the Balls are held for Grinding. Fig. 10. Method of holding Steering Post Cones on the Grinding Machine

a wooden guard which keeps out a great deal of the emery and saves the bed from the wear occasioned by contact with wrenches and pieces of work.

Grinding the Races of Large Ball Bearings

In the shop of the Becker Milling Machine Co., Hyde Park, Mass., the races of large ball-bearings are ground on the No. 5 Rivett grinder. Some finished work is shown at the right of the machine in Fig. 4, and one of the pieces is shown mounted

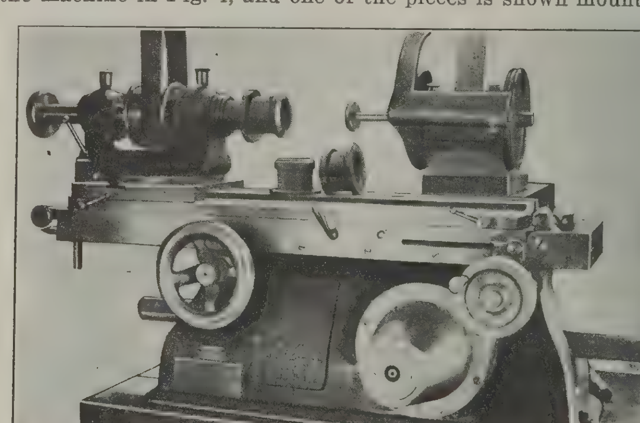

Fig. 8. Grinding Steering-post Cones

in the chuck of the machine. The method of holding the work is shown in Fig. 5. The rings are held in a chuck *A*, being gripped from the inside by means of chuck jaws *B* and held back against the jaws by means of four screws *D* whose heads extend over the inside edge of the work. In setting up the machine for this job the locating fixture shown on the end of

the machine in Fig. 4 is used. This locating fixture consists of a base *A* having, on its under side, a projecting stud that fits into a recess over the swiveling point of the work slide. At the top of arm *B* a thin steel disk of the proper radius is located, it also being at the correct distance from the center. By inserting the stud of this gage in the recess in the grinder bed, the chuck may be moved the proper distance from the swiveling point, thus insuring that the work will be ground at the right radius and to the proper diameter.

Fig. 6 is an illustration of the method used by the Stevens-Duryea Co., for holding similar ball bearing parts for grinding. This device consists of a faceplate *A* having a central stud *B* over which the ball bearing member is a close fit. For holding the work shown at *C* against the faceplate, four clamps *D*, held by screws *E*, are used. This work is ground at a spindle speed of 150 revolutions per minute, the wheel traveling at the rate of 17,500 revolutions per minute. Richardson elastic wheels, grain 80, grade 2R, are used.

Grinding Balls

One of the most difficult of grinding jobs is the grinding of a ball. This operation is shown in Fig. 7; the method of

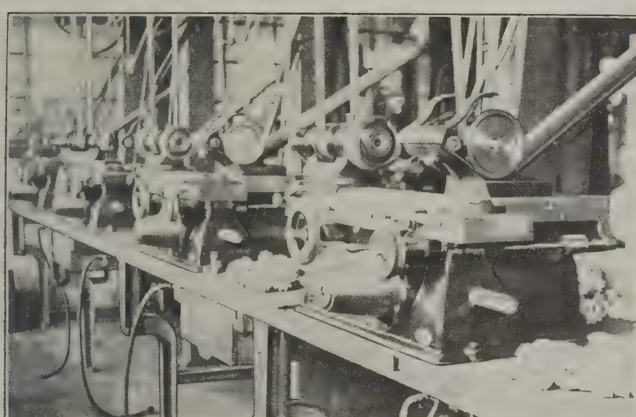

Fig. 11. A Row of Rivett Grinders in the Brown-Lipe-Chapin Gear Co.'s Factory, Syracuse, N. Y.

holding the balls for grinding is shown in Fig. 9. The holding fixture consists of a solid shank which is held in the grinding machine by the same method as an ordinary draw-in chuck. The end of this shank is tapped to receive set-screw *B* whose body is tapered to fit the tapered hole in ball *C*. After locating the work slide at the proper distance from the swivel post, it is easy to grind the balls spherical.

Grinding Steering-post Cones

The No. 3 Rivett grinding machine is also used for grinding steering post cones, an operation shown in the half-tone illus-

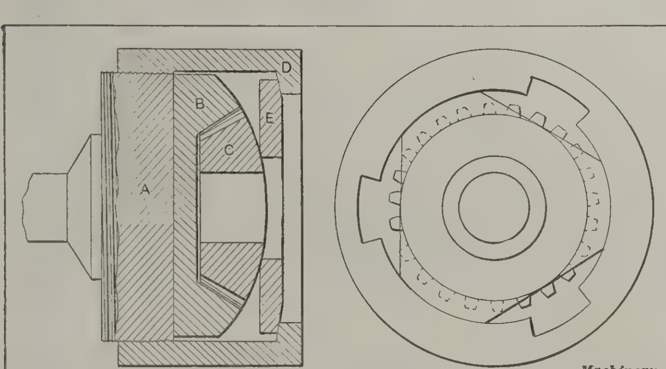

Fig. 12. Special Chuck for holding Bevel Gear Pinions for Grinding the Holes

tration Fig. 8. These cones are made from low-carbon steel and casehardened. The method of grinding these pieces is shown in Fig. 10. The work is held upon a threaded stud *A* which engages the internal thread in the piece to be ground, *B*. It is then a simple matter to grind the inside to size and also to grind the outside flange, finishing the three surfaces indicated by *F*. The work spindle revolves at the rate of 200 revolutions per minute and the wheel spindle at 17,500 revolutions per minute. The wheels used are of Norton make, being of J grade and 38-80 combination grit. The internal size must be accurate to within 0.001 inch. It is on work of this kind that the improved method of traversing the table is used to advantage, because it is essential that these pieces be ground straight—without bell-mouthing.

The Rivett Grinding Machine on Automobile Gear Work

The machines shown in Fig. 11 were photographed at the shops of the Brown-Lipe-Chapin Co., Syracuse, N. Y., where they are used for grinding the bores of small bevel gear pinions. These pinions are made from low-carbon steel and pack-hardened. As will be seen by referring to the grinding

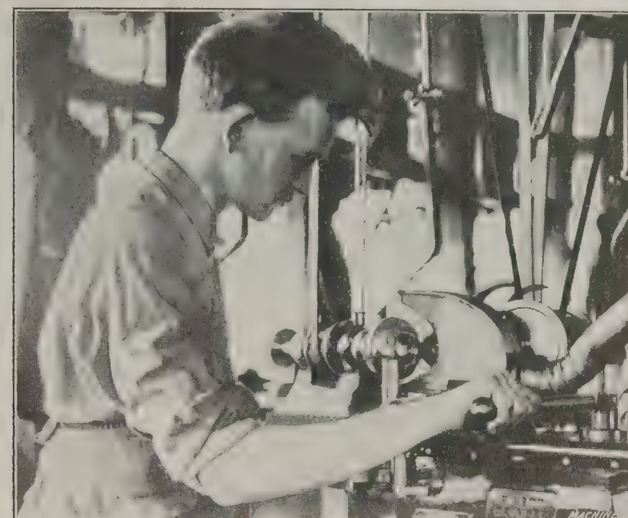

Fig. 13. Grinding the Spherical Faces of Bevel Gear Pinions

machine in the foreground, the gears are held by a special chucking device. This chucking arrangement is shown in the line illustration Fig. 12 and consists of a threaded base *A* held in the work spindle. Against the outside face of this base rests the lead matrix *B* which receives the bevel pinion *C*. A sleeve *D* is threaded onto the base and serves to draw the plate *E* down against the gear and matrix, pressing both against base *A*. In this position the bore of the pinion may be con-

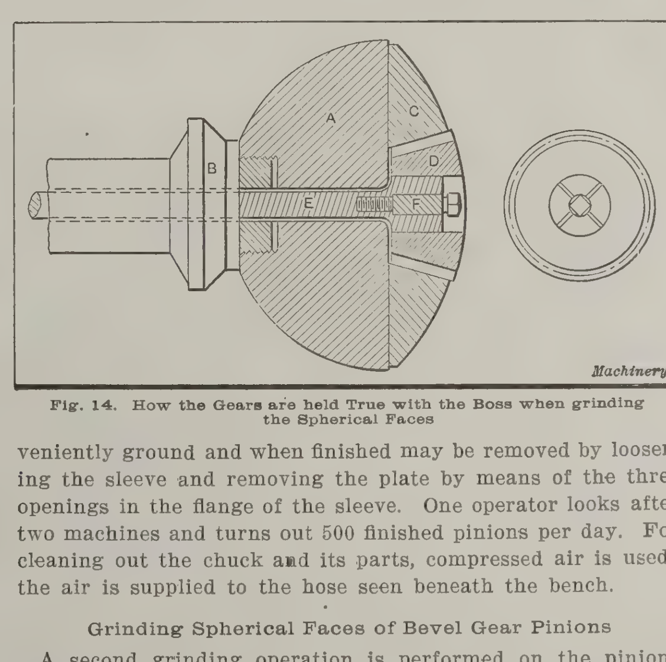

Fig. 14. How the Gears are held True with the Boss when grinding the Spherical Faces

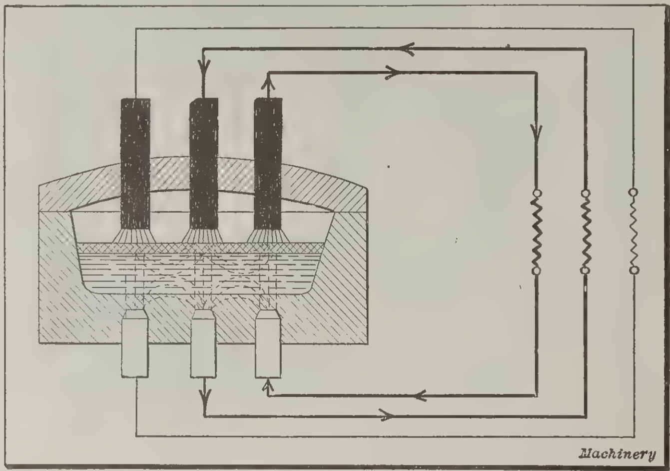
veniently ground and when finished may be removed by loosening the sleeve and removing the plate by means of the three openings in the flange of the sleeve. One operator looks after two machines and turns out 500 finished pinions per day. For cleaning out the chuck and its parts, compressed air is used; the air is supplied to the hose seen beneath the bench.

Grinding Spherical Faces of Bevel Gear Pinions

A second grinding operation is performed on the pinions mentioned above. This operation consists in grinding the spherical face, as shown in Fig. 13, the method of holding the work being shown in Fig. 14. A base *A* is threaded to the work spindle *B*. Against this base rests the lead matrix *C* in which the pinion is seated. This matrix is free to slide upon the face of the base *A*. By means of a split arbor *E*, expanded by set-screw *F*, the pinion is held by its bore, and after being gripped, is pulled back into contact with the matrix by the draw-in spindle integral with the expanding arbor. The faces of these pinions must be ground very accurately, a variation of 0.0005 inch from standard being the limit allowed. An average day's production is 650 gears.

IMPROVEMENTS IN ELECTRIC FURNACES

A paper was recently read before the Iron and Steel Institute of Great Britain by Mr. H. Nathusius on "Improvements in Electric Furnaces and their Application in the Manufacture of Steel." In this paper the author first took up the induction furnace and then the arc furnace, calling attention to the advantages and disadvantages of each. One of the disadvantages of the induction furnace is that the electrically induced heat can only be generated in the metal bath and not in the slag, which must, therefore, be heated indirectly by the underlying metal. It is, however, uneconomical to heat the slag by means of molten steel as the melting point of the latter is lower than that of the slag. Consequently, a higher



Diagrammatical View of the Nathusius Electric Furnace

temperature has to be imparted to the metal bath than would otherwise be necessary.

The objection to the arc furnace, while it otherwise has exceptional advantages, is that while it heats the slag and the surface of the charge exceedingly well, it does not offer as good a means for heating the charge itself as does the induction furnace. Mr. Nathusius has, therefore, for many years made a special study of arc furnaces and their working conditions, and while he was soon obliged to acknowledge the great advantages of electric arc heating, the idea occurred to him at the same time that it might be possible to combine the advantages of the arc furnace (good heating of the slag) with the advantages of the induction furnace (heating in the charge itself), and thus avoid the disadvantages of both systems. It became evident to him at once that the electric current offered the possibility of applying heat not only at the surface of the charge, but also at any part where an intense heat is required, such as in the charge itself and especially at the bottom of the furnace. He also recognized that the natural method of heating consisted in applying heat not from above but below. If this could be effected by some simple means a substantial advantage over other arc furnaces would be gained.

In order to meet these requirements, he has constructed a furnace which consists of a combination of an arc and resistance furnace, as indicated diagrammatically by the accompanying engraving. The characteristics of this furnace are that it has three carbon electrodes above the surface of the charge which project through the roof into the furnace, and three or a multiple of three bottom electrodes of mild steel rammed in the hearth. The upper as well as the bottom electrodes are arranged in an equilateral triangle. In this way as much as possible of the energy required for a particular furnace may be transferred to the bottom of the bath and the method of heating thus approximates that of an induction furnace. By the aid of special means for the distribution of the current, it is possible to transfer a greater or smaller amount of energy to the arcs at the surface or to the bottom electrodes, as desired. The current employed is a three-phase alternating current.

The three surface carbon electrodes are connected to the outer terminals of the secondary windings of the furnace transformer and the three bottom electrodes are connected to the three inner terminals of the secondary coil. The three inner terminals of the transformer are obtained by separating the windings at the neutral point where the three secondary windings of an ordinary three-phase transformer are connected. By this means the neutral zone—it is permissible for the sake of clearness to thus represent the electric conditions—is transferred to the bath itself and the current must gravitate from all points of supply toward this neutral point. In other words, the current, though supplied from a single source only, is forced to flow not only between the upper and bottom electrodes, but also between any upper electrode and any bottom electrode. It is thus possible, with a single source of current, to heat the charge in all parts, provided that its resistance is sufficiently high or that the current is strong enough to produce sufficient heat in the charge when the resistance is low.

INTERESTING PRINCIPLE APPLIED TO A BORING JIG AND PLANING FIXTURE

An interesting principle applied to boring and planing jigs is shown in the accompanying illustrations. Fig. 1 shows a jig which was made for boring the holes in the head of the boring machine built by the Cleveland Machine Tool Works, Cleveland, Ohio. The jig consists essentially of a planed and grooved base to which brackets carrying bushings for guiding the boring-bar are attached. The principle followed in boring these brackets for the guide bushings is illustrated in Fig. 2.

The bracket *A*, at the extreme right in Fig. 1, is slid along to the other end of the fixture, as shown in Fig. 2, and then the other bracket *B* is clamped to the right of it. This is done so that the lugs at the base of the brackets do not interfere with clamping them close together. This arrangement facilitates the accurate boring of the holes in the brackets, both laterally and vertically. Slight errors in alignment existing when the holes are bored are greatly reduced when the brackets

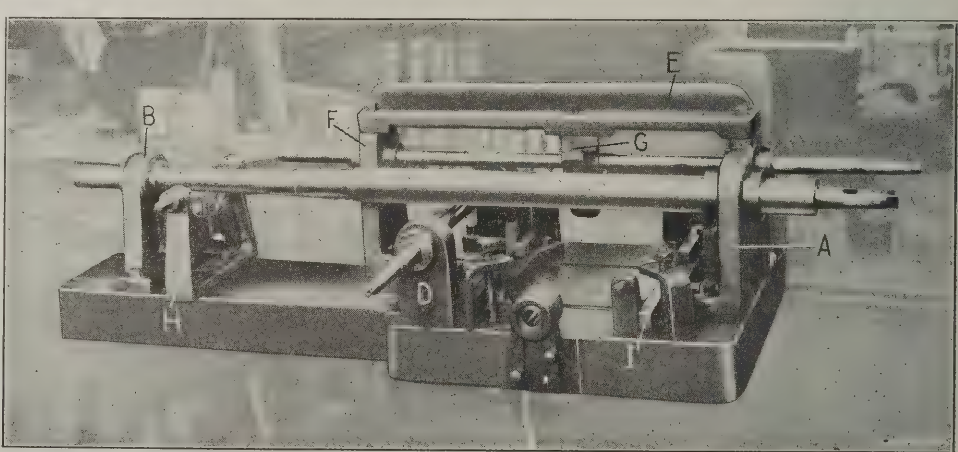


Fig. 1. Boring Jig used by Cleveland Machine Tool Works for boring Machine Heads

are set at opposite ends of the base. In fact, the principle insures that the centers are practically the same distance from the base and in line with the axis of the base slot or groove when they are placed in their respective positions on the fixture. The brackets, of course, are provided with lugs formed on their bases, which accurately fit in corresponding grooves in the jig base.

The bushing guide holes in the bracket *A* and the corresponding holes in the other bracket were at the vertices of a triangle, as is shown at *C* in Fig. 2. The lines joining their centers were neither parallel to the platen nor to the vertical travel of the boring machine head. So the lengths of the bases a, a_1 and altitudes b, b_1 of the triangles were computed to obtain the correct settings of the boring machine head for the various holes, and the settings of the head and platen were accom-

plished by means of the scales and verniers regularly supplied on these boring machines.

When the three holes in the two brackets were bored, the fixture was swung around to bore the two side brackets, one of which is shown at *D*, Figs. 1 and 3, with a boring-bar in place. The center lines of the four brackets *A*, *B*, *D*, and the one on the far side (not shown) must be at right angles. The bridge *E* was bolted and doweled to the brackets *A* and *F*, and then the center bracket *G* supported by the bridge was bored and bushed.

To clamp the work in the fixture, it is adjusted centrally in the saddle *H* by means of the screws. Then the wedges *I* under the front and rear of the right-hand end of the work are adjusted, clamped and the screws in the saddle tightened, as illustrated in Fig. 3. This gives a three-point bearing or support. To hold the work rigidly in position the wedges to the right of the center of the casting at the front and rear are adjusted and clamped. This method of clamping the casting prevents straining it, and holds it rigidly. When the wedges were first considered as a means of adjusting the work, it was thought that they would move under the cut, and thus require adjusting screws to hold them. This, however, was not the case, for after three years' service, the wedges have not been found to slip. The taper on the wedges is three-quarters inch per foot. Thirty-three boring and facing operations and six milling operations are performed on the head casting before it is unclamped from this combined jig and fixture.

This same principle of aligning the brackets applied to a planing jig is illustrated in Fig. 4, the brackets *J* and *K* at each end being bored in a manner similar to those of the jig illustrated in Figs. 1, 2 and 3. The bar *L* is employed to set the casting so that the face to be planed shall be parallel with the axis of the hole in which the bar is placed.

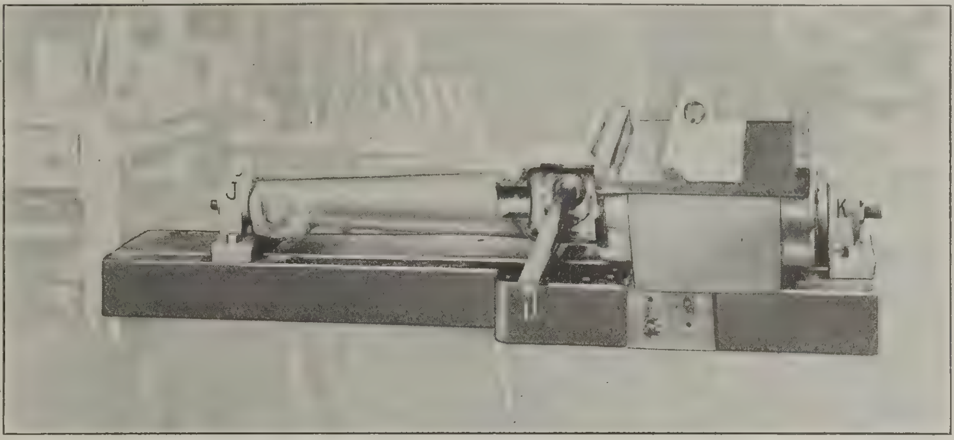

Fig. 4. Planing Fixture for Heads, made on Same Principle as Jig in Fig. 1

* * *

The Hamburg-American liner *Imperator*, for the time being the largest ship afloat, was launched in May at the Vulcan Works in Hamburg. The length of the new vessel is 880 feet and the width, 98 feet. The gross tonnage is about 51,000 tons and the speed at sea will be 22 knots. It is equipped with four classes for passengers and can carry 700 first class, 600 second class, 940 third class, and 1750 fourth class passengers. The crew will number about 1100 so that the total number of persons on board with the accommodations fully used will be about 5100. As an indication of the enormous size of the fittings of the vessel, it may be mentioned that the weight of the anchor and chain is about 225 tons (of 2000 pounds). The diameter of metal in the individual links in the anchor chain is about four inches. One hundred life-boats will be provided on the vessel and the latest design of davits has been adopted. The electric lighting installation includes about 10,000 lamps. The vessel will be driven by four four-blade propellers of 16½-foot diameter, which are driven by steam turbines at a normal rate of 185 revolutions per minute.

PROPOSED CHANGES IN PATENT LAWS

Several bills have been introduced in Congress during the present session relating to changes in the patent laws. In one of these, introduced by Mr. Oldfield (House Bill No. 23,417), a number of clauses are included which are of considerable interest, some of which are quoted in the following. Section 17 relates to the term of patents and their compulsory working, and reads as follows:

"Sec. 17 (R. S., sec. 4884). Every patent shall contain a short title or description of the invention or discovery correctly indicating its nature and design, and shall have annexed thereto and made a part thereof a copy of the specification, claims, and drawings of the application therefor, to which it shall refer for the particulars of the invention or discovery, and contain a grant to the patentee, his heirs or assigns, of the exclusive right to make, use, and vend the invention or discovery throughout the United States and all Territories and possessions under the jurisdiction thereof, for the term of seventeen years. But every patent granted for an invention shall be so limited as to expire nineteen years from the date of the filing, in this country, of the application upon which the patent was granted, exclusive of the time actually consumed by the Patent Office or the courts in considering the application, and where the application has been involved in interference, of the actual time in which it has been so involved, and in no case shall the patent be in force more than seventeen years.

"If at any time during the term of the patent, except the first four years, the patented invention shall not be manufactured, or the patented process carried on within the United States, its Territories, or possessions aforesaid to an adequate extent by the owner thereof, or by those authorized by him, then any person demanding it shall be entitled to a license from the owner of the patent to manufacture the invention or to carry on the patented process, unless the owner shall show sufficient cause for such inaction. Upon the refusal of such a license by the owner of the patent, the person seeking such license may apply to the district court, in the district wherein the owner has a residence or an established place of business, to compel the granting of such license. The court shall thereupon hear the person applying for said license and the owner of the patent, and, if the court is satisfied that the reasonable requirements of the public in reference to the invention have not been satisfied by reason of the neglect or the refusal of the patentee, his legal representatives, or those authorized by him to make, use, or vend the invention, or to grant licenses to others on reasonable terms to make, use, or vend the same, said court shall issue an order requiring the owner of the patent to grant a license to the person applying therefor in such form and upon such terms as to the duration of the license, the amount of royalties, security for payment, the period within which the patented invention shall be manufactured or the patented process carried on, and otherwise, as the court, having regard to the nature of the invention and the circumstances of the case, deems just.

"From the order of the district court granting or refusing to grant such a license, appeal may be taken (by the party aggrieved) to the circuit court of appeals in the same manner and form as in other cases arising under the patent laws: *Provided*, That the citizens of any country which by treaty, convention, or law provides that the manufacture of the patented invention or the carrying on of the patented process in the United States shall be equivalent to the manufacture or the carrying on of the process in such country, will be considered to have sufficiently complied with the requirements of this section if the invention is manufactured in said country within the period heretofore mentioned.

"If at any time during the life of a patent a material and substantial improvement shall be patented, the manufacture of which would be an infringement of the original patent, the owner of the improvement patent may apply to the district court in the district wherein the owner of the original patent has a residence or an established place of business to compel the granting of such a license as will enable the improvement to be manufactured. The court shall thereupon hear the respective parties, and if the court is satisfied that the improvement is of such a material and substantial nature that the reasonable requirements of the public demand that it should be manufactured and sold, the court shall issue an order requiring the owner of the original patent to grant a license to the owner of the improvement patent in such form and upon such terms as to the duration of the license, the amount of royalties, security for payment, the period within which the patented invention shall be manufactured or the patented process carried on, and otherwise, as the court, having regard to the nature of the original invention and improvement and the circumstances of the case, deems just.

"From the order of the district court granting or refusing such a license appeal may be taken by the party aggrieved to the circuit court of appeals in the same manner and form as in other cases arising under the patent laws."

Section 19, relating to the conditions under which applications must be made, reads, in part, as follows:

"Any person who has invented or discovered any new and useful art, machine, manufacture, or composition of matter, or any new and useful improvements thereof, not known or used by others in this country before his invention or discovery thereof, and not patented or described in any printed publication in this or any foreign country, before his invention or discovery thereof, or more than two years prior to his application, and not in public use or on sale in this country for more than two years prior to his application, unless the same is proved to have been abandoned, may, upon payment of the fees required by law, and other due proceeding had, obtain a patent therefor."

Section 32, relating to the use of patented articles by persons to whom the patentee has sold or otherwise transferred the right to use or sell the article, reads as follows:

"Sec. 32 (R. S., sec. 4899). Every person who purchases of the inventor or discoverer, or, with his knowledge and consent, constructs any newly invented or discovered machine, or other patentable article, prior to the application by the inventor or discoverer for a patent, or who sells or uses one so constructed, shall have the right to use, and vend to others to be used, the specific thing so made or purchased without liability therefor.

"Any person who purchases of the owner of a patent, or of any interest therein, any machine, manufacture, or composition of matter covered by such patent, shall have the unrestricted right to use, vend, or lease to others to be used the specific thing so purchased without liability to action for infringement; and it shall not be lawful to insert a condition in any contract relating to the sale, lease, or license to use any article or process protected by a patent or patents, the effect of which will be to prohibit or restrict the purchaser, lessee, or licensee from using any article or class of articles, whether patented or not, or any patented process supplied or owned by any person other than the seller, lessor, or licensor or his nominees; and it shall not be lawful to insert a condition in any contract relating to the sale, lease, or license to use any article or process protected by a patent or patents, the effect of which will be to require the purchaser, lessee, or licensee to acquire from the seller, lessor, or licensor, or his nominees, any article or class of articles not protected by the patent, and any such condition shall be null and void as being in restraint of trade and contrary to public policy."

Two bills have also been introduced in The House of Representatives, by Mr. Thayer, being, respectively, House Bill 11,380 and 11,381, differing only in some minor details and in respect to the penalties imposed for violations. These bills would legalize contracts to the effect that users of patented articles must buy all such supplies as are used in connection with the operation of the patented article from the owners of the patent. Bill 11,380 reads, in part, as follows:

"No person, firm, corporation, or association engaged in interstate commerce having any interest, whether as owner, proprietor, beneficiary, licensee, or otherwise, in any tool, implement, appliance, or machinery shall, directly or indirectly, in making any sale or lease of or any license to any article, restrain or attempt to restrain or prevent the vendee, lessee, or licensee from using any tool, implement, appliance, machinery, material, or merchandise not furnished by the vendor, lessor, or licensor, whether by making any condition or provision, express or implied, against such use by a term of any sale, lease, or license to use, or by requiring any obligation, express or implied, against such use from the vendee, lessee, or licensee of the article, or by imposing any restrictions upon the use of the article sold, leased, or licensed, or by making in the price, rental, royalty, or other terms of any such sale, lease, or license any discrimination based upon whether the vendee, lessee, or licensee uses or purchases any such tool, implement, appliance, machinery, material, or merchandise or not, or by any other means whatsoever: *Provided, however*, That nothing in this Act shall be construed to prevent any such vendor, lessor, or licensor from requiring that during the continuance of any letters patent on any such article no component or constituent parts of the tool, implement, appliance, or machine required for use thereon be purchased except from such vendor, lessor, or licensor, or from requiring that material to be used in the operation of any machine must be obtained from the vendor, lessor, or licensor."

* * *

A HANDY SURFACE PLATE

A convenient arrangement for holding a surface plate is used in the shops of the Cutler-Hammer Mfg. Co., Milwaukee, Wis. It consists of a heavily built and well braced table, fitted with good sized castors. The surface plate is supported on this table, which can be wheeled to any point where it may be wanted. Taking the surface plate to the work often eliminates considerable trucking of the work.

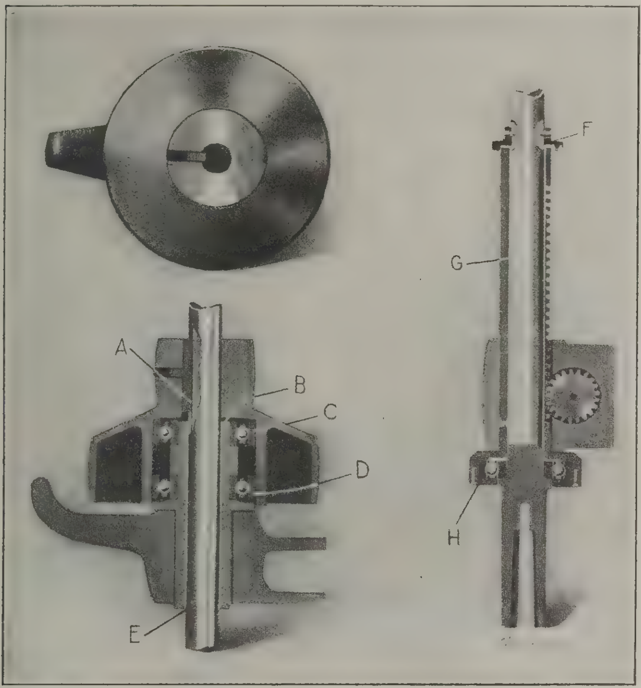
LETTERS ON PRACTICAL SUBJECTS

We pay only for articles published exclusively in MACHINERY

TOO MANY PATENTS A HINDRANCE TO PROGRESS

The article in the May number of MACHINERY on "Too Many Patents a Hindrance to Progress," raises a very interesting question: What is, in equity, a reasonable basis for the granting of patent rights? The writer of the article mentioned uses as a peg on which to hang his argument the granting of patents on the application of ball bearings to sensitive drilling machine spindles, and suggests that such patents would be valueless were it not that the maker's name and position acted as a watch dog against encroachments.

As the article in question hails from England, it appears as though allusion were made to the construction of the Alfred Herbert sensitive drilling machine. If this is so, the present



Sectional Views showing Alfred Herbert Ltd., Coventry, England, Sensitive Drill Ball Bearings—A, spindle centered by this hole; B, fixed sleeve; C and D, pulley bearings; E and G, clearance, no sleeve bearing; F, dust cap, no thrust bearing; H, the only spindle bearing

writer has no hesitation in asserting that, although the particular construction of this machine—in so far as the spindle is concerned—entails but a particular arrangement of ball bearings, there exists in this instance extraordinarily good grounds for the granting of a patent.

Novelty is a good basis, and novelty may exist in an arrangement. If mere arrangements are to be barred, then the great majority of inventions could not form suitable subjects for patents. In the drilling machine in question the spindle construction is decidedly novel—nay, more—bold. It is indeed probable that had this particular firm not put this arrangement into use, no one else would have been sufficiently bold to risk such an arrangement. As a matter of fact, ball bearing manufacturers prophesied a failure. The firm, however, in introducing it, knew from experiments that success would be assured; and, after all, if ball bearing manufacturers had but given the matter the careful attention it deserved, their own previous statements would have been sufficient evidence. Most of the catalogues of these firms recommend that journal bearings should not be subjected to more end thrust than 25 per cent of the journal pressure. This statement implies that if a journal bearing be subjected to end thrust only it would be sufficient to choose one large enough, and success would be assured. Here is now an individual who has realized this fact for the first time. Should he be debarred from obtaining a patent? If so, where must a line be drawn, in view of the fact that today the ground of mechanisms has been so covered as to make it almost impossible to invent anything entirely new?

To enable readers to judge of the merits of the case, the spindle construction is shown in the accompanying engraving. The particular advantages claimed are: First, entire absence of journal friction; note the clearance between spindle and pulley support and rack sleeve; second, cheaper construction; any other method of obtaining the same end is only possible by having one bearing to take the thrust from drilling, another to bear the weight of the spindle, and still another for the journal load; third, little necessity for oil beyond the initial supply (grease is used); the makers claim that the machine needs oiling but once a year; fourth, no adjustment necessary, the construction rendering adjustment impossible. Cone bearings—a possible construction—are by no means as efficient, and wear renders some provision for adjustment imperative.

It might be interesting to cite the fact that on machines supplied to the makers of the S. K. F. bearing, these bearings were fitted and were successful. These machines have been on the market now some four years, probably a thousand or more having been turned out in this time. This is in itself sufficient evidence of success.

The following particulars will give some idea of the power of the machine. The spindle, 1 inch in diameter, is driven by a 1½ inch belt. Without appreciable slip, ⅞ inch holes, 1 inch deep, may be drilled in cast iron (hardness: 238 Brinell) at 600 revolutions per minute in four seconds; and in machinery steel (52,000 pounds tensile strength) at 900 revolutions in 7 1/5 seconds. The accompanying table shows the complete range of the possible output:

The writer, who has had the pleasure of operating one of these machines, can assert that in drilling holes up to about ½ inch diameter, no matter what amount of weight is applied at the lever, it is impossible either to break a drill or slip the belt. In the case of the larger holes, the belt is the limiting

TABLE OF TIME FOR DRILLING ON ALFRED HERBERT SENSITIVE DRILLING MACHINES

Cast Iron			Machinery Steel		
Diameter of Drill	Speed of Drill	Time to Drill 1 Inch Deep, Seconds	Diameter of Drill	Speed of Drill	Time to Drill 1 Inch Deep, Seconds
$\frac{1}{4}$	2050	$1\frac{1}{5}$	$\frac{1}{4}$	2050	$2\frac{2}{5}$
$\frac{3}{8}$	900	2	$\frac{3}{8}$	900	$3\frac{2}{5}$
$\frac{1}{2}$	900	2	$\frac{1}{2}$	900	4
$\frac{5}{8}$	600	$2\frac{1}{2}$	$\frac{5}{8}$	900	$5\frac{3}{5}$
$\frac{3}{4}$	600	3	$\frac{3}{4}$	900	6
$\frac{7}{8}$	600	4	$\frac{7}{8}$	900	$7\frac{1}{5}$

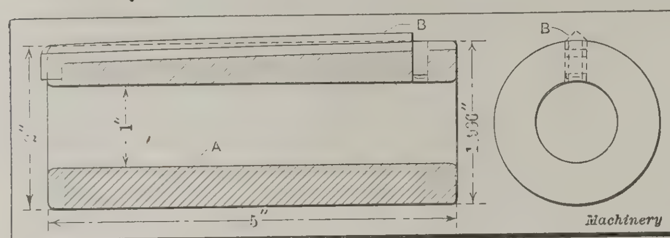
factor, but then a machine designed to drill ⅞-inch holes at the same rate as ¼-inch holes, could no longer be termed a sensitive machine. If made for ⅞-inch holes, it would be too cumbersome for ¼ inch. If it were not for the belt slipping, the journal "thrust" bearings would probably fail on the larger holes.

Didsbury, Manchester, England. FRANCIS W. SHAW

BABBITT EXPANDER AND OIL-GROOVE FORMER

Considerable trouble is met with in babbitting solid bearings when a shaft or mandrel is used as a core. When babbitt is cast around a mandrel it shrinks and grips the latter, at the same time becoming loose in the casting. In order to overcome this difficulty and at the same time provide for an oil groove in the babbitt lining, the device shown in the accompanying illustration was made. It consists of a piece of machine steel *A* which is turned and bored to the dimensions indicated, one end being 0.004 inch smaller in diameter than the other end, so as to make it easier to knock it out when fast in the babbitt. The so-called expander *B* is a piece of ¼-inch square key steel, bent over at one end, and having an angular top of about 90 degrees included angle. This piece

fits loosely in a milled slot in the sleeve *A*. The device is used as follows: A 1-inch shaft is placed through the hole in the sleeve, and the sleeve with its key is turned on the shaft until the key is in the position where the oil groove is required in the babbitt bearing. Now cast the babbitt around



A Babbitt Expander and Oil-groove Former

this sleeve and when it has set and tends to shrink away from the casting, pull the sleeve with its key out toward the left. The babbitt is then compressed upward and sideways by the key, as it passes toward the left, just enough to force it firmly into the cast iron surrounding it. J. S. B.

FIXTURE FOR FACING GAS ENGINE CYLINDERS

The fixture shown in Fig. 2 is fitted to a drill press and is used for finishing the inside face *A* of the boss of a gas engine cylinder as shown in Fig. 1. This face *A* is located in such a position that it is difficult to machine, and it is impossible to do so with a side milling cutter, so some other means had to be provided to accomplish the work. About 3/8 inch of material is to be removed from the boss.

Referring to Fig. 2, the frame of the fixture *A* is clamped to the spindle sleeve of the drill press by two bolts which are inserted through the holes in the upper part of the frame. The bar or spindle *B* is provided with a Morse taper shank which fits in the spindle of the drill press and is driven by it. The lower boss of the bracket *A* is bored out in line with the spindle of the drill press, and is bushed with a hardened and ground steel bushing *C*. Inserted in this bushing *C* is another hardened and ground bushing *D* which is prevented from rotating by means of the screw *E* fitting in the keyway cut in the bushing. Inside of the bushing *D* is a cam *J*, which is a good running fit on the bar *B*. This cam is provided with a

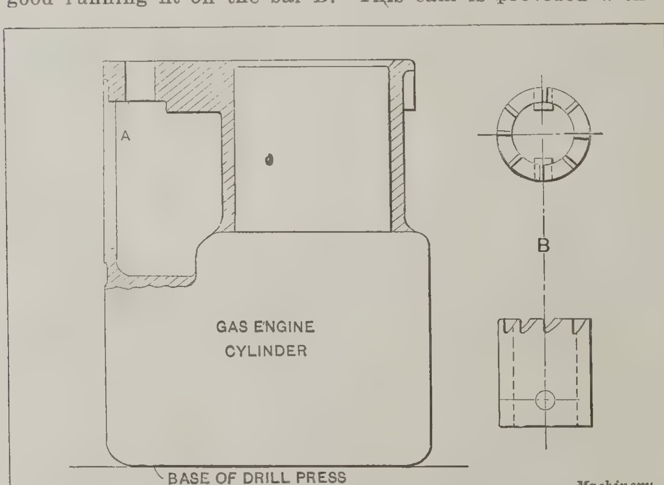


Fig. 1. The Gas Engine Cylinder and the Cutter used in Facing the Boss

spiral groove having a lead of 3/4 inch to one turn. Fitting in the spiral cam groove is a screw *F* screwed into the bushing *D*. To locate this screw in the bushing *D*, a hole *K* is drilled in the bracket through which the screw is inserted; then the bushing is rotated through an angle of 90 degrees to bring the screw into the position shown in the illustration. The lower end of the cam *J*, which is cylindrical in shape, rests on the top face of the cylinder casting and is operated by means of a handle *G* screwed into it. A thrust ball bearing *H* is interposed between the top face of the bushing *D* and the shoulder on the bar *B* to reduce the friction between these surfaces.

In operation, the spindle of the drill press with the fixture attached to it is lowered until the spindle *B* is located in the hole in the cylinder casting. Of course the cutter cannot be placed on the spindle *B* until the latter is located in the hole in the casting. When this is done, the cutter, as shown at *B* in Fig. 1, which is provided with two pins is slipped onto the end of the spindle *B*, the pins fitting in vertical grooves cut in the spindle. These grooves terminate in additional grooves, cut part way around the circumference, so that it is a simple matter to push up the cutter, turn it around, and thus lock it in position. These grooves are cut in such a manner that the cutter when in operation will be held securely.

When the cutter *I* is put in position on the spindle *B*, the operator grips the handle *G*, turning the cam in the direction indicated by the arrow. This movement of the cam imparts an upward motion to the bushing *D*, which, in turn, raises the spindle *B* and also the spindle of the drill press and the fix-

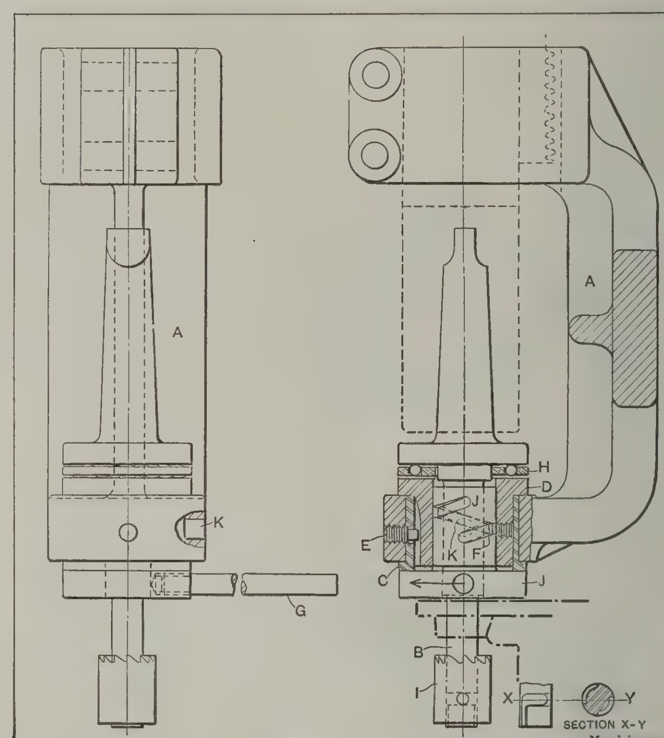

Fig. 2. The Fixture used in Facing the Boss, showing the Manner in which it is applied to the Drill Press

ture which is attached to it, the spindle being disconnected from the worm. This action brings the cutter in contact with the work, when the boss can be faced to the desired distance by simply continuing the movement of the handle *G*. The idea in designing a fixture of this type was to equalize the pressure on the casting while the facing operation was being performed. By constructing the fixture in this manner, the whole weight of the fixture is thrown down upon the bottom of the cylinder, so that the action of the cutter up against the cylinder causes an almost equal and opposing force at that point.

Detroit, Mich. WALTER F. WAGNER

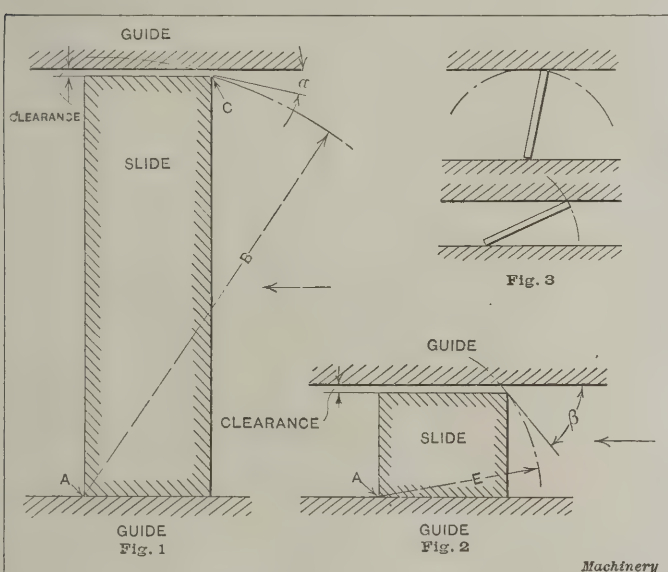
WIDE VS. NARROW GUIDES

The writer has been greatly interested in the discussion of wide versus narrow guides and believes that the ground has not yet been quite covered. Personally, he cannot agree with the conclusions of either Mr. Burley or Mr. Millar, and must endorse the view expressed in the editorial note on the subject accompanying Mr. Burley's article in the April number. Of course one must concur with some of Mr. Millar's remarks, as for example, his conclusions Nos. 3 and 4, but the conclusions Nos. 1 and 2 the writer does not think are yet proved, still holding the idea that the advantages to be gained by a narrow guide are a direct function of the relation of the slide's width to its length. His reasons for so thinking are substantially those advanced in the editorial note just referred to.

Perhaps the accompanying illustrations will make the idea plainer and introduce one element not yet touched upon, and upon which perhaps the whole matter hinges. When a slide advances between parallel guides, cross-wind may be caused

by an obstruction to one edge of the slide or by the eccentric application of the propelling force. The simplest case of an obstruction would be some grit at one edge of the slide as at A, Figs. 1 and 2. That edge is retarded and the diagonally opposite corner at once rises the clearance distance and strikes the guide. In other words, the slide in Fig. 1 when retarded at A tends to rotate with point A as a center, and the edge C describes a circular path with a radius B, the action being limited by the amount of the clearance.

Assume that the wide and narrow guides in Figs. 1 and 2 have the same clearance; when the point C of the wide guide approaches the upper guide it will do so along a certain arc, as illustrated in Fig. 1. By drawing a tangent to this arc at its point of intersection with the line of the upper guide, we form the angle α (see Fig. 1) or β (see Fig. 2) which angle may be called the "angle of approach." This angle determines the binding effect. If the angle is small, as seen in the wide guide, the friction becomes great, but if the angle is large, as in the narrow guide, the binding effect is minimized. It is really a toggle action in an unusual form. In Fig. 3 is shown a bar or gage between two walls. The binding effect is greatest when the bar can be placed in a nearly vertical position between the guides, as in the upper part of Fig. 3, while the binding effect is practically nil when the bar is at an in-



Figs. 1 to 3. Diagrammatical Views illustrating the Action of Slides having Wide and Narrow Guides

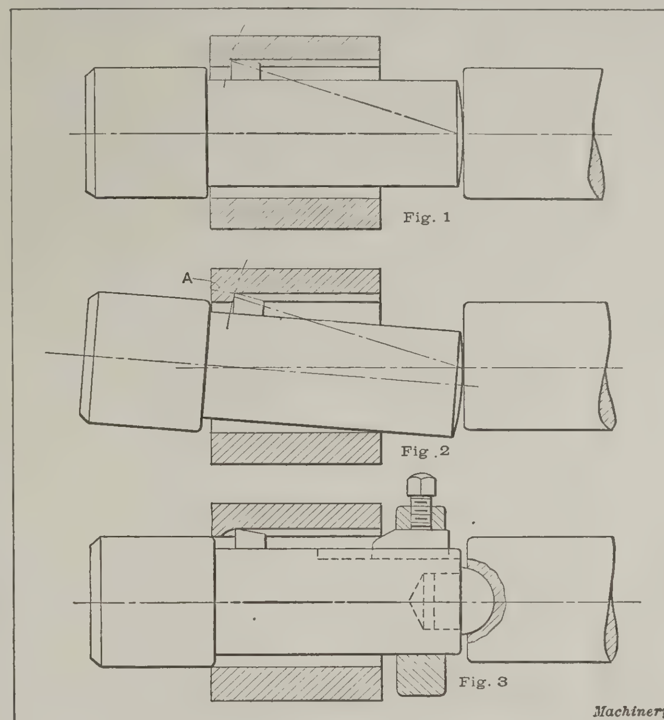
clination as shown in the lower part of Fig. 3. The writer believes that every mechanic who has noted the ease with which a plug gage, say ½ inch in diameter, 1 inch long, can be inserted in a hole and pushed along it, and who has also noted the extreme difficulty experienced when the gage happens to be of the same length, but say about 6 inches in diameter, will agree that the theory just presented is borne out by practice. S. M. RANSOME

Cleveland, Ohio.

CUTTING OIL-GROOVES IN BUSHINGS

In the article entitled "Cutting Oil-grooves in Bushings," published in the May, 1912, number of MACHINERY, an appliance similar to one which the writer saw a few years ago, but which proved to be a failure, is illustrated and described. The construction of the appliance seen by the writer is indicated in Fig. 1. This device was arranged to be used on a turret lathe, the cutter and holder being pressed in by a plain bar fixed in one of the turret holes. Instead of operating as intended, however, the shank assumed the position shown in Fig. 2 immediately after the guiding part of the cutter holder had passed out of the bushing. The cutter, instead of slipping out of the work, would proceed to cut a groove, the bottom of which would be at an angle as indicated by the dotted line A.

Now, even if the end of the shank had been flat instead of rounded, the cutter would not have left the work, but would have proceeded to cut the groove clear through. An examination of Fig. 1 will show that the cutting face of the cutter cannot possibly come out of the groove, as it is in effect undercut in relation to the path of its travel when retreating from the groove, as indicated by the circular arc shown. In order to try to improve matters, a ball and socket joint and an adjustable wedge, as shown in Fig. 3, were fitted, with the idea of compelling the cutter to leave the groove. This arrangement was fairly successful, but owing to the fact that the tool was so



Action of Device for Cutting Oil-grooves in Bushings

short, considerable force was needed, tending to damage the mouth of the hole.

Another point that might be mentioned is that the tool as shown in Fig. 1 began to tilt long before the guiding portion left the hole, and the back end of the hole was, therefore, somewhat mutilated.

The writer would like to know if your former contributor had to use any special appliances in order to insure success in his arrangement. The device shown in the accompanying illustration was abandoned and substituted by a simple slotting operation in an ordinary slotting machine. SLOTTER

SPHERICAL TURNING DEVICE

The lathe attachment shown in the accompanying illustrations, Figs. 1 and 2, and described in the following, has given good results for a long time. It was designed for the require-

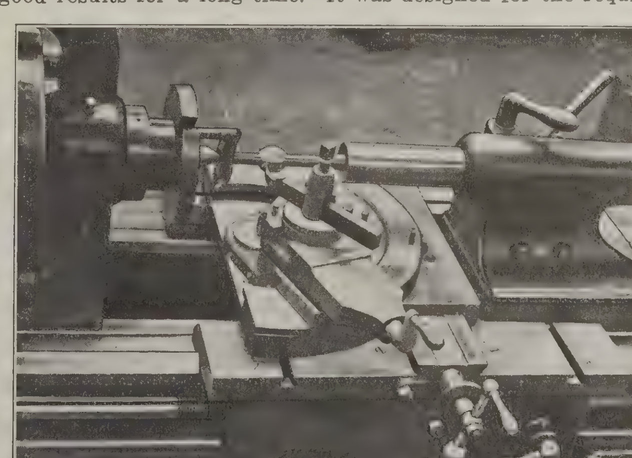


Fig. 1. Spherical Turning Device for Accurate Turning

ments met with in turning balls or other spherical parts which must have accurate dimensions, an operation which is rather difficult to carry out by hand. The appliances on the market for the purpose failed to give accurate results. The device shown is strong and capable of producing a practically

exact sphere. It is applied to an 18-inch Hendey-Norton lathe.

In Fig. 2, *B* is a cast-iron plate which is fixed directly on the dovetail slide of the lathe carriage by means of taper gibs *C*. The dovetailed groove of the plate *B* has parallel sides, and the two taper gibs, which have the same amount of taper, are introduced one from the front and the other from the back, so as to compensate for the taper. By being attached in this way, plate *B* rests rigidly on the carriage and can be fitted and taken out very easily, or adjusted to any position of the dovetailed guide. On plate *B* is fitted and rotates the turntable *D* provided with a dovetailed groove for the toolpost *P*. The turntable rotates on pivot *E*, which is fixed to plate *B* by four screws. The turntable is also guided by a circular gib *F*.

A circular rack *G* is fixed with screws in a groove provided for it; this groove is protected from chips as indicated. Rack *G* meshes with gear *H* which is fastened by a key to a worm-wheel which, in turn, is carried by shaft *I*. Plate *B* is also provided with two brackets carrying the screw *L* of the carriage. This screw meshes with the worm-wheel to which the bevel pinion *H* is fastened. The circular movement of turntable *D* is thus obtained from the carriage screw *L*, and, as this screw, through the design of the lathe, is provided with several speeds, a suitable feed can also be chosen for the spherical attachment. Stops *M* and *N* are provided in order to prevent the turntable *D* from swiveling too far. Felt packing is used to keep the working surfaces clean and free from dirt and chips. The pivot *E* has a hole in the center which is carefully ground to fit pin *O*. This pin is used for rapidly locating the carriage with relation to the center of the ball to be turned. It can be withdrawn during the operation. If particularly accurate results are required, the rotating axis of the fixture must intersect the axis of the lathe spindle. The fixture is then first located by means of pin *O* and may be adjusted by subsequent trials until a perfect sphere is formed. The form and position of the tool have no bearing on the accuracy of the work.

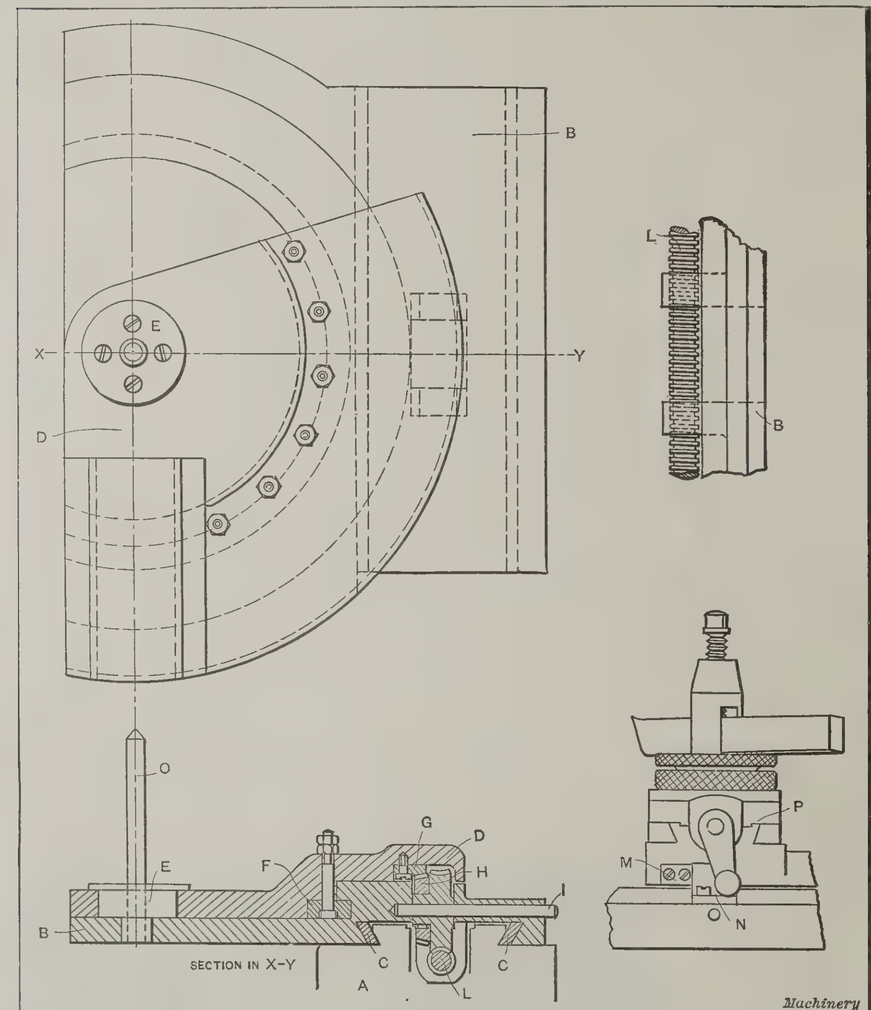

Fig. 2. Design of Spherical Turning Device

By moving the axis of the fixture in or out from the axis of the lathe spindle, circular surfaces such as rims of hand-wheels, faces of worm-wheel blanks, and similar work, can be turned. Work turned by this fixture can be finished in the same time as would be required for plain turning, and the design of several pieces has been modified so as to be turned by this fixture in order to obtain a more finished appearance.

Turin, Italy. C. Boella

OBSERVATIONS ON GEARING

In the April number of Machinery Mr. F. D. Buffum alludes to the necessity of proportioning gear teeth not merely to resist the load stresses which tend to cause breakage, but also to provide against excessive wear under continuous loads. He also asks for information relative to steel gears which are continuously transmitting the loads allowed by the Lewis formula.

During the writer's experience in designing gear mechanisms as embodied in geared heads and feed motions, there has not been a single case where steel gears running together have proved successful at tooth velocities exceeding about 400 feet per minute. A few have given trouble at even a lower speed, although in these cases the holes were hardened, ground and lapped to prevent the wear of the shafts upon which they rotated, and the gears were running in oil. In many cases the material had been changed on account of unsuccessful results.

It may be of interest to relate how one failure was dealt with. The mechanism consisted of a cone of gears driven from a long pinion through an intermediate gear—the usual tumbler gear arrangement. The long pinion was of 0.50 carbon steel; the intermediate and cone gears of 0.30 carbon steel, and soft. The whole gear mechanism was splash lubricated and the workmanship was good. Trouble first arose from the rapid wear of the tumbler gear, the only gear in continuous service. This was replaced by a casehardened gear which quickly "chewed up" the long pinion which was integral with the shaft and, therefore, could not be easily hardened. The material of the tumbler gear was then changed to phosphor-bronze, but the steel gears now wore out the phosphor-bronze gear. The final solution lay in making the tumbler gear of malleable cast iron, the idea being to provide a material somewhat more durable than phosphor-bronze but not as hard as the casehardened gear. The greasy nature of malleable cast iron probably also influenced the result.

In ordinary cases—cast iron to cast iron, or dissimilar metals, splash lubricated—the theoretical width of the face of gears as required by the Lewis formula has sometimes been cut down as much as 30 per cent. In these cases the tooth stresses have been calculated from the power delivery capacity of the belt under high tension (80 pounds per inch of width) and not from the amount of power actually delivered, which would probably not exceed more than one-half of the belt capacity. In cases of a "jam," the stresses are not always as great as might be imagined, for the reason that the shafts yield torsionally to a considerable extent, and thus relieve the stresses which would otherwise be borne by the teeth.

As regards shaft center distances, the writer does not agree with the statement that a small increase over the theoretical distance is of any great importance. In certain experiments made by the writer in which two gears of different diameters were mounted in such a way that the center distance could be varied to test the comparative noise developed at different center distances, it was found that in the case of eight-pitch gears, a closing up of the center distance of about 0.005 inch

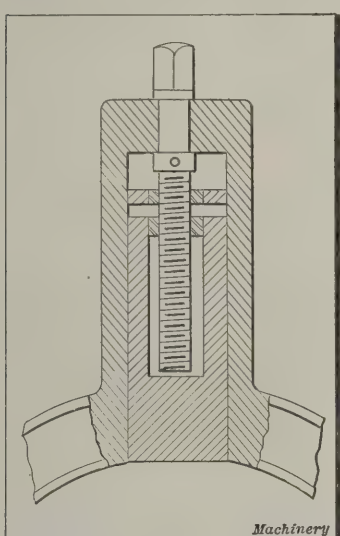
made no appreciable difference; beyond this point, owing to the jamming of the teeth, the noise increased considerably. Increases in the center distances above nominal up to about 0.125 inch also made no appreciable difference, but after this point the noise gradually increased up to the point of separation of the teeth. It is presumed that noise is a good index of the amount of wear. Backlash is of little importance if the load is continuous and not reversible.

As regards the comparative values of spur, bevel and worm-gearing, the writer would put spur gearing in the first place, unless the worm-gearing be so designed that the pressure angle is of maximum efficiency and the material the most suitable for the purpose. Either spur or worm-gear drives, however, are preferable to bevel gears. Difficulties in cutting accurate bevel gears, the unbalanced area of the tooth surface, the difficulties in setting to the correct pitch cones, all tend to prevent their successful application.

Didsbury, Manchester, England. FRANCIS W. SHAW

A LATHE STEADYREST OF UNCOMMON DESIGN

In the April number of MACHINERY, Mr. H. Terhune describes a steadyrest which the writer thinks impracticable. The writer does not understand the method of obtaining the chamber or body size hole in the jaw, or the method of assembling the screw with the top of the rest. The design is also rather expensive. The accompanying engraving shows a design which would entail the least expense, although even this construction should be used sparingly, as it will be found quite expensive.



Improved Design of Lathe Steadyrest

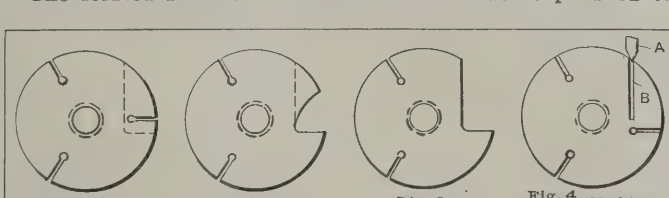
Dexter, Me. E. W. TATE

[Without entering into any discussion of the relative merits of the designs presented, it is safe to say that lathe manufacturers could undoubtedly afford to give more consideration to the design of steadyrests, even if the cost should be increased thereby. The steadyrest constitutes an important part of the lathe equipment, and if its efficiency can be increased, the comparatively slight increase in cost should not be begrudged.—EDITOR.]

TO FACILITATE THE GRINDING OF FORMING TOOLS

Figs. 1, 2 and 3 illustrate the methods which are most commonly used for making circular form tools. The saw cuts in the form tool, Fig. 1, are intended to relieve the strains due to hardening. Before this cutter can be used, however, the portion indicated by the dotted lines must be ground off. The method described by the writer in the following is intended to facilitate this operation.

The formed surface of a circular tool must be polished to remove the scale if good results are desired. For this reason most form tools are made as shown in Fig. 1, and after the cutter is hardened and polished, a cut, as shown in Fig. 2, is ground into the cutter, after which the cutter is ground as indicated by the dotted line to the appearance shown in



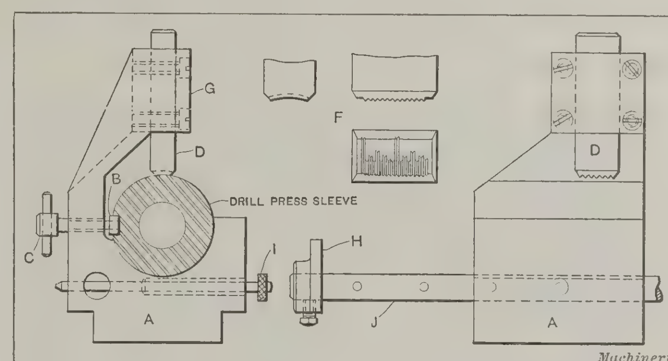
Figs. 1 to 4. Various Methods of Making Forming Tools

Fig. 3. A wide tool made in this manner will require several hours for grinding in order to remove the metal without drawing the temper of the tool. On the other hand, if the tool was originally milled before hardening, as shown in Fig. 3, it would be almost impossible to polish the tool after hardening.

The simplest and most effective means for overcoming this difficulty is indicated in Fig. 4; this will save considerable expense in the making of circular form tools. The cutter is made with an extra slot, as shown, and after the tool is hardened and polished, the piece *B* is easily broken out, without injury to the cutter, by driving in a wedge as at *A*. The cutter may be held in a bench vise and only a slight tap of the hammer is necessary, after which the cut can be quickly finished off with an emery wheel. S. NEVIN BACON

GRADUATING DRILL PRESS SLEEVES WITH A STAMP

The accompanying illustration shows a device which was used satisfactorily for graduating a drill press sleeve with a stamp. The device consists mainly of a casting *A* which is machined out to fit the drill press sleeve. The sleeve has a spline in which the block *B* is held by the screw *C* for retain-



A Device for Graduating Drill Press Sleeves with a Stamp

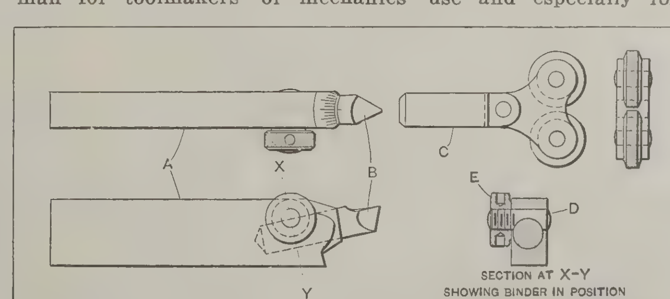
ing the sleeve in the correct position. The stamp *D*, also shown enlarged at *F*, is made to graduate 1 inch, the graduations being 1/16 of an inch apart. The stamp *D* is held in a slot in the fixture by means of a cap *G* and screws as shown.

In operation, the drill press sleeve is placed in the fixture and the end of it brought up against the stop *H*. The stamp is then given a blow with a hammer, after which the spring plunger *I* is pulled out allowing the rod *J* carrying the stop *H* to be shifted to the next hole. The spring plunger is now inserted, the stamp struck and the preceding operations continued until the sleeve is graduated to the desired distance.

J. S. B.

UNIVERSAL KNURLING AND TURNING TOOL HOLDER

The accompanying illustration shows a handy and useful knurling and turning tool holder, designed by a fellow workman for toolmakers' or mechanics' use and especially for



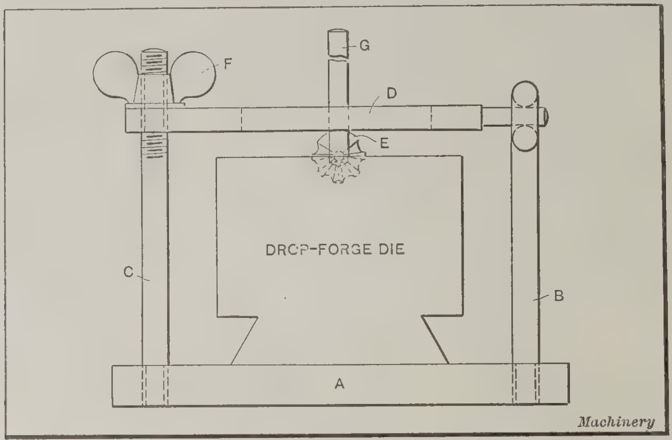
A Universal Knurling and Turning Tool Holder

those employed in experimental work. This device consists essentially of a holder *A* in which the turning tool *B* or knurling tool *C* can be held with the clamping screw *D* and clamping nut *E*. The turning tool is made from drill rod or from high-speed steel if preferred, and is cut off and ground to the required shape. It will be noticed that the hole in the front end of the holder is inclined at an angle

with the base of the holder, the purpose of which is to obtain a positive rake on the turning tool for steel, etc. A holder containing a single roll knurl can be made and inclined in either direction at any angle with the axis of the work; for this purpose the front end of the holder is graduated in degrees, as shown in the illustration. The knurl-holder shown is supplied with two knurling rolls. C. F. S.

A CHERRYING FIXTURE FOR A DROP-FORGE DIE

The accompanying illustration shows a fixture which was designed for cherrying a hole in a drop-forge die. The hole to be produced is full at both ends, as indicated in the illustration, so that an ordinary milling cutter could not



A Cherrying Fixture for a Drop forge Die

be used for producing it. The hole to be cherried is first chipped out as near as possible to the required shape, care being taken to leave an equal amount of metal on both sides of the hole to prevent the cherry from "crawling."

The drop-forge die is placed on the bed *A* of the fixture, which is provided with two studs *B* and *C*, and a strap *D* is used for applying pressure to the cherry *E*. The stud *B* has an eye-bolt on its upper end, and the strap *D* is turned down to fit it. The bolt *C* is threaded to fit a wing-nut *F* which is used in connection with the strap for applying pressure to the cutter, the cherry being worked back and forth by means of the handle *G*. The cherry or cutter *E* is provided with teeth cut both right- and left-hand, starting from the central tooth. The handle *G* is driven into a hole drilled in the cherry. C. H. WILCOX

Springfield Mass.

BEATING THE SWEDISH GAGES

In relating the following incident, I ask the readers' indulgence for not giving names, as I fear that my reception at the works where the thing happened might not be as pleasing the next time I call, should I disclose too many of the true facts in the case.

Not long ago, a well-known company producing a very fine quality of machine work, got the improvement "bug" in its head and threw out some fair machinery in order to put in the very latest types. The result of this improvement proved quite satisfactory, and the quality of the product improved correspondingly. In showing the customers through the remodeled plant, much stress was placed upon the high-class workmanship obtained by the use of the new machines. All visitors were duly impressed with the fact that the shafts were right up to their correct diameters, that the holes were just right for running fits, that plane surfaces were spotted all over with contact spots, and that every piece interchanged with every other. The general manager was usually doing the showing around, and he did not look sorry to see the president loom up in the distance and join the group. Indeed the latter person was also duly impressed with what he was shown.

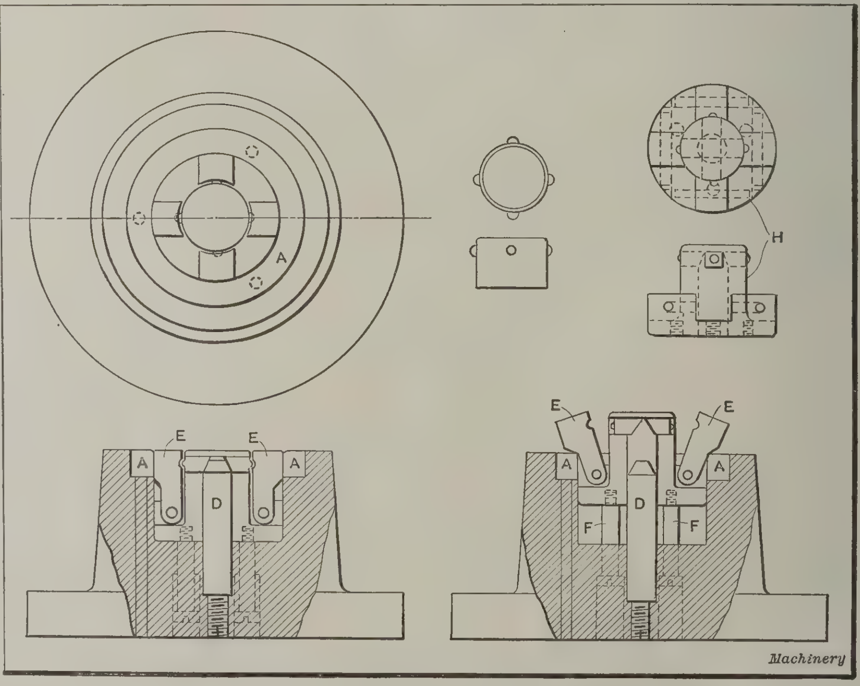
One day as the manager took a little group of visitors—prospective customers—through the plant, the climax was reached when he picked up some hardened and ground steel rings. He piled five or six on each other, in an absent-minded way, and was probably as much surprised as his visitors when he found that the surfaces were so perfect that he could lift the whole pile by the top ring. He instantly realized that this "beat the Swedish gages all hollow," and so he took full advantage of the situation, and puffed to a great extent.

A few days later he started to show another visitor this fine work, talking loudly and impressively about it, but, lo! there was "nothing doing," for just the top ring remained in the manager's hand as he lifted it up, while the others were left "peacefully at rest" upon the bench. Evidently these rings were not as well ground as the previous lot, and he asked the grinder hand why they were not as carefully ground as the lot that were lying on the bench a couple of days ago. The grinder hand claimed that he had ground but one lot of rings, and that, undoubtedly, the rings now lying on the bench were the same as the ones that had been there a few days ago. There was an old hand around the shop, however, who had seen the manager grow up in it, and had never been able to get over calling him "Jimmy," and he offered the explanation: "Well, I nearly died laughing to see you showing up the fine work of the grinder to that crowd. It did look good, sure, but it was not the grinder but the magnetic chuck that should have had the praise for the job." W. D. F.

TOOLS FOR RAISING LUGS ON SHELLS

The accompanying engraving shows a method for shaping half-spherical lugs on brass shells. The lugs were to be in an exact position in order to engage with grooves in a mating part. The method proved very successful and may be of interest to others.

A ring *A* is turned, hardened, and ground, and driven into



Method of Producing Half-spherical Lugs on Small Brass Shells

a cast-iron bolster. The upper inside corner of the ring is well rounded. In the center of the device is provided a holder for the brass shells, this holder being shown in detail at *H*. Four square holes are provided in the upper part of the holder for the punches with half-spherical ends which form the lugs. The punches are a good sliding fit in these holes, and are tapered at the back end and expanded by means of plunger *D*, which is the shape of a truncated pyramid on the end. This piece is hardened and driven lightly

into the bolster, and adjusted by means of a screw from the bottom. The four jaws E are attached to the central holder and secured by a plain pin. They are hardened and polished on the outside. The central holder is a sliding fit in the bolster and is raised by means of three springs beneath it (not shown), the limit of the movement being governed by the screws F. The two positions of the jaws and punches shown indicate clearly the operation of the device. When the jaws are in the outward position, after the lugs have been formed, the shell may be removed. The removal of the shell pushes the small punches in flush with the holder, which is then ready for the next shell. Any plain, flat punch may be used in the press. J. GALLIMORE

Meriden, Conn.

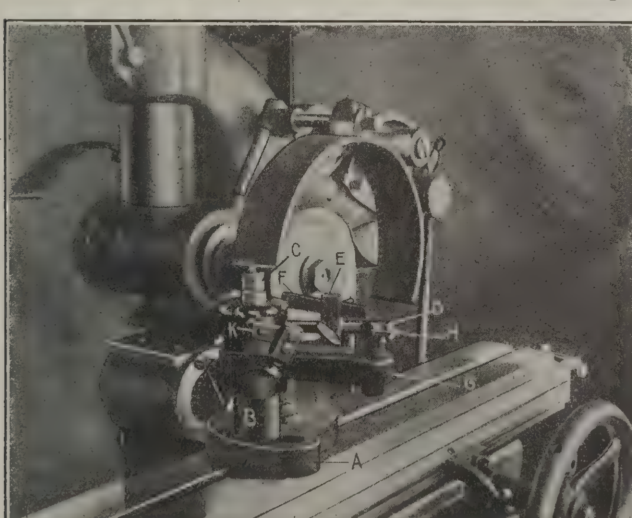
STANDARDIZATION OF GRINDER SPINDLES

The other day the writer overheard a manufacturer saying: "If the grinder spindles only were alike, how much it would save." Quite a number of different makes of machines for rough and finish grinding were used in this shop. If both roughing and finishing grinding is to be done on the same machine, it is necessary to carry a full set of wheels for each machine. On account of the different sizes of the spindles, this requires quite a large investment in emery wheels and considerable storage room for the wheels as well. Standardization with respect to the grinder spindles, especially in the larger types of machines, would be of considerable value. The change may involve some trouble to the machine manufacturers, but, when the necessity is realized—in other words, when the buyers "holler" loud enough—this change will, undoubtedly, come about. J. M. HENRY

New Britain, Conn.

A GRINDING ATTACHMENT

The grinding attachment shown in the accompanying illustration is intended for correcting errors in forming cutters caused by the hardening process. It is often said that when forming cutters are ground, they must not be indexed from the back of the tooth, because this does not give equal spacing. Now, we do not really care for equal spacing; what we want is to have all the teeth of the same length. In hardening, the cutter loses its shape, and the teeth become of different lengths,



Attachment for Grinding Form Milling Cutters

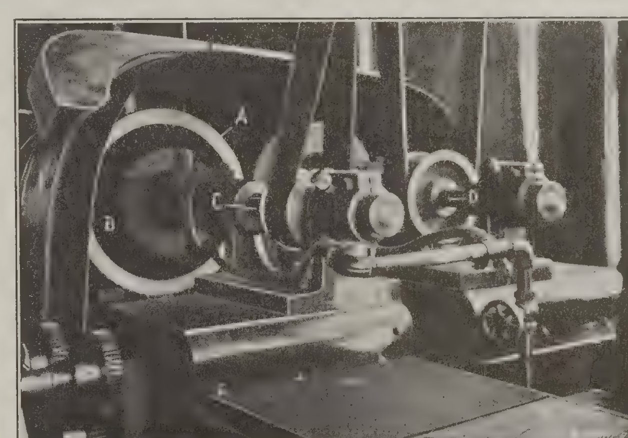
but the error can usually be easily corrected. On gear-cutting machines one tooth of the cutter often does all the work. The arbor is frequently blamed for this, but in most cases it would be found that one or more teeth are too long. These long teeth should be ground on the face until the teeth are all of equal length, as tested by an indicator, with the cutter on a mandrel between centers. This grinding will produce an uneven spacing, but it will produce a cutter where all the teeth will cut, and the cutter will remain in this condition, practically, until worn out.

The device shown in the illustration can be used on almost any cutter grinder. It takes but a short time to set up and gives satisfaction. The construction of the device, which might be varied to suit individual conditions, is apparent from the illustration. It consists principally of a base A to which is fitted an upright stud B, turned down at its upper end C to take the cutter. On the stud is also mounted a collar having an arm D. To this arm is clamped a bracket E into which is inserted the spring F which acts as a stop against the back of the tooth. The arm G is fastened by a set-screw to upright stud B, and, by means of adjusting screw H, the arm D with spring F can be slightly adjusted, relative to the fixed parts of the device, so that the cutter tooth can be gradually fed in towards the grinding wheel. A gage K is clamped to the device in such a manner that it will just touch the top of the tooth when this is of correct length, and by means of this the length of the teeth can be accurately measured. The whole device is simple, but it is possible, by means of it, to grind each tooth independently of the rest, gaging each in turn to make sure that they are all of correct length.

Nashua, N. H. CHARLES E. JACOBS

SIMULTANEOUSLY GRINDING INTERIORS AND EXTERIORS OF RINGS

In building the Dayton swaging machine, the Excelsior Needle Co., Torrington, Conn., grinds all hardened parts that are to serve as bearing surfaces in connection with the operation of the machine. The machine shown in the accompanying



Method of Grinding Interior and Exterior of Swaging Machine Rings Simultaneously

engraving was improvised to grind the interior and exterior of the steel ring that is forced into the head of the swaging machine. It is essential that the interior and exterior of the ring be true with each other; therefore, both of these surfaces are ground at one setting of the work. The ring, shown at A, is soldered to the special faceplate B. The wheel for grinding the interior of the ring is mounted on spindle C, while the wheel for the external grinding is mounted on spindle D. These spindles are mounted upon carriages on the same cross-slide and are driven in the usual manner. Provision is made for cooling the work at each of the cutting points. The method has proved very satisfactory. C. L. L.

TAPS AND THEIR WORK

Though many of the questions in connection with taps and their work have been decided, and admit of no discussion, some points still remain on which a diversity of opinion exists. These should be rapidly reduced in number when investigators are not only willing to build testing machinery and carry on expensive tests, but freely give the world the benefit of the results of these investigations. The article on "Taps and Tapping" which appeared in the April, 1912, number of MACHINERY reflects credit on the investigators, but the writer would like some further information.

If but fourteen taps were used in obtaining the data presented in Table I, it is not at all surprising that the amount of power consumed increased rapidly after tapping the two crucible tool-steel nuts. It will be seen that the second nut of this metal required more power than the first in more than half of the fourteen cases. In other words, the taps dulled

rapidly. The same holds true in the case of the phosphor-bronze nuts. Hence, it seems that the comparison between the power consumed in tapping hexagon drawn brass and that consumed in tapping phosphor-bronze is scarcely a fair one, as the tap gradually becomes dull. While it may be said that tapping ten nuts need not make much difference with a tap, the figures given show an average increase of power consumed by the second nut tapped in each kind of metal.

It is interesting to note the reduced amount of power consumed by tap No. 10 in tapping its second nut in both the third and fourth metals tapped, and the increase of 65 per cent in the case of the second phosphor-bronze nut. The hexagon screw stock seems to require less power for tapping in the case of the second nut, but for steel the average is slightly greater for the second nut. From these irregular results it would seem that such experiments should include scores of taps and hundreds of nuts, in order to reduce the effect of such amounts of power as are consumed by taps Nos. 8 and 10.

The fact that decreasing the diameter of the hole to be tapped by a ½-inch tap from 0.425 to 0.400 inch increases the amount of power consumed about 100 per cent, is not surprising, as the amount of metal removed is, thereby, also increased nearly 100 per cent, and the chance of clogging the flutes is very much greater, as we have less room in which to take care of nearly double the amount of chips.

Could not someone who has the facilities for carrying on tests of this kind also let us know the amount of power consumed in removing the metal from a thread groove under conditions as similar as possible to tapping, but with the wedge and chip-choking elements eliminated? Comparison between the amount of power consumed in tapping and in cutting threads externally would also be interesting. Has not the large amount of tool surface in contact with the work and the ever-present tendency to wedge a great deal to do with the amount of power consumed by the taps?

As a cutting tool a non-relieved tap is not an inviting proposition, but when a tap must be reversed a relieved land is supposed to gather small chips and thus dull and even break the teeth. Most tap makers avoid the tendency to wedge by making their taps slightly "reverse" taper. A reverse taper tap cannot do perfect work, but the very slight inaccuracy of thread angle caused by the reverse taper used is in most cases negligible. Reverse taper taps, however, consume much less power than parallel taps.

Hamilton, Ohio. W. S. Rowell

[With regard to the methods of making the tests recorded in Table I, in the article on "Taps and Tapping" in the April number, we are informed by the test department of the Wells Bros. Co., Greenfield, Mass., that the figures in the chart "represent the average variation of a number of tests of each material. In making these tests different sequences were used (with regard to the different materials tapped), so that the tests would be absolutely fair to each material."—Editor.]

OVERHANG IN MACHINE DESIGN

In the March number of Machinery, "Onlooker" quotes, "Overhanging is a vital error in design," and adds, "Mechanical designers are beginning to recognize this fact to a marked degree." Assuming that by "overhang" is meant the condition of a part similar to a cantilever and that a "vital error" means an absolute mistake, the writer takes exception to these statements, and will attempt to show that the former is not a practical proposition so far as design of machinery is concerned.

It is obvious that there are many types of machines impossible to design so that they will fulfill the object for which they are intended, without overhang. A radial drill, for example, of the general kind, must necessarily have an arm that can be quickly and easily swung from one position to another. If an outer stay is provided, the machine becomes restricted in its capacity. Such stays are often supplied as temporary attachments, but it is often impossible to apply them when the heaviest duty is required from the machine. Hence, the arm is made strong enough to safely withstand the strain imposed upon it by the work performed without the use of the stay.

Some English makers have eliminated the overhang of the drill spindle from the arm by designing what is called a "central thrust" arm. Thus the torsion is eliminated, but the deflection of the arm upward, with relation to the column, is not affected thereby. The deflection due to three inches of overhang is eliminated, but that due to, say, forty-two inches remains unaltered. In a well designed machine without the central thrust arm, the torsional deflection is not appreciable, even under maximum duty, so that this attempt to avoid overhang is of little practical value, as it is often obtained at a sacrifice in handiness of operation.

The shaper offers another example of a machine where overhang is unavoidable. For a large class of work it is much more suitable than the planer, although in the latter the tool is carried on a beam supported at each end. (The uprights, by the way, which carry this beam, are "overhung" from the bed, so that even the planer does not answer the requirements for a good comparison.) It is not practicable to use some kind of a support for the outer end of the shaper ram, as the usefulness of the machine would then be greatly reduced. Some makers, however, place a support under the table so as to minimize the effect of the overhang. The advantage gained by so doing may be more apparent than real, for with a given pressure between the tool and the work, the sliding ram is deflected to a greater extent than when the table is not supported; yet, this support may be useful when very heavy work is secured to the table. Notable cases of overhang are also met with in gear teeth, most cutting tools, lathe spindles, tailstock spindles, etc.

The objection to overhang is, of course, deflection under load, but this is not avoided if a beam supported at its ends is substituted for a cantilever. Under similar conditions of length and section it is reduced, but the difference is one of degree, not of kind. The writer does not, of course, advocate overhang when it can be advantageously avoided, but he realizes that conditions exist which call for a compromise, and he does not agree to the statement that "overhang is a vital error in design," and does not believe that it should be accepted without some qualification. Joseph Jewsbury

Birmingham, England.

[While somewhat erroneously expressed, it is, of course, clear that "Onlooker" did not intend to convey the idea that overhang was never permissible in machine design. Read in connection with the paragraph in which the expression occurred, it is reasonably clear that the idea in "Onlooker's" mind was that overhang was a serious error in all cases where there was no need for it—where ample support underneath or near the end of a cutting tool, for example, was possible. Undoubtedly, "Onlooker" did not intend to be taken quite so literally as our correspondent has understood him.—Editor.]

HEATING HIGH-SPEED STEEL IN A BLACKSMITH'S FORGE FOR HARDENING

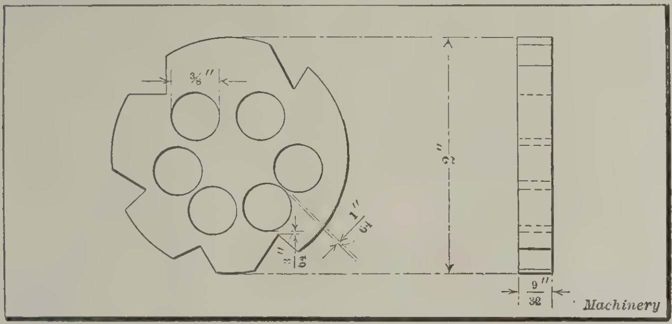
Various receipts and methods have been given for hardening high-speed steel, but the factor which renders most of these methods unsuitable for the "backwoods" mechanic is that they require conveniences not often found in a small shop. The heating appliances usually consist of a pail of water and a blacksmith's forge. With these facilities one is expected to perform any operation of heat treatment from the welding of a broken crankshaft to the hardening of a "circle tool."

Not long ago the writer was employed in a small shop as foreman, and having difficulty in getting the high-speed cutters through the hardening process satisfactorily, he investigated the methods used. The trouble seemed to be that the cutters came out either without good "red hardness," which constitutes the peculiar value of such steels, or else though hard, they would be blistered and the corners so rounded that they were spoiled. Occasionally the tools would be both soft and blistered. Inquiry revealed the fact that the soft but unspoiled cutters were heated in a gas muffle furnace which had been installed for hardening punches and dies,

while those rendered unfit for use by scaling were hardened in a blacksmith's forge with soft coal and plenty of blast.

As it was a rather hopeless task to change the gas outfit so that it would produce the required heat for high-speed steel, some experimenting was done with the forge fire, and it was finally discovered that if the work was covered with a thin coating of fire clay and salt, and further protected by a thin shield of sheet metal, it could be subjected to a coal fire. After being brought to the required heat, the tool was cooled in a tank of kerosene without removing the shield.

The accompanying illustration gives the dimensions of a piece that was hardened in this manner. The holes were drilled and then reamed with a 3/8-inch reamer, and all of the sharp corners were milled. Some idea of the lack of scaling or warping may be obtained from the statement that after the dirt was cleaned out of the holes, the shank of the same reamer could be put through. The burrs caused by milling and reaming were still as sharp and pronounced as before heating. The wall between two of the 3/8-inch holes was only 1/64 inch thick, and the wall between the milled corner and one of the holes was 3-64 inch thick. No cracks developed, nor was there any noticeable warping at these



A Piece of Work heated for Hardening in an Ordinary Blacksmith's Forge, without Scaling or Warping

points. The condition of the sharp edges would warrant the belief, that, if it had been a cutting tool it would have been in a fit condition to use without sharpening.

As to the degree of hardness obtained, the writer kept the piece in the condition in which it came from the hardening bath—without tempering—and afterward had the opportunity to test it with the scleroscope; with this instrument a reading of 105 was obtained. This reading compares very favorably with that obtained with the best grade of carbon steel hardened in a satisfactory manner. The piece illustrated is made from Bohler's rapid Styrian steel (high-speed). Judging from various other experiments which were tried, the writer has come to the conclusion that the prime necessity in hardening high-speed steel is to have plenty of heat, and to provide shields for the work to prevent the scaling which is due to exposure to the atmosphere when the tool is at the temperature for hardening. It does not especially matter when using the shield, whether the work is heated in a muffle, a barium chloride bath, or some home-made affair like that previously mentioned. With proper care excellent results may be obtained, even with that old standby, the blacksmith's forge.

F. A. Parsons

Milwaukee, Wis.

BURNISHED THREADING DIES

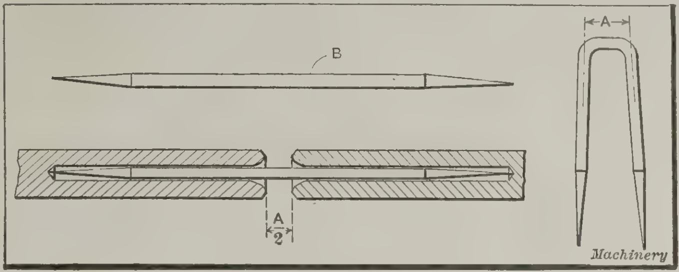
Threading dies of the button or spring types will last much longer and produce superior threads if the threads in the dies are burnished after cutting, and also after hardening, than if left unburnished as they ordinarily are. The burnishing is accomplished with a threaded master plug, which is hardened and lapped, but not fluted. This threaded plug is run through the die, which is left from 0.001 to 0.0015 inch small when the thread is cut. Lard oil is used as the lubricant. After the die has been hardened and tempered, the threaded plug is run through again.

Another advantage gained by putting the plug through the die after hardening, is that the lead of the threads, which is distorted in the hardening process, is corrected. A die made in this manner will cut clean and smooth, and will stand up much better than a die that has not been burnished because the material about the threads is compressed by the burnishing plug and all the burrs are removed.

D. T. H.

DEVICE FOR MAKING STAPLES

The accompanying engraving shows a simple device for making staples of the type shown to the right. The method is as follows: Cut off the wire to the proper length and point it as indicated at *B*. The device for bending consists of two pieces of steel rod, slightly less in diameter than the width *A* from center to center of the staple legs. Drill a hole in the end of each of these two pieces. The hole should be slightly larger than the diameter of the wire, and the depth of the



Method of Making Wire Staples

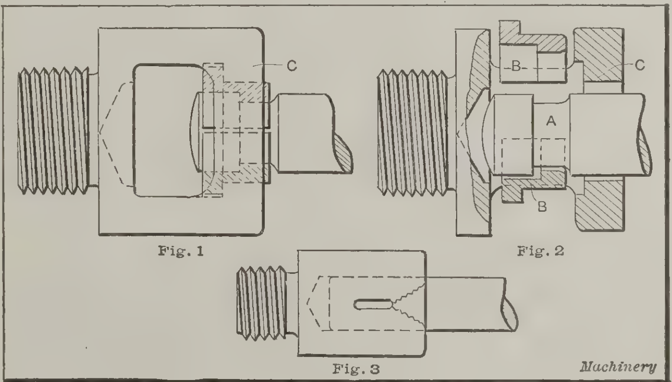
hole should be about one-half the length of the wire less one-quarter of the distance *A*. The holes should be slightly chamfered, or bell-mouthed, and the corners should be slightly beveled, as shown. When the wire is placed in these handles, they are forced together to a parallel position. The beveled corners come together and act as a fulcrum and a smooth, even bend results.

C. M. S.

IMPROVED FORM OF PULL-BUSH FOR BROACHES

The broach used with the "La Pointe" broaching machine is usually secured to the pull-bush by means of a cotter passing through the bush and broach. This connection frequently fails, the pull-bush giving way as shown in Fig. 3; or worse still, the end of the broach gives way. The trouble can be overcome by using a pull-bush of the type shown in Figs. 1 and 2.

The end of the broach is reduced in diameter as shown at *A*, leaving a shoulder; half-bushes are turned to suit the bore of the pull-bush *C*, and bored as shown at *B* to freely fit the end of the broach. The pull-bush has a slotted hole, wide enough for the insertion of these split bushes.



Improved Design of Pull-bush for Broaches

In use, the broach end is inserted through the hole in the pull-bush, the half bushes are placed on the neck, and are then drawn back into the hole as shown in Fig. 1. By making the bore large enough when designing a pull-bush of this description, it is quite a simple matter to arrange for one bush to cover a large range of broaches, and in each case retain the greatest possible strength in the broach. Split bushes are made to suit each size of broach. This cannot be done when using a cotter, and therefore the connection is cheaper to make. The half-bushes are easily made as compared with the cutting of the slots for the cotters, and it is advisable to make them so that if anything gives way, it shall be these parts. A little care in determining the width of the shoulders in these split bushes will allow for this tak-

ing place before either the main pull-bush or the broach end can give way. G. R.

SOLVING OBLIQUE-ANGLED TRIANGLES

The writer wishes to add a few words in reply to the inquiry of O. E. H. in the How and Why columns of the February number of MACHINERY. When two sides (a and b) and the included angle (C) are given, the third side (c) can be found directly from the formula:

$$c = \sqrt{a^2 + b^2 - 2\,a\,b\cos C}$$

This formula is not very convenient to use except when a and b are numbers easily squared; however, this is generally not the case. By using the formulas:

$$\sin x = \frac{2\cos\frac{1}{2}C}{a+b}\sqrt{a\,b}$$

and

$$c = (a+b)\cos x$$

the computation will be much facilitated, especially when using logarithms. By using functions of the half angle we also obtain greater accuracy and avoid the difficulties met with when using negative values. WM. W. JOHNSON

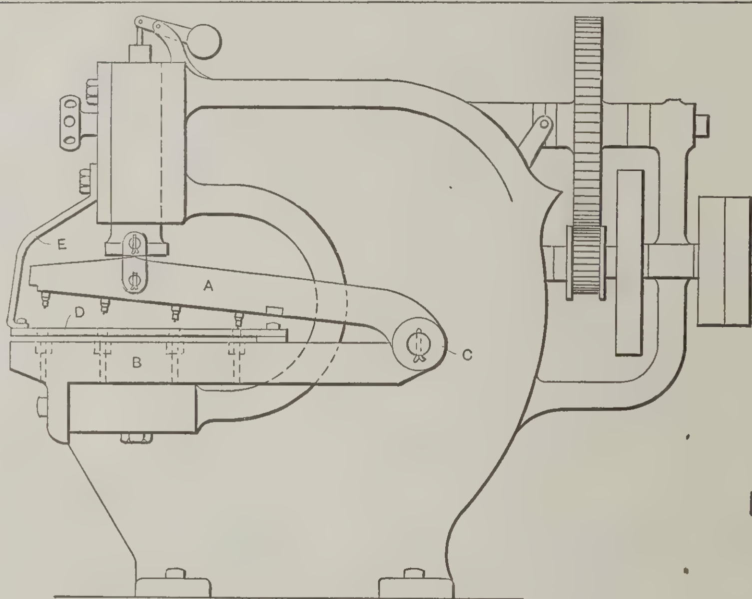
Cleveland, O.

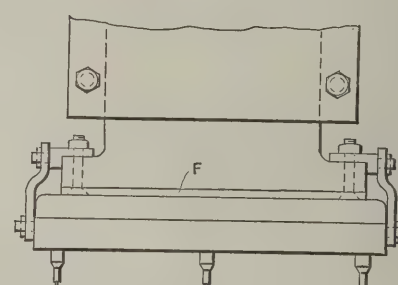
ATTACHMENT USED FOR GANG PUNCHING

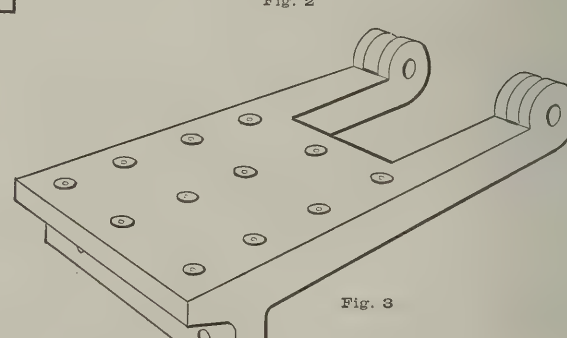
When it is desired to use a gang punch on the ordinary punching and shearing machine and the positions of the holes are such that some of them are a considerable distance outside of the lower face of the crosshead, it is not practicable to use ordinary punch and die blocks. Punching of this kind, however, can be easily done by means of an attachment such as shown in Fig. 1, which represents a side view of an ordinary punching and shearing machine equipped with punch and die blocks for gang punching. The punch block A is attached to the crosshead by means of links as indicated, while the die block B is fastened to the bed plate by any ordinary means. The punch and die blocks are connected by a hinge at C; D is the stripper and E one of the two braces supporting the front of the stripper.

In Fig. 2 is shown a front view of the punch block illustrating the manner of connecting it with the crosshead. The wearing plate F, shown in this illustration, is attached to the crosshead and bears against the punch block. In Fig. 3 is shown a perspective view of the die block giving a clear idea of its construction, the stripper being removed in this illustration. No attempt has been made to show the means of securing the punches and dies in their respective blocks, or the provisions made for getting rid of the punchings. This latter may be accomplished, for the central dies, by drilling holes at an angle from the bottom of the die to enter the opening usually provided in the center of the bed plate, and for the others by holes so drilled that the punchings are discharged at the front, back or on the sides of the bed plate.

This device has been used for punching plates about 3/16 inch thick, of high-carbon steel, which is difficult to punch. If thicker plate is to be punched, the distance back to the hinge or fulcrum C must be proportionately increased in order to give as nearly a perpendicular motion to the punch as possible. The parts are hinged together sufficiently rigid so that the punches strike the plates squarely over the holes in the dies. It would seem, at first sight, as if there would be enough of a bending action on the punches to easily break them off, but this is not the case, providing, of course, that the fulcrum C is placed at a suitable distance away from the center of the crosshead. W. L. B.







Figs. 1 to 3. Attachment for Gang Punching

SAVING A SHAFT BY KNURLING

Referring to the article, "Saving a Shaft by Knurling," in the April number of MACHINERY, the writer would like to say a few words. It would seem that a straight knurl would be best for this purpose—one that makes parallel, longitudinal grooves and ridges. It would seem that the spiral or cross-cut knurl would hardly be practicable to use. The best results are obtained when the size is increased only enough to make it possible to obtain a press fit, but it should be remembered that the bearing surface is reduced and, therefore, when an allowance of only 0.0005 to 0.0015 inch is required for a tight fit with a smooth surface, the knurling must increase the diameter from 0.002 to 0.003 inch, in order to produce just as good a fit. The ridges tend to cut into the sleeve, and if the assembled details are taken apart, the fit is none too good the second or third time.

Nevertheless, the method has its advantages. It is cheap, and the fitted part runs true, which it does not always do when some other methods for saving the work are resorted to. Although the writer has never seen the method tried for the purpose, he does not think that it would be suitable where an air- or liquid-tight joint is required, as the sleeve is generally considerably scored when the knurling is heavy.

Erie, Pa. A. N. HAMMOND

CASEHARDENING GEAR TEETH WITHOUT DISTORTION

In the May number of MACHINERY a brief item is published on the casehardening of gear teeth without distortion. The writer wishes to make some friendly criticisms on the methods there set forth. It is stated that the gears are copper-plated all over before taking a finishing cut on the teeth. The finishing cut removes the copper plate from the tooth faces and flanks, and when casehardened, these parts only become hard, the carbonizing effect of the pack being prevented on the other parts of the gear by the copper-plate. The practical result is casehardened teeth with so little distortion of the gear as a whole that it can be corrected to practically perfect accuracy by means well-known to gear makers. The well-known means alluded to are, presumably, "setting" under the press, or similar means. This, in the writer's opinion, is very bad practice, as the means used to correct the gear sets up internal strains, which are retained in the gear. Should the gear at any time receive a sudden shock, it may upset the molecular structure of the steel, and so relieve the strains. One often wonders why gears when first placed in a car appear fairly quiet, and then, while on test, suddenly become noisy, and finally have to be replaced—a procedure which has often come to the writer's notice. A great deal of noise and hammering can be traced to "setting" under the press. To overcome the trouble already stated, it should be strongly advised to leave metal for supporting the gear while undergoing heat-treatment and to take a cut all over after carbonizing except on the tooth faces and flanks. Then only these latter parts will harden.

Finally, after hardening, the gear should be located true with the teeth, ignoring all other parts, and then the surplus metal left for supporting the gear should be removed, at the same time truing it up with the teeth. This, obviously, does away with the necessity of "setting" the gear under the press.

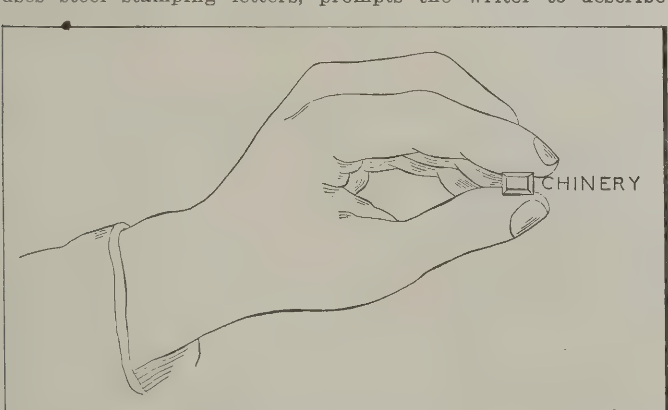
The writer does not want anyone to think that he is in any way condemning copper-plating for preventing parts from casehardening. He has seen this method in use for bicycle bottom bracket axles some ten years ago. The axles were copper-plated all over and then the plating was removed from the ball races only. It is also good practice to copper-plate the threads on the ends of hardened shafts and the like.

Anyone who wishes for further information upon the matter should refer to the article, by the writer, in another part of this issue entitled "Processes in Production of Automobile Transmission Gears."

Birmingham, England W. BETTERTON

USING STEEL STAMPING LETTERS

The "Remarks by the Onlooker," in the February number of MACHINERY, relating to the way the average machinist uses steel stamping letters, prompts the writer to describe



Method of using Steel Stamps

a method which he has used successfully. Others who have been told about it have found this method equally good, and it is, therefore, submitted with the hope that it will prove useful to someone.

The accompanying engraving shows fully as well as a description the principle of the method. The words are stamped backwards, beginning with the last letter. By doing so, it is possible to see exactly what one is about. The hand does not cover up the letters already stamped. A guide line should be scribed for the figures, so that they will line up properly.

In addition, attention should be called to the fact that cast iron should not be stamped without first chipping off the hard skin. To do so will improve the appearance of the stamping and will considerably lengthen the life of the steel stamps. A nick should be filed across the upper side of the type so that one can see or feel instantly when the right side is up. In this way, stamping of the letters upside down is avoided.

Christchurch, New Zealand. PERCY FRAMPTON

SEASONING CAST IRON FOR MACHINES

Having noticed the request for suggestions from readers as to ways and means of cheaply accelerating the seasoning process, the writer offers the following:

First, under the title "The Mobility of Molecules of Cast Iron," (a contribution to a discussion of the physics of cast iron), a resumé of some protracted investigations of this subject may be found in the transactions of the American Institute of Mining Engineers, 1896 (Vol. xxvi, beginning page 176).

Second, it was shown therein that release of cooling strains in iron castings may be very greatly accelerated—without heat annealing—by subjecting such castings to repeated shocks or vibrations while cold. In the case of ordinary test bars of one inch square section, broken transversely, with supports twelve inches apart, there was a gain in strength of bars subjected to shocks in a tumbling barrel for one hour of about twenty per cent, as compared with companion bars of the same size cast from the same ladle, not so treated.

Third, in a report of the committee of Science and Arts of the Franklin Institute on this discovery, entitled "The Molecular Changes in Cast Iron Caused by Vibration," dated May 5, 1897, and printed in the *Journal of the Franklin Institute* July, 1898, a maximum increase in load of 42 per cent and increase in deflection of 55 per cent is shown in a table giving tests of 166 bars, 26 by 2 by 1 inch tested flat, twenty-four inches between supports 83 of which were subjected to shocks as compared with untreated companion bars.

Fourth, the release of cooling strains in castings by shocks without aid of heat having been fully established by these and numerous similar and independent tests, the American Society for Testing Materials inserted a clause in its revised specifications for iron castings to the effect that test bars must not be subjected to shocks or vibrations prior to testing.

Fifth, the most effective and thorough method of removing internal stresses in iron castings "to prevent warping after finishing" is the old one of annealing by heat to cherry-red before machining, but this is impracticable in many cases, and careful tests have shown that an analogous effect may be produced by subjecting the castings while cold to rapid vibrations or shocks, thus accelerating the removal of internal stresses by molecular movement.

Sixth, finally it may be accepted as a fact that all iron castings improve with age, owing to the slow or gradual escape of cooling stresses due to rearrangement of molecules.

Metallurgist with William Sellers & Co., Inc.

A CUTTING LUBRICANT FOR COPPER

Copper, as most mechanics know, is very difficult to work with the ordinary steel tools, but if the following method is used good results will be obtained. Grind the tool as for cutting steel, giving it as much top and side rake as possible. The most important point is to have the tool well oil-stoned, not along the cutting edge but on the top, as the cutting edge must be kept clear of chips at all times. For a lubricant, use sweet cow's milk. This may seem strange, but it has proved to be about the only lubricant that will produce a surface on copper as smooth as glass.

Milwaukee, Wis. FRED FRUHNER

HOW AND WHY

DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST

Give details in full and name and address. The name and address will not be published with the answer.

STANDARD PITCH FOR PIPE

W. K.—Why was 11½ pitch selected as the standard for pipe 1 to 2 inches in diameter? It is inconvenient to gear up for in the lathe, requiring a special change gear. Why would not 12-pitch have answered exactly as well?

A.—Twelve pitch would have been exactly as good as 11½ pitch and is sometimes used when gearing is not available for the standard. For the reason why 11½ pitch was adopted, we refer you to the readers of MACHINERY. If anyone can offer a reasonable explanation, we shall be glad to hear from them.

CAST-IRON PACKING RINGS

L. H.—Why is cast iron so generally employed for piston rings? Has it proved superior to other metals for the purpose? I have searched through several books on machine design without finding the desired information.

A.—Cast-iron packing rings are almost universally used in the pistons of small reciprocating engines and generally in the largest ones. The reasons are that cast iron is low priced; it can be cast in hollow cylinders suitable for making rings and requiring a minimum of machine work; it is close grained, tough and elastic, in suitable mixtures; it wears quickly to a mirror-like surface when working in contact with the wall of a cast-iron cylinder, being an exception to the rule that like metals do not wear well together; it is available wherever ordinary castings are made; and it is easily turned, bored and faced on the lathe. Steel, on the other hand, is higher priced; it must be forged and welded into rings, unless special machinery is available for rolling the rings up to shape; it must contain sufficient carbon to give it temper, if the rings are to be as elastic as cast iron; it wears quickly, working in contact with cast iron, and wears the cast iron rapidly also; and it is harder to machine than cast iron. Some of the bronzes make excellent packings for steam engine pistons, but they are costly and not readily obtainable. The principal objection to cast iron is that the rings are likely to break under shock; in some situations steel must be used because of this defect, especially in steam hammers.

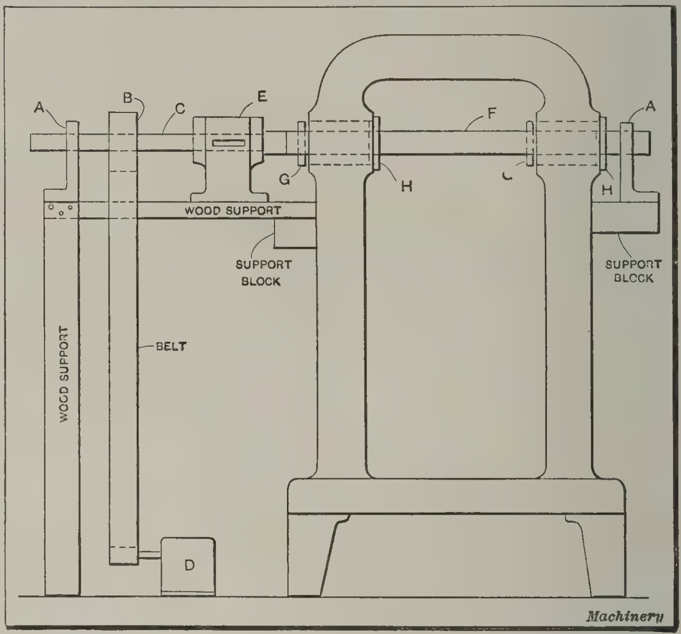
STRAIGHTENING DRILL ROD

D. A. H.—The writer would like to have proposed a method for straightening drill rod 0.105 inch in diameter, furnished in 24-inch lengths. The accuracy must be such that when the rod is rolled on a flat surface no part will be more than 0.005 inch out of true. Also, a method is required for giving a spring temper to these rods and yet have them remain straight. The writer has had to straighten many thousand pieces of untempered commercial rods, as well as a large number of spring tempered rods, and has come to the conclusion that there is no royal road to success in this respect. It seems that this is too close work for wire straightening machines, and, of all the methods tried, none approaches hand straightening. An intelligent helper after careful instruction and some practice has been found to be able to straighten fifteen to thirty rods per hour of unhardened, and ten to twenty of hardened rods, depending on the hardness of the stock, the number of short kinks, etc. The method used has been to mount a hard cast-iron surface on a bench, placing it about on the level with a man's eyes when seated. When the rod is laid on this surface the high spots show the light under them and are straightened by a blow from a 4 ounce hammer. When spring tempered rods are wanted, however, the difficulties are greater, and every rod has to be straightened after hardening. The writer learned from a steel salesman that "our steel can be hardened straight very easily; all you have to do is to heat it uniformly and dip it in water, end first." Marvelously simple until you try to do it! It is possible that someone has had similar work to do and has been more successful than the writer. If anyone has accomplished this work in a more satisfactory manner than outlined above, his experience would prove valuable and interesting.

PORTABLE BORING-BAR

Answered by William N. John, Milwaukee, Wis.

In the How and Why columns of the May number of MACHINERY, J. H. asks for a suggestion for methods to be used for reboring punch and stamping press journals. A couple of months ago we had occasion to rebore the 6-inch bearings in a No. 75½ Bliss power press. We made use of the rigging shown in the accompanying engraving. A scaffold was first erected of 3- by 10-inch planks. Then the saddle or sliding head and spindle were removed from a 24-inch back-geared drill press, the spindle being used to drive the boring-bar. On the scaffolding we also attached the lathe steadyrests from a 16-inch lathe to support the ends of the spindle and bar. On the spindle a 12-inch pulley was fastened with a feather key, this pulley being driven with a 3-inch belt from a 2½-inch pulley on a ¾ horsepower motor fastened to the floor. The boring-bar consisted of a piece of cold-rolled steel about one-half the diameter of the journal. The first cut with the boring-bar enlarged the hole about 1/16 inch. The



Diagrammatical View of Arrangement used for Reboring Bearings in a Stamping Press

cut was reduced each time the boring-bar was run through the journals, until a smooth bore was obtained; about 1/16 inch was planed off from the caps.

In the illustration *A* are the steadyrests; *B*, the 12-inch pulley; *C*, the drill press spindle; *D* the motor; *E*, the sliding head; *F*, the boring-bar; *G*, the boring-bar cutters; and *H*, plates having holes which are lined up with the old bore and which support the boring-bar. The illustration simply shows the arrangement in a diagrammatical way.

The work on this rigging was begun when the plant was shut down Saturday, and the punch press was ready for work Monday morning.

MACHINE TOOL EXHIBITION AT OLYMPIA, LONDON

The Machine Tool and Engineering Association, Ltd., of Great Britain has organized a machinery exhibition covering principally machine tools, to be held from October 4 to 26, at Olympia, London. Nearly two hundred firms have signified their intention to take part in this exhibition so far, and a casual perusal of the list of exhibitors indicates that the exhibition will be of unusual interest to mechanical engineers and to machine tool builders and users. Not all of the exhibitors, of course, are engaged in machine tool manufacture, but a large portion are makers of either machine tools or accessories. A feature of the exhibition which will be of considerable interest, will be the application of the electric drive to a great many of the tools exhibited. The arrangement for safeguarding machines will also be of interest, as it is required by the committee that passes on machines and appliances to be exhibited that all machinery and tools must be properly guarded to meet with the requirements of the ordinances of the London County Council. Altogether, the exhibition will form an unusual opportunity for studying the present status and trend of the machine tool industry in Great Britain.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

THE DAVIS-BOURNONVILLE "OXYGRAPH"

The "oxygraph" is a recent development effected by the Davis-Bournonville Co., 97 West St., New York, for cutting steel by the oxy-acetylene process. It is constructed on the pantograph principle and is so arranged that steel of several inches thickness can be cut to any desired shape by simply guiding the pantograph arm, which is equipped with a cutting torch and a mechanically propelled tracer. When the steel is to be cut accurately to a given shape, a drawing is placed on the table of the machine, and, as the operator guides the tracer along the outline of the drawing, the cutting torch is given a corresponding movement on a reduced scale. In this way, intricate shapes can be cut with considerable rapidity.

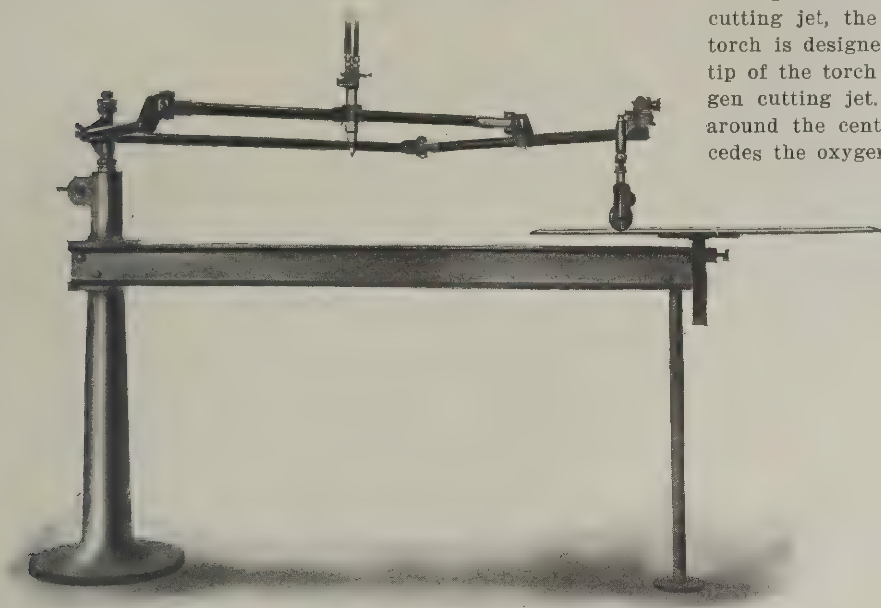

Fig. 1. The Oxygraph—A Machine for Cutting Steel by the Oxy-acetylene Flame

The oxygraph, which is shown in Fig. 1, is very simple, both as regards its construction and operation. It consists of a heavy cast-iron column and an outboard standard, upon which are mounted horizontal supports for holding the work. At the left end of the work-table, the pantograph arm is pivoted, and at the opposite end there is a steel table for holding the drawing corresponding to the outline of the form to be cut. The tracing wheel, which is a thin steel disk, is attached to the outer end of the pantograph arm and rests on the drawing-table. This wheel is positively rotated by a small motor attached to the end of the horizontal arm, and it can be swiveled about a vertical axis for moving in any required direction. This mechanical propulsion of the tracing wheel is a novel and valuable feature and has two decided advantages: In the first place, it provides a uniform predetermined speed for the cutting torch, so that the latter moves at the proper rate to obtain the greatest efficiency; and, in the second place, it is much easier for the operator to follow the lines on a drawing, because his entire attention can be given to the control of the tracing wheel, the latter simply being turned one way or the other, as may be required. The motor is connected with the tracing wheel through small gearing and shafts, and it is started or stopped by a switch conveniently located above the wheel. The motor is small and compact and requires very little power. It can be operated either by a small storage battery or a wire attached to an electric light fixture.

This machine will cut steel three inches thick at a speed of six inches per minute, and the company expects to increase this capacity considerably. It should be mentioned that the cutting is done with the oxy-acetylene flame and the oxygen cutting jet, the same as in ordinary practice, although the torch is designed especially for use with the oxygraph. The tip of the torch has five jets for heating and one larger oxygen cutting jet. The heating jets are arranged in a circle around the central cutting jet, so that a heating flame precedes the oxygen jet regardless of the direction in which the torch is moved, and another heating flame also follows the oxygen jet. It has been found that this arrangement of a heating jet in front and another to the rear of the oxygen jet is much superior to the usual one.

This machine will doubtless prove invaluable in die-making and for a great many other purposes. Fig. 2 illustrates the possibility of cutting out small crankshafts, these shafts having been cut from one-inch steel plates in 8½ minutes. With a high quality of oxygen, the kerf left by the cutting flame is narrow and a clean, sharp cut is obtained. Straight, curved or irregular outlines can be followed easily, and square corners are also cut without difficulty. The piece shown to the right in Fig. 3, was cut out by the writer without any previous experience whatever in operating the machine. This block is illustrated merely to show that straight lines, curves or right-angle turns can be followed by an inexperienced operator. This is made possible by the mechanically propelled tracing wheel, which simply needs to be guided, but takes care of itself as far as the forward movement is concerned. When a corner is reached, the wheel is given a quick turn, and, being motor-driven, immediately starts off in the other direction, so that the corner is cut clean and sharp, which would not be the case if there were any delay. The sides of the narrow path or kerf left by the flame, are remarkably smooth as shown by the sample piece at the left in Fig. 3.

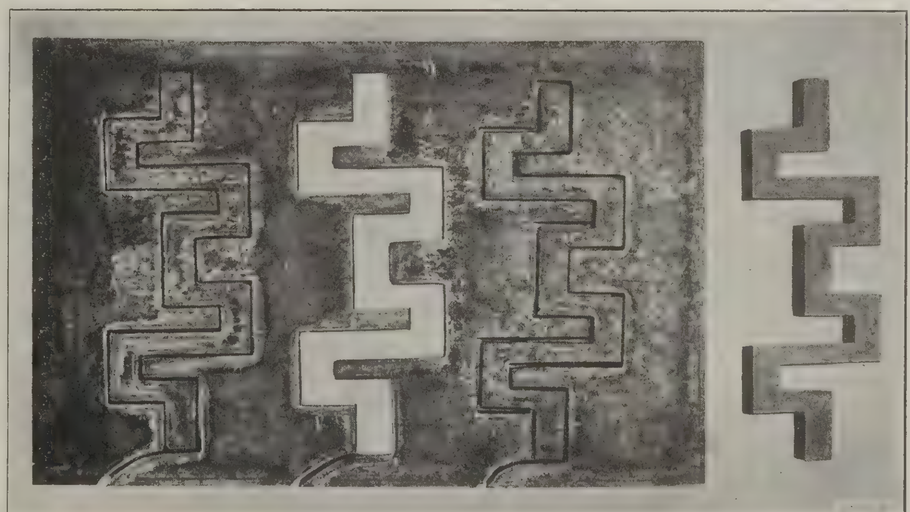

Fig. 2. An Example of Work done by the Oxygraph

The pantograph arm is made of light steel tubing, and the joints are provided with ball bearings to give a free movement. The arm can be adjusted vertically to suit the height of the work, and the drawing-table also has a vertical ad-

justment. The torch tip is about 1/8 inch above the metal when in operation, and the latest designs will have a fine, vertical adjustment of the torch so that its height can be varied in case the material being cut has an uneven surface. This machine has a capacity for widths up to 18 inches, without moving the piece being cut.

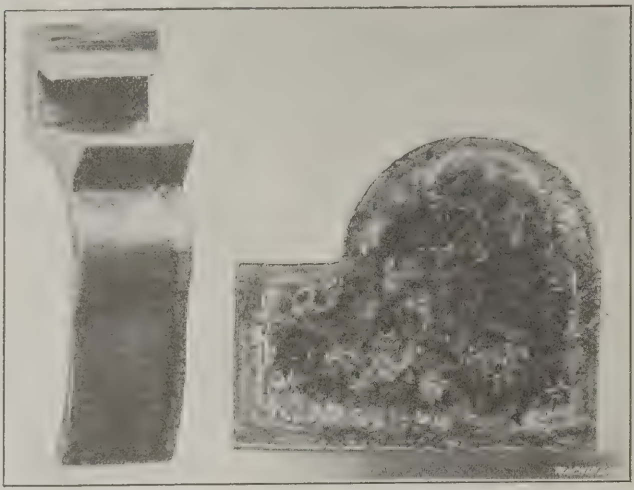

Fig. 3. Sample Pieces cut from Steel Plate by the Oxygraph

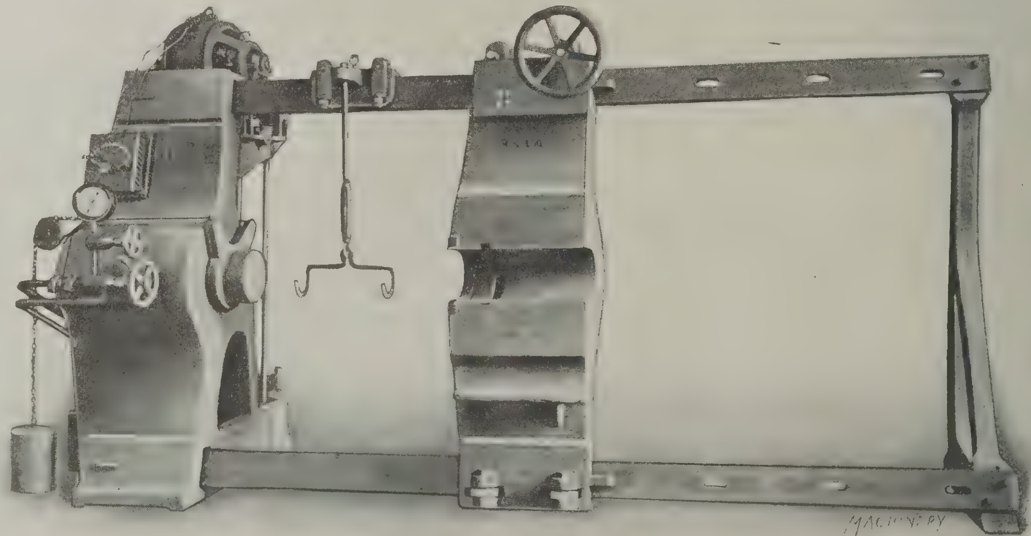
The first public demonstration of the oxygraph was given at the Master Mechanics and Master Car Builders convention recently held in Atlantic City, where it attracted considerable attention.

CALDWELL MOTOR-DRIVEN HYDRAULIC WHEEL PRESS

The motor-operated wheel press shown in the accompanying illustration, is manufactured by E. R. Caldwell & Co., Bradford, Pa. This press is a modern design having a rapid adjustment of the ram and a combination of high and low pressures, which facilitate its operation.

For convenience in handling heavy work such as locomotive drivers and irregular-shaped parts that cannot be rolled to and from the press, the upper horizontal parallel bar is not directly above the lower one, but at a slight angle which permits handling the work with an overhead crane. The plungers (not shown in the illustration) are operated by eccentrics on a back shaft which is driven through cut gears having a ratio of 3½ to 1. The plungers operate without vibration and are practically noiseless. The ram is drawn back automatically as soon as the pressure is shut off from the pumps. An extra valve to connect with the city water line is furnished, when it is possible to have such connection. By opening this valve before using the pressure from the pump, the steel-faced ram is moved out against the work more rapidly than would be possible with the pumps; the city water line valve is then closed, the pump valve opened and the plungers started.



Motor-driven Hydraulic Wheel Press built by E. R. Caldwell & Co.

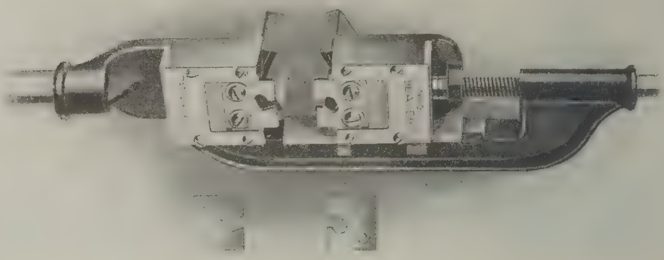
The press is equipped with low- and high-pressure pumps. The low-pressure pump operates the ram up to a certain pressure with a greater speed than the high-pressure pumps, and, consequently, increases the amount of work that can be handled by the use of the high-pressure pumps alone. The low-pressure cylinder is arranged with a relief valve, so that the pump works until there is about 50 tons pressure, when it is automatically "cut out" and the pressing operation is continued at a slower rate by the use of the high-pressure pumps.

In pressing off work, this automatic device is especially efficient. The low-pressure pump works until there is about 50 tons pressure and then the high-pressure pumps begin to operate, and continue until the work is pressed off far enough to enable it to be finished with the low-pressure. As will be apparent, this feature enables the work to be done in a minimum of time.

The pump cylinders are cast from a special semi-steel mixture which gives them great strength, and makes them proof against leakage. All presses are provided with a safety valve to prevent overloading. The plungers are driven by a direct-current, 7½-horsepower, Westinghouse motor.

BEAVER SQUARE-END PIPE CUTTER

The Borden Co. of Warren, Ohio, has brought out a new pipe cutter which severs the pipe by turning or cutting, rather than by squeezing it apart with disks or wheels. This cutter is equipped with square-end turning or parting tools that sever the pipe the same as a lathe tool. The arrangement and form of the tools or blades, and the construction of the central part of the cutter, are shown by the accompanying illustration. There is a tool on each side of the pipe, and, as these tools revolve, a narrow annular groove is cut through the pipe wall. The tools feed inward automatically, and the cutter is turned by two handles the same as a die-stock. The No. 5 size illustrated herewith, has a capacity for pipes varying from ½ to 2 inches. This cutter is said to sever a pipe square and clean and without leaving any burr to remove by filing or reaming. The inside diameter is not reduced and the square end makes it much easier to start the threading die. The cutter is strong and durable, and its blades will sever a great many pieces of pipe without requiring to be reground.



Pipe Cutter equipped with Turning or Parting Tools

BEAMAN & SMITH CYLINDER BORING AND MILLING MACHINE

The machine shown in Figs. 1 and 2 of the accompanying illustrations is a combination type designed to bore two twin-cylinder automobile engine castings simultaneously, and, at the same time, mill the flanges on two other castings. After one set of castings has been milled, it is moved into position for boring by simply revolving the table.

The machine has a substantial bed which supports at one end a carriage with two boring heads, each of which carries two spindles. This is the head seen to the left in the illustration. At the other end of the main bed there is a small cross bed located at right-angles, upon which is mounted a saddle carrying the two milling spindles. The revolving table is located near the center of the main bed. It is 54 inches square and is provided with a ball bearing, which when raised into position by a handwheel, takes the weight of the table and allows it to be revolved easily. The table, however, does not rest upon this ball bearing when the machine is in operation, but on a scraped surface of large diameter. The table has four stop-pin holes and it can be securely fastened after being located by the locking pin.

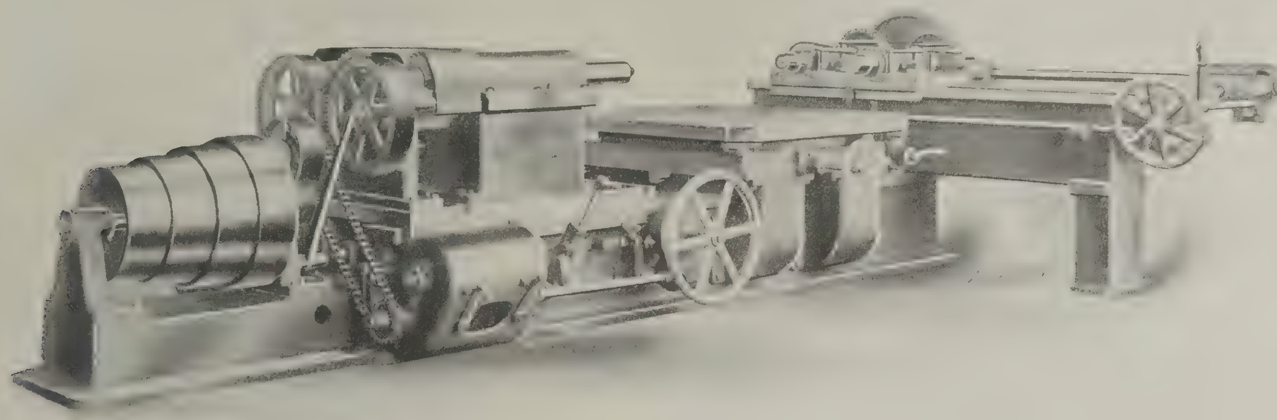


Fig. 1. Beaman & Smith Universal Cylinder Boring and Milling Machine

The carriage upon which the boring heads are mounted, is 34 inches wide, 54 inches long, and has a 30-inch movement on the bed operated by a screw of large diameter which engages a bronze nut. The thrust is taken by ball bearings and the carriage has a quick movement of six feet per minute in either direction. The front end of the carriage extends beyond the ends of the spindles (as shown in Fig. 2) and passes under the table which is bridged across the bed. This extended bearing is for distributing the wear as equally as possible.

The carriage has positive geared feeds which vary from 1/32 to 1/4 inch per revolution of the spindle. The feeds for the milling heads vary from 1 inch to 4¼ inches per minute, for any spindle speed. The four boring spindles are of crucible steel and run in boxes of hard bronze. The ends are made to fit cutters according to specifications. Each of the front bearings is 4 inches in diameter and 6 inches long, and the rear bearings are 2¾ inches in diameter and 5 inches long. Means are provided to compensate for wear. The spindles are fitted in twin heads, and the center distances are made to suit individual requirements. Gearing in the ratio of 8.4 to 1. gives speeds varying from 22½ to 44 revolutions per minute.

The boring spindles are driven by a 6-inch belt operating on a four-step cone, and the milling spindles are driven by a 5-inch belt operating on a three-step cone. The saddle for the milling spindles is 20 inches wide and 41 inches long and has a movement of 52½ inches on the cross bed. It is also provided with a quick power movement, varying from 6 to approximately 12 feet per minute in either direction. This rapid traverse is driven by a 4-inch belt operating on a 10-inch pulley. The milling spindles are also made of crucible steel and run in hard bronze boxes. They have tapered ends 3 inches in diameter for receiving face milling cutters. The front bearings are 4 inches in diameter and 6 inches long, and the rear bearings, 3 inches in diameter and 5 inches long. Gearing in the ratio of 21½ to 1, gives speeds of 7½, 10, and 14 revolutions per minute.

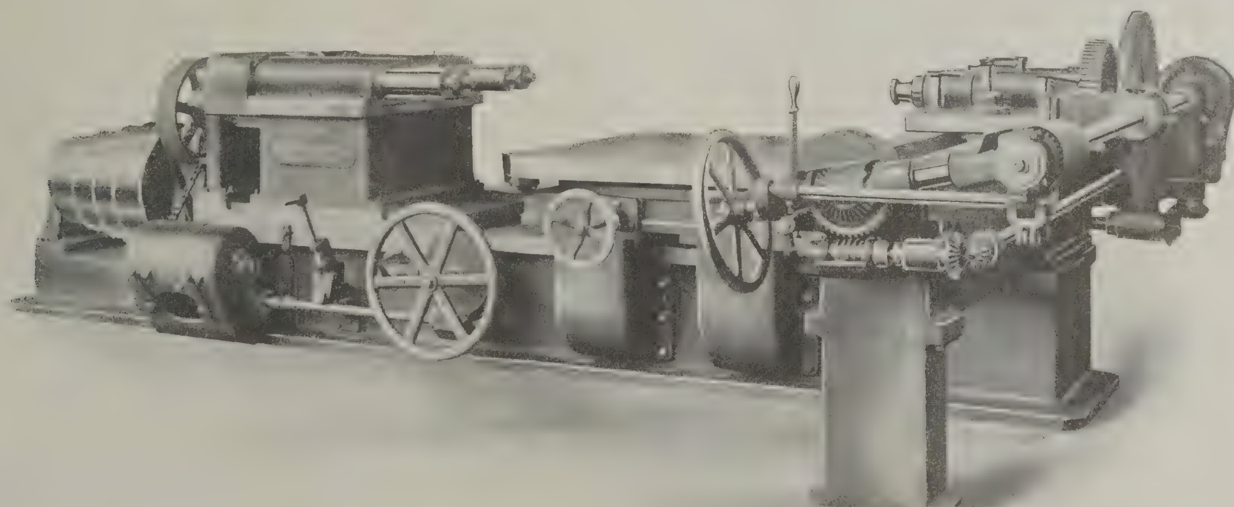

Fig. 2. Another View of the Beaman & Smith Machine

The minimum distance from the center of the table to the face of the boring heads is 27 inches, and the maximum, 57 inches. The minimum and maximum distances from the center of the table to the end of the milling spindles are, respectively, 28¾ and 31¾ inches. The vertical height from the center of the spindles to the top of the table is about 9¾ inches. The weight of this machine is approximately 28,000 pounds. It is known as the No. 2 universal, cylinder-boring and milling machine, and is built by the Beaman & Smith Co., Providence, R. I.

OESTERLEIN MOTOR-DRIVEN MILLING MACHINES

The application of variable- and constant-speed motor drives to the milling machines built by the Oesterlein Machine Co., Cincinnati, Ohio, is illustrated herewith. Fig. 1 shows a direct-connected, variable-speed, motor-driven machine. This same drive is applied to all sizes of plain and universal milling machines built by this company. A large driving gear, which runs loose on the spindle, drives the latter either by connection to the face-gear or through the back-gearing. The intermediate gear is made of hard fiber so that the drive is practically noiseless. With the push-button starter, which is located on the right side of the column above the spindle, the machine is automatically adjusted to the speed for which the motor is set.

The No. 20 plain or universal machines are equipped with a two-horsepower motor, and with a 6 to 1 speed variation all spindle speeds from 19 to 400 revolutions per minute can be obtained. A 4 to 1 variable-speed motor will give all speeds from 21 to 85 and from 100 to 400 revolutions per minute. For the single back-geared No. 24 or 28 plain and No. 25 universal machines, a three-horsepower motor is used, and with 6 to 1 and 4 to 1 variations, the same spindle speeds are obtained as previously given for the No. 20 machines. A double back-geared No. 24 plain, No. 28 plain, and No. 25 universal machine should have a three-horsepower motor, and a 3 to 1 variable-speed type will give all spindle speeds from 14 to 400 revolutions per minute. The No. 34 plain and No. 30

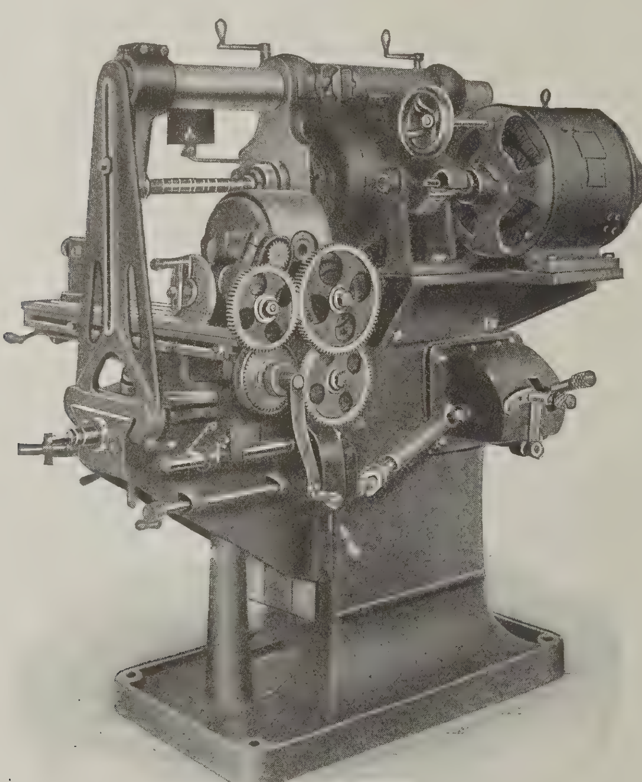

Fig. 1. Oesterlein Direct-connected Variable-speed, Motor-driven Machine

universal machines use a five-horsepower motor. The spindle speeds in any case can be changed by altering the pinion on the motor shaft.

A constant-speed motor-driven machine is illustrated in Fig. 2. The arrangement of the drive is clearly shown by the illustration. The motor may be an alternating or direct-current type. The motor shaft carries a two-step pulley which drives the two-step pulley on top of the machine. On this upper pulley shaft there is a pinion which drives a large gear inside the cone. This gear is secured to the cone, and the latter is bronze-bushed and runs loose on the shaft. The upper pulley shaft is eccentrically mounted and its position can be varied by the belt-tightening lever seen on the right-hand side of the cone. With this lever, a proper belt tension can be secured or the belt can be loosened to permit shifting it easily. The lever between the two cones is provided to facilitate the shifting of the belt.

The single back-geared machines have four-step driving cones operating at two different speeds, so that, in connection with the back-gear, 16 single speeds are secured. The double back-geared machines have three-step driving cones, which, with two speeds and double back-gears, give 18 spindle speeds

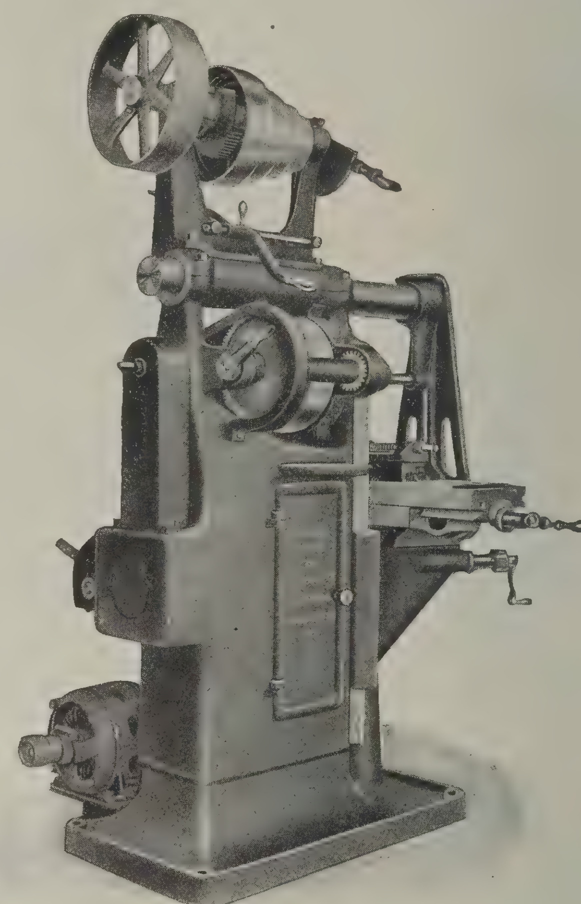

Fig. 2. Oesterlein Constant-speed Motor-driven Machine

varying in geometrical progression. A two-horsepower motor is recommended for the No. 20 plain and universal machines; a three-horsepower size for the No. 24 and 28 plain, and No. 25 universal machines, and a five-horsepower motor for the No. 34 plain and No. 30 universal machines.

CINCINNATI PRECISION ADJUSTABLE REAMER

The adjustable reamer shown in Fig. 1 has been designed by the Cincinnati Precision Lathe Co., Cincinnati, Ohio, for accurate work. The blades of this reamer are inserted in slots cut in a steel shell which is fitted to a taper shank, and held in position by a taper pin which passes radially through

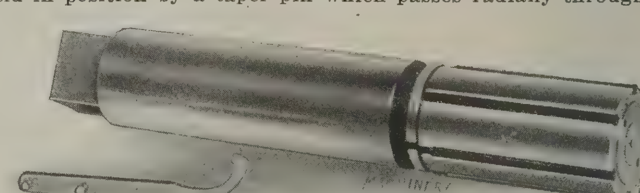

Fig. 1. Cincinnati Precision Adjustable Reamer

both shell and shank. The slots extend clear through the shell, excepting at each end, so that the blades rest directly upon the taper shank. The latter is threaded at each end of the taper, and upon the threaded parts are screwed angular collars which retain the blades, as clearly illustrated in Fig. 2, which shows the reamer with the slotted shell and the angular collars removed.

The blades are also adjusted radially by these collars, the adjustment being made by screwing the collars one way or the other and thus shifting the blades up or down the taper

shank. By employing a ground taper shank as a seat for the reamer blades, a fine degree of accuracy is obtained. The blades, which are jig ground, are exact duplicates, and the slots in the shell are accurately milled to fit the blades.

This construction gives a uniform movement and adjustment of all the blades, so that each one cuts when the reamer is in use. By adjusting the collar next to the body and then turning the collar at the small end of the taper shank, a corresponding amount, the blades are moved along the taper

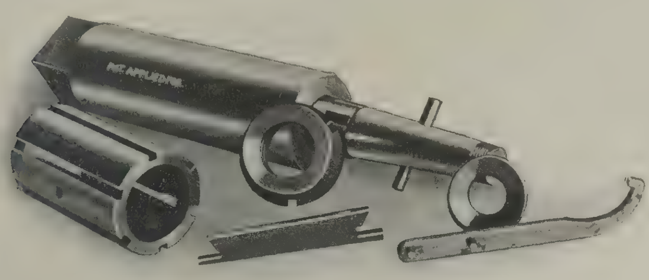

Fig. 2. Component Parts of Adjustable Reamer

uniformly and cannot become eccentric to the body of the reamer. The inner sides of the collars, which engage the ends of the blades, have a 30-degree angle so that the blades are firmly clamped against the taper shank. All threads and inner working parts of this reamer are protected from chips or other foreign material. The single combination wrench seen in Fig. 1, is used for making all adjustments.

MODERN MACHINE TOOL CO.'S FLAT TURRET LATHE

The Modern Machine Tool Co., 4657 Spring Grove Ave., Cincinnati, Ohio, is now manufacturing the flat turret lathe shown in Figs. 1 and 2. Careful attention has been given to the arrangement of the various parts so as to secure a compact, simple construction and a convenient control. The various parts of the lathe have been made extra heavy.

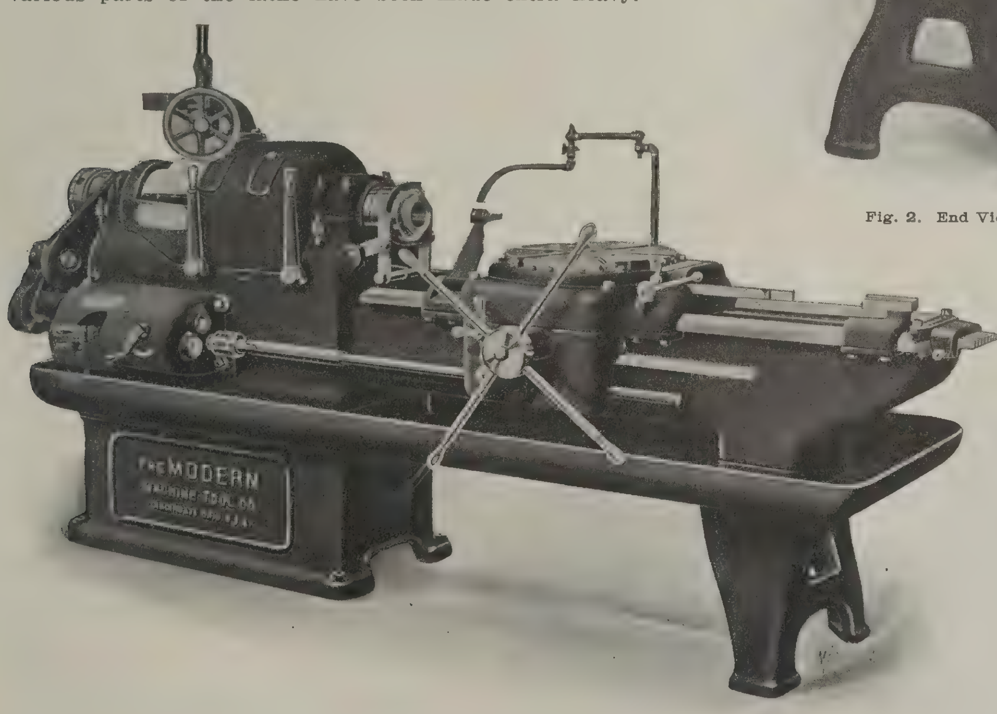

Fig. 1. Flat Turret Lathe built by Modern Machine Tool Co.

The head is very massive and is cast integral with the bed. The head contains the cone pulley for driving the machine, the friction back-gears and the automatic roller feed and chuck. The back-gears are located directly under the spindle. These gears, in conjunction with the three-step cone, give 12 spindle speeds varying in geometrical progression. The bed, which rests on a tripod bearing, is deep and heavy, and is reinforced under the front spindle bearing.

The chuck is operated by a single movement of the lever seen in front of the head. It has a strong unyielding grip and no overhang or end motion. One set of jaws can be adjusted for the full capacity of the machine, and the jaws and seat are hardened and ground. The chuck is constructed for handling rough bars, and the jaws can be made for any size or shape within the spindle's capacity. The automatic roller feed has only three moving parts. It is mounted on the spindle just back of the front bearing and is operated by the same lever that opens the chuck.

The carriage is gibbed to the outer edge of the bed by flat gibs extending its entire length. The bearing on the bed is not recessed, but there is a full contact from end to end. A binder is provided for securely clamping the carriage to the bed during forming or cutting-off operations. The backward movement of the carriage automatically indexes the turret the instant the tool leaves the work. The arrangement is such that the turret can be turned to any one of the six positions without making any other stops.

Fig. 2. End View of Flat Turret Lathe

The adjustable dog for operating the index bar is clamped to the V and governs the position of the saddle at the time the turret begins to revolve.

The carriage has twelve independent adjustable stops which operate automatically for each position of the turret and can be used in any desired combination when two or more are needed for any position of the turret. The turret is a flat circular table 18 inches in diameter, and has T-slots for clamping the tools in position. The tools can be attached to the turret for turning several diameters simultaneously when desired. The index is very large in diameter and the lock-bolt is located directly under the working tool, and so close to it that lost motion is eliminated.

The feed gear box is driven from the spindle. Eight feed changes are available for each of the twelve spindle speeds, and a graduated plate shows the amount of feed for different positions of the change gear levers. All gearing is covered.

The machine has a mechanical belt shifter which is operated by a handwheel located at the front of the head. This wheel operates two shifting arms, one of which is located

above the cone pulley on the machine and the other near the cone pulley on the countershaft. Connection is made between the upper and lower arms by a vertical shaft. By means of this mechanical shifter, the position of the belt can be changed quickly and without danger to the operator.

Bar stock up to 2¼ inches in diameter can be fed through the automatic chuck and lengths up to 26 inches can be turned. The swing over the bed is 20 inches, and over the carriage, 16 inches. The net weight of the machine is 4500 pounds. This lathe is manufactured on the unit system and the parts are interchangeable. The plain bearings are scraped to master surface-plates and straightedges, whereas shaft bearings are ground and fitted with removable bushings which can be replaced when worn, without disturbing the shaft alignment. Efficient means for lubrication are provided.

WILMARTH & MORMAN CUTTER, REAMER AND DRILL GRINDER

The cutter, reamer and drill grinder manufactured by the Wilmarth & Morman Co., 580 Canal St., Grand Rapids, Mich.,

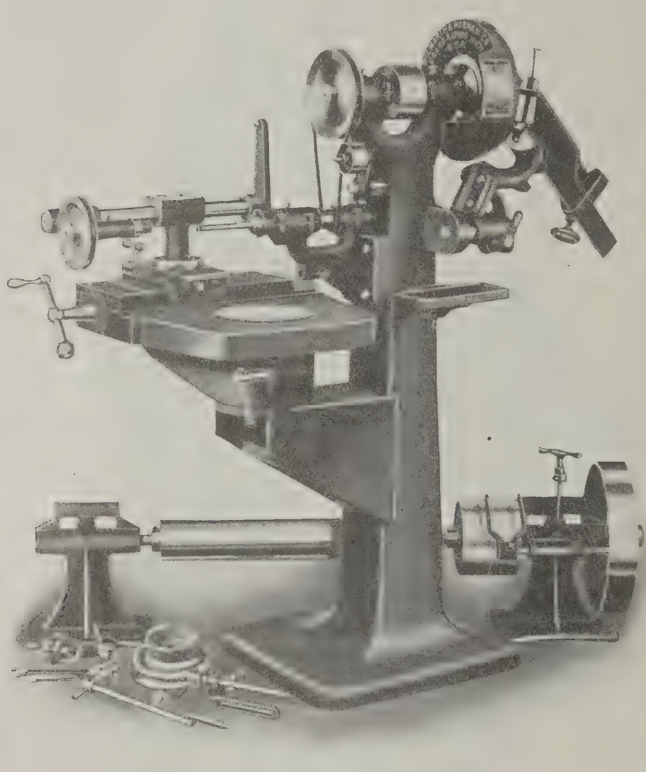

Fig. 1. "Yankee" Cutter, Reamer and Drill Grinder with Cylindrical and Internal Grinding Attachment

has been re-designed to make it more universal than the former machine. With the old-style grinder, the table of

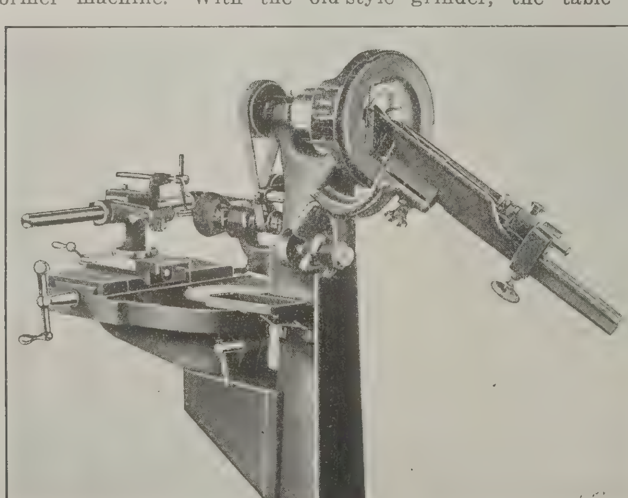

Fig. 2. Grinding Reamer with Face of Cup Wheel

the cutter grinding attachment was permanently bolted to the column and the small wheel-head was bolted to the table. With the new machine, the table and its slide is mounted on a knee so that it can be swiveled with relation to the grinding wheel, approximately 180 degrees, which permits using a cup wheel and makes it possible to apply the work to either side of a plain wheel.

Fig. 1 shows the machine complete, with a cylindrical and internal grinding attachment, in addition to the regular drill grinder. The way the machine is arranged for grinding

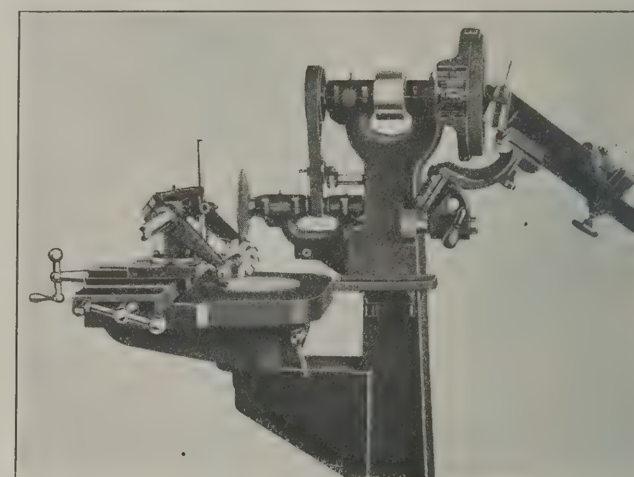

Fig. 3. Grinding Formed Cutter

reamers when using the face of a cup wheel, is illustrated in Fig. 2. This particular reamer is straight, but taper reamers are ground in the same way, except that the standard carrying the reamer, is swiveled to the required angle. In case it is desired to grind a reamer by using the periphery of a plain wheel instead of a cup wheel, this can be done by swinging the table around to bring the slide parallel with the wheel spindle. The table can be swiveled to either side, so that the wheel will grind either up or down, with relation to the teeth.

Fig. 3 illustrates the grinding of a formed cutter. The work is mounted on a suitable arbor which is placed between

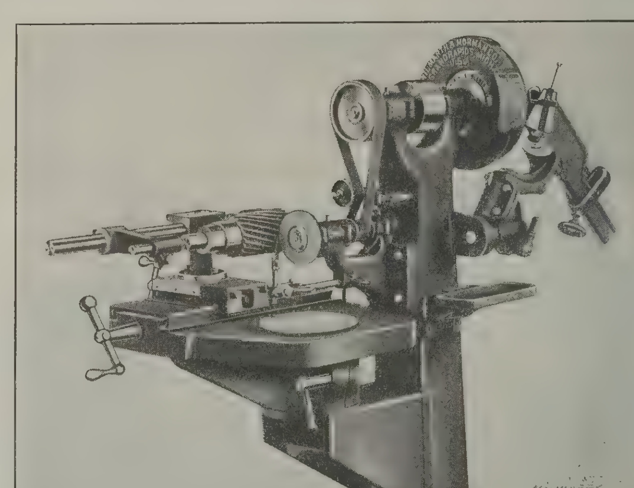

Fig. 4. Grinding Cylindrical Cutter

the centers as shown, and the teeth are ground by passing the cutter under a saucer-shaped wheel. The feed is regulated by the cross-screw movement of the upper or cross-slide which carries the swivel or standard. Hobs, gear-cutters or taps can also be ground in the same way. When grinding the flutes of a tap, the latter is, of course, held by its own centers and no arbor is needed. Fig. 4 shows the method of grinding a plain, spiral-tooth milling cutter by using the periphery of a straight wheel. A cup wheel can also be employed by setting the machine as illustrated in Fig. 2.

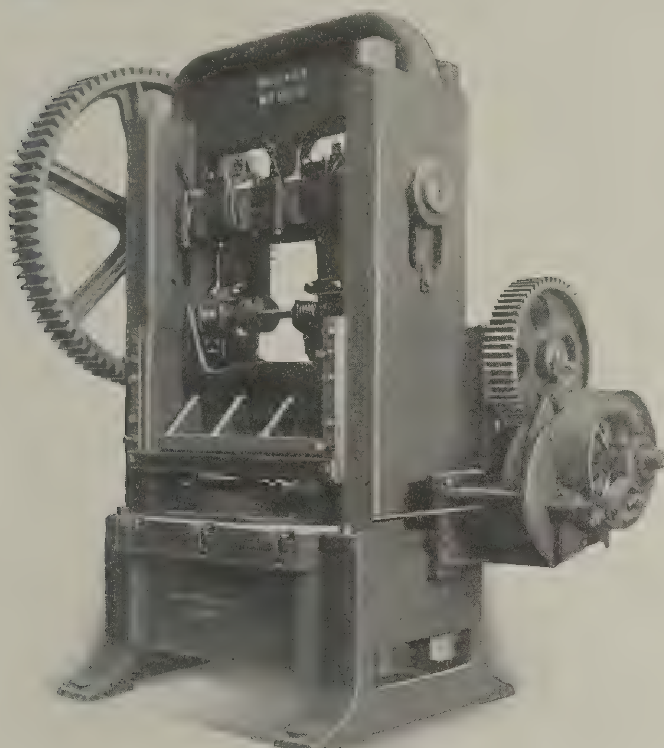
This machine is also adapted to the grinding of angular cutters, as well as face or side mills. When grinding angular cutters, the table is swiveled to the required angle as indicated by the graduated base. A vise can be furnished with this machine in case it is to be used for surface grinding. This vise is interchangeable with the regular swivel standard and has a graduated base which can be swiveled for angular grinding. The vise can also be tilted in a vertical plane, from

a 45-degree position to a point slightly beyond the perpendicular, and provision is made for securely locking it in position. This vise is intended for small hardened parts, such as vise jaws, small tools, cutters, keys, etc.

This machine has a capacity for side and face milling cutters up to 12 inches in diameter, and angular or plain cutters up to 8 inches in diameter. It will grind cylindrical work (straight or taper) up to 7¼ inches in diameter and 11½ inches long. The maximum distance between the centers is 17 inches.

NIAGARA DOUBLE-CRANK PRESS

The straight-sided, double-crank, power press shown in the accompanying illustration, was recently designed by the Niagara Machine & Tool Works of Buffalo, N. Y. The press



A Large Double-crank Press built by Niagara Machine & Tool Works

was built for the manufacture of gear guards for electric traction engines, but is suitable for a general line of heavy stamping and blanking operations. The frame is of the built-up type with tie-rods, and the slide and gibs have convenient adjustments.

Particular attention has been given to the arrangement of the press, so as to obtain a compact design occupying a minimum amount of floor space. Outboard bearings are entirely eliminated, and all parts of the drive which require occasional adjusting, are easily accessible.

The friction clutch is of the multiple-disk type. The friction surfaces are lined with end grain hardwood blocks. The clutch is entirely encased and all projecting rotating parts which might endanger the operator when oiling the clutch, are eliminated. The clutch is operated by four sets of toggles and links, which are made of steel. The brake which works in unison with the clutch, consists of two brake levers, which are actuated by a pair of toggles. An interesting feature of this construction is that the pressure on the brake blocks is always equalized, thus avoiding transmitting the pressure of the brake arms to the shaft bearings.

These presses are built in different sizes varying from 48 inches to 12 feet between the housings, and weighing from 30,000 to 150,000 pounds.

ROCHESTER BORING, MILLING, DRILLING AND TAPPING MACHINE

A horizontal boring machine of the "table type," which embodies many interesting features, has been brought out by the Rochester Boring Machine Co., Rochester, N. Y. This machine, besides performing the usual operations of boring,

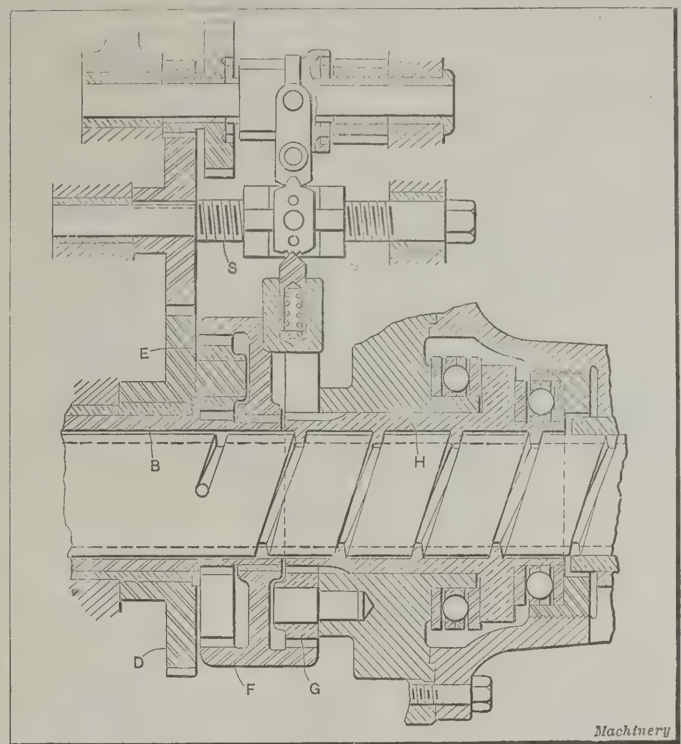


Fig. 1. Differential Feed Mechanism and Automatic Limit Stops for Spindle of Machine shown in Fig. 2

milling, and drilling, can also be arranged for tapping, splining oil grooves or thread cutting. The control of the machine is centralized, it being possible to make feed or speed changes, operate the rapid traverse movements, or start, stop and reverse the machine from one position convenient to the operator. No two feeds can be engaged at the same time, and it

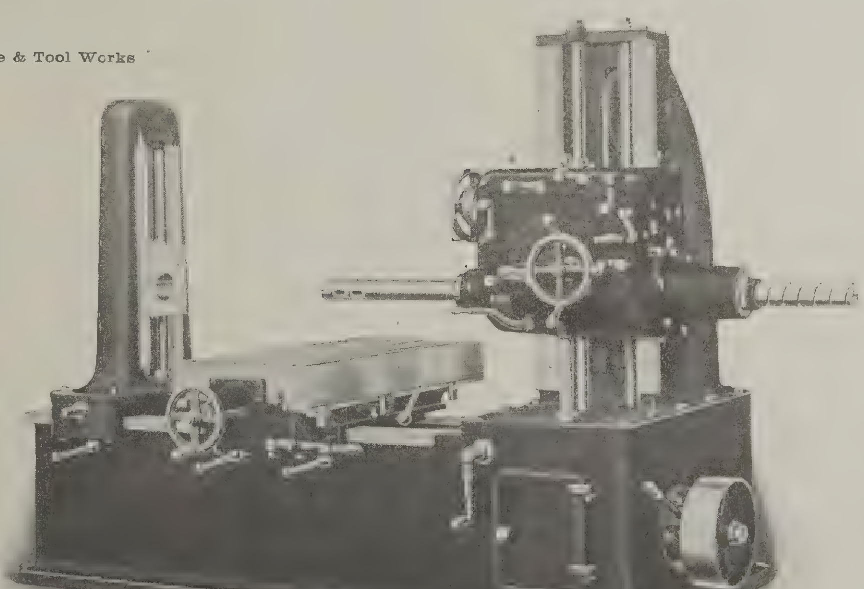

Fig. 2. Rochester Boring, Milling, Drilling and Tapping Machine

is also impossible to engage simultaneously the rapid traverse for different directions.

The main drive through the bed to the operating mechanism is simple and direct. The pulley shaft can be arranged either parallel to the machine, as shown, or at right-angles to the bed. The single, constant-speed driving pulley has a friction clutch for starting or stopping, which is controlled by the

small lever seen to the left of the pulley in Fig. 2. The horizontal lever on the lower left-hand corner of the saddle, can also be used for starting, stopping or reversing. This machine can be equipped with a motor drive, if desired. For a standard electric drive, the motor is mounted at the top of the column and connects direct with the vertical driving shaft. The motor can, however, be applied to the driving pulley shaft, if desired. Constant-speed motors for either alternating or direct currents are used, as all speed changes are obtained mechanically.

The bed has a continuous web construction and is closely ribbed in both directions. Chutes are provided in the bed for removing chips at the rear, and there is also a reservoir in one end for cutting oils or lubricants. The upright column upon which the saddle travels, is bolted and doweled to the bed and has a deep section with large surface bearings.

The mechanism for feeding the main spindle operates on the same principle as the feed mechanism illustrated in MACHINERY for July, 1910, in connection with a description of the floor-type machine built by this company. The feeding movement is transmitted from the change-gear mechanism to a differential geared drive which rotates a long bronze nut mounted directly on the spindle and engaging a square thread. The driving gears for the spindle are mounted on a sleeve *B* (see detail sectional view, Fig. 1) which has its own independent bearings. Clearance is provided between the sleeve and spindle and the latter is rotated by long splined keys fitted in the driving sleeve and engaging double splines, thus giving a balanced drive. Sleeve *B* has gear teeth cut on the end shown in Fig. 1, which mesh with three pinions *E* mounted on studs that form part of the differential feed-driving gear *D*. By means of a double internal gear *F* and three other pinions *G*, which mesh with the spindle feed nut *H*, the latter is positively rotated at the same speed and in the same direction as the spindle, so long as gear *D* remains stationary, which is the case when the feeds are disengaged. When the feed is applied, the spindle nut either rotates faster or slower than the spindle and this differential movement between the nut and spindle, gives a feed in one direction or the other.

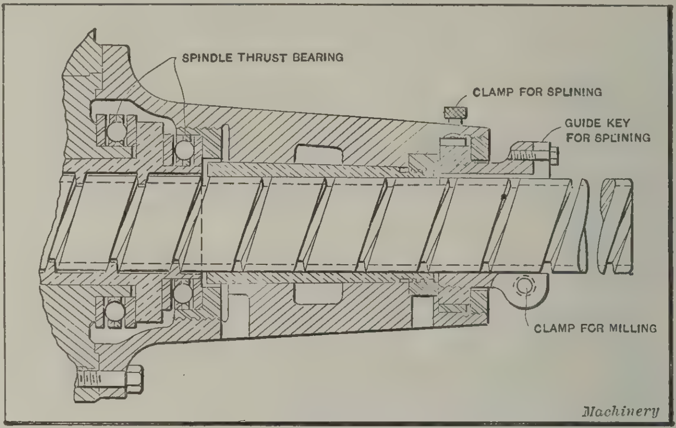

Fig. 5. Rear Spindle Bearing

The nut makes contact with the sides of the thread only, and the end-thrust is taken direct by the large ball bearings shown. The end-thrust for milling is taken by a bronze thrust bearing independent of the end-thrust for boring. All feeds, before being applied to the different parts, are transmitted through a friction clutch which enables instantaneous engagement or disengagement and provides a yielding point when desired. The reverse mechanism is located at the source of power and the feed can be reversed without stopping the machine.

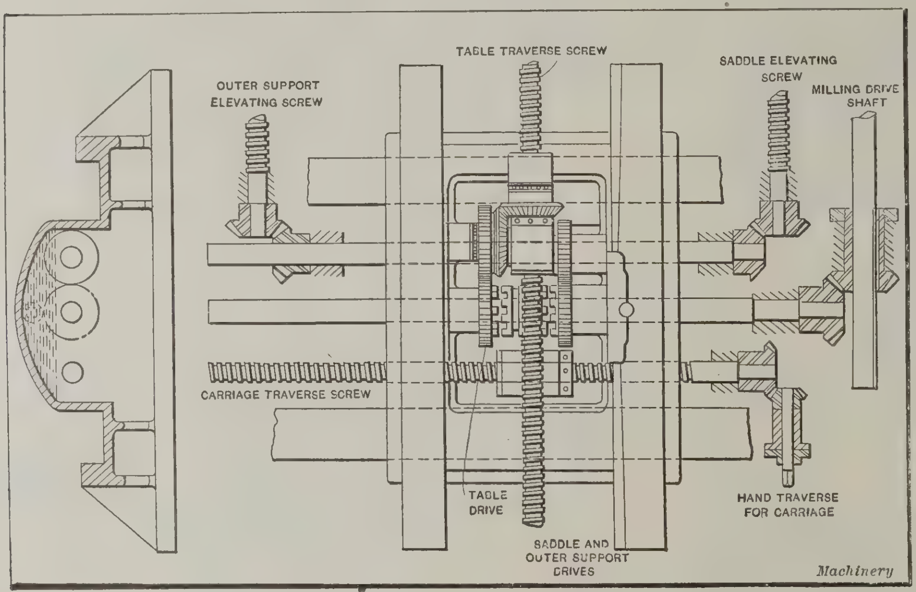

Fig. 3. Diagrammatical View showing Table, Carriage and Power Distribution

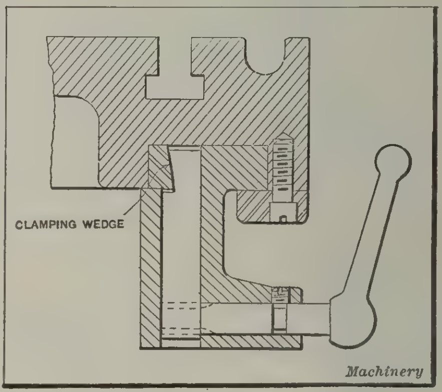

Fig. 6. Locking Clamp for Table

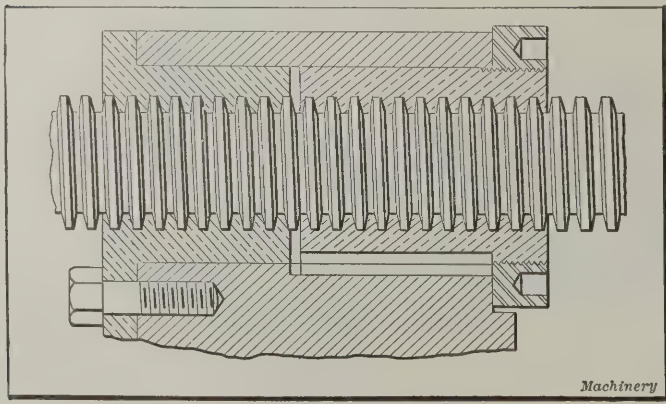

Fig. 4. Two-part Nut for Taking up Wear

Sixteen boring and drilling feeds are provided and a similar number of different milling feeds for the saddle and table. These feeds and the rapid power traverse, are applicable to the spindle, saddle, table and carriage. Automatic limit stops are arranged for movements in either direction, in addition to adjustable knockouts for the table feeds. It is impossible to engage two feeds, speeds or traverses at the same time. The driving and feed gearing is enclosed and runs in oil. The lubricant is forced to a reservoir at the top of the saddle by a pump and from there it is distributed by leaders to the different bearings, and the overflow runs over the gears.

The feeding and traversing movements are transmitted to the table through a vertical shaft in front of the saddle and a shaft in the bed. At the table the feed is distributed either for the cross-wise movement or for elevating the saddle and outer support. Fig. 3 shows a diagrammatical plan view of the carriage for the table and illustrates the arrangement of the mechanism. A power cross feed is provided for the table and also a power lateral traverse for the carriage, when specified. The nuts for the screws are made in two parts, as shown in Fig. 4, for taking up wear or backlash. One section of the nut has a flange, as shown, and the other part can be adjusted longitudinally by a threaded collar, but is held against rotation.

The bearings for the spindle are located at the extreme ends of the saddle, thus giving a rigid support. A sectional

view of the rear bearing is shown in Fig. 5. These bearings are of phosphor-bronze and can be easily adjusted from the outside, in case of wear. The knockout or limit stop for the extreme travel of the spindle is shown in Fig. 1. An intermediate gear located between the feed change gears and the feed driving gear, rotates screw *S*. A nut on this screw is moved a certain predetermined distance, representing the maximum travel of the spindle. At the extreme travel of the nut, a lever segment is automatically actuated, which disengages the feed back-gear clutch and throws it to the neutral position, thereby stopping the feed.

When the machine is used for splining, the spindle is moved in and out without rotating, by the rapid power traverse. The spindle gear clutch is set in the neutral position, thus disengaging the spindle driving gears, and a guide key (see Fig. 5) is inserted in the milling clamp collar at the end of the saddle. This key engages one of the splined ways in the spindle, and the collar is held against rotation by a friction band which is tightened by a thumb-screw on the outside of the bonnet. Both the collar and spindle are held in this way against rotation, and the spindle is guided, as it moves lengthwise, by the key previously referred to. Spiral oil grooves of different pitches can also be cut by using the rapid power traverse in conjunction with the rotary movement of the spindle. When cutting spiral grooves, the clamp collar used for straight grooving is, of course, disengaged.

Graduated dials reading to thousandths of an inch are provided for all movements, and precision screws are used throughout. On the front end of the saddle there is an "indicator" corresponding to the center of the spindle, which is convenient for adjusting to a given height with a surface gage, when boring. The table is clamped directly under the spindle and the form of locking binder used is shown in Fig. 6.

These machines are built in two sizes at the present time, the principal dimensions of which are, respectively, as follows: Spindle diameter, 3 and 3½ inches; longitudinal traverse of spindle, 32 and 40 inches; spindle speed changes, 12 for both machines; feed changes, 16; vertical traverse of saddle, 21 and 25 inches; maximum height from table to spindle, 22 and 26 inches; maximum distance between saddle and outer support, 5 feet and 6 feet; table cross-feed, 30 and 36 inches; lateral traverse of table, 36 and 42 inches. These machines are so constructed that the standard range can be varied easily to suit special requirements, when necessary.

GARVIN AUTOMATIC-INDEX MILLING MACHINE

The milling machine shown in Fig. 1 is an automatic-indexing type, especially adapted to tap manufacturing plants. This machine is built by the Garvin Machine Co., Spring and Varick Sts., New York. In addition to the automatic fluting of taps and reamers, the machine can be used for cutting gears, ratchets or for repetition work of a similar nature. The modifications introduced in this design comprise quick-acting work-holding apparatus, automatic indexing, automatic feed with a quick return effected by a long spring and checked by an air cushion, and automatic stopping of the machine when the work is completed.

When a cut is finished, the table is tripped by the dog seen to the left, which releases a latch and allows the feeding worm to drop out of mesh with the worm-gear. As the table is then disengaged from the power feed, it is moved rapidly to the other end of its travel by a spring enclosed in a tube at the end of the table. The arrangement of the feed gearing and quick-return mechanism is shown in Fig. 2. The rapid motion of the table is checked before the fixed stop is reached, by an air cushion formed in the cylinder shown by the section to the right.

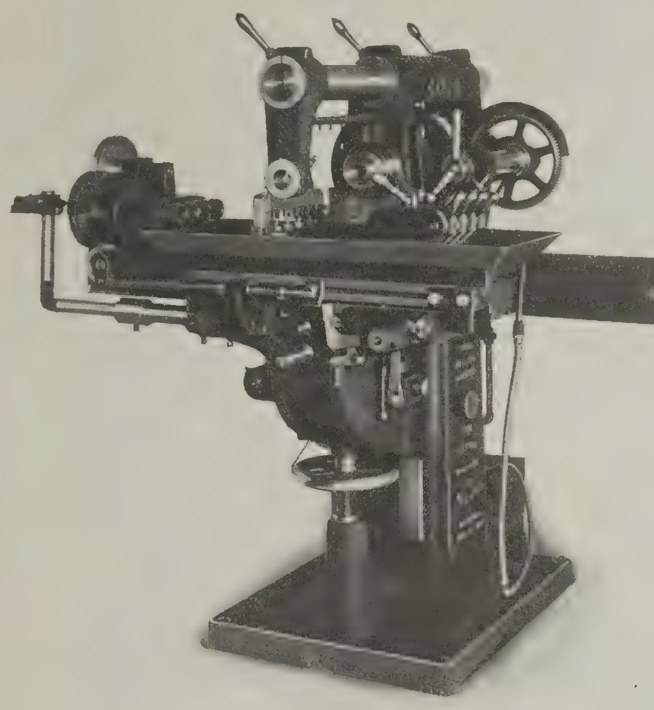

Fig. 1. Garvin No. 13 1/2 Automatic-index Milling Machine

At the same moment that the dog trips the table, the left-hand stop-collar on the screw seen in front of the machine to the left, Fig. 1, comes in contact with a stationary bracket; this trips the tilting table of the machine by means of a cam shown to the left in Fig. 2, the shaft carrying this cam being operated by the longitudinal movement of the screw on which the stop-collar is mounted. As the cam is turned, the table swings downward slightly, the swiveling movement being around a pivot at the right-hand end. This prevents the cutter from dragging when the work is being returned for another cut. As the table approaches its extreme position on the return stroke, the right-hand dog at the front strikes a stop-plunger, thus shifting the worm back into mesh with the worm-gear at the same moment that the table comes to rest. As the table reaches the end of its travel, the right-hand stop-collar on the screw previously referred to, strikes a stationary bracket and operates the cam lifter, thus tilting the table back to its working position. The index pawl is also lifted so that the dial can index, after which it falls back instantly.

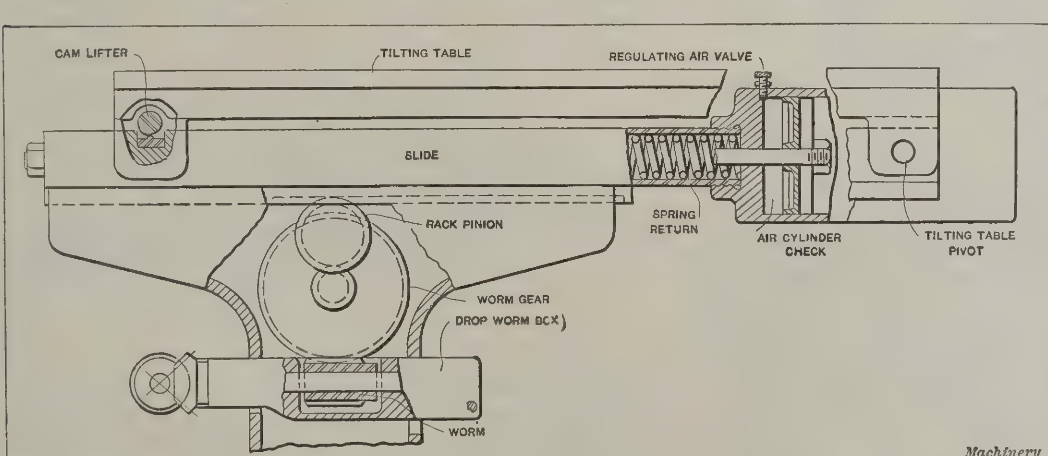

Fig. 2. Feeding and Quick-return Mechanism of Garvin Machine

The machine is now ready for another cut, and this operation of feeding forward, returning rapidly and indexing, continues until the work is finished. The machine then trips

again and, on indexing, a projecting pin on the index dial pushes a sliding pin on the telescope bar seen to the left of the machine, and releases a rope connecting with a spring on the countershaft, thus stopping the machine.

The maximum distance between the centers is 16 inches, and a cut 7½ inches long can be taken anywhere within this distance. The centers have a capacity for holding work on all four spindles up to 2 inches in diameter, and diameters up to 4 inches can be handled, when only the two outer spindles are used. The weight of the machine is 2200 pounds.

HOSKINS RECORDING PYROMETER

A new recording pyrometer which is now being built by the Hoskins Mfg. Co., 459 Lawton Ave., Detroit, Mich., is shown in Fig. 1. The record chart of this pyrometer is always visible, thus making the instrument "indicating" as well as recording, and the electrical movement, as well as the clock and marking device, is at all times entirely enclosed, even when changing charts. In designing this pyrometer, the principal points aimed at were accuracy, reliability and simplicity.

The electrical movement of the pyrometer is a finely built milli-voltmeter of the D'Arsonval type. It is sensitive to a fraction of a milli-volt and was especially designed for this pyrometer. It is claimed that this milli-voltmeter is much less susceptible to outside temperature conditions than the ordinary types. It is actuated by the electro-motive force

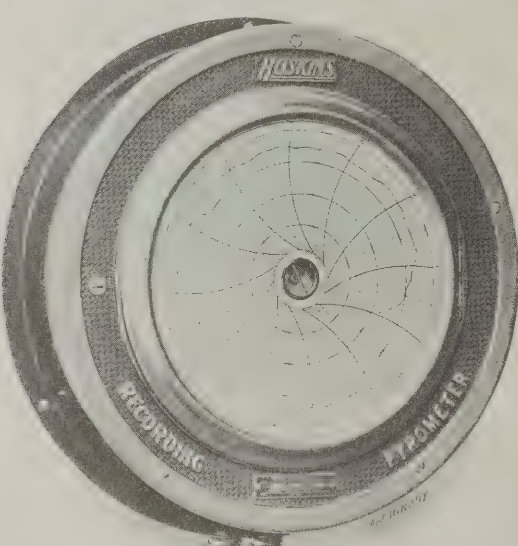

Fig. 1. Recording Pyrometer made by Hoskins Mfg. Co.

set up by a base metal thermo-couple which is connected by wire leads to the binding posts shown at the bottom of the meter case. This thermo-couple, when subjected to heat, is said to generate an electro-motive force four times as great as that of the ordinary platinum-rhodium couple, for a corresponding temperature; the additional power thus gained adds to the accuracy and reliability of the pyrometer.

The record chart is caused to revolve by a clock movement contained within the meter case. The chart is a circular disk of paper which is thin and translucent but strong and durable. It is clamped in place on the revolving clock shaft by a small thumb-screw. A circular disk of carbon paper of the same size as the chart, is also clamped on the shaft, back of the chart and with the carbon side toward it. When a chart is being put in place, as shown in Fig. 2, it is held temporarily against a stationary dial-plate which completely covers the electrical and clock movements.

The clock also actuates an arm which is curved to correspond to the arc through which the end of the recording pointer travels. At half-minute intervals the curved arm momentarily brings a small stylus or metal point, carried at the end of the recording pointer, against the carbon paper, thus making a dot on the back of the chart. As the chart revolves, these dots, which are plainly visible from the front, continue to be made, giving the appearance of a continuous line, as shown in Fig. 1. The location of the dots relative to the concentric circles printed on the chart, indicates the temperatures to which the thermo-couple has been subjected. The charts are made to indicate degrees Centigrade or Fahrenheit, or milli-volts, as desired, and to cover periods of twelve or twenty-four hours.

This method of making records permits two records to be made at the same time, just as duplicate letters are made on the typewriter. When a considerable number of copies of any particular record are wanted, blueprints may be made directly from the chart. On the margin of the chart, a place is provided upon which to mark the date and time at which the

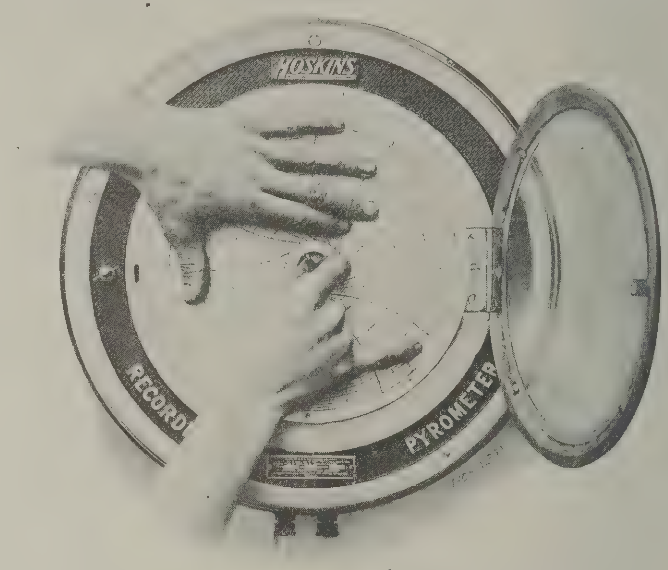

Fig. 2. Placing a New Chart in Hoskins Pyrometer

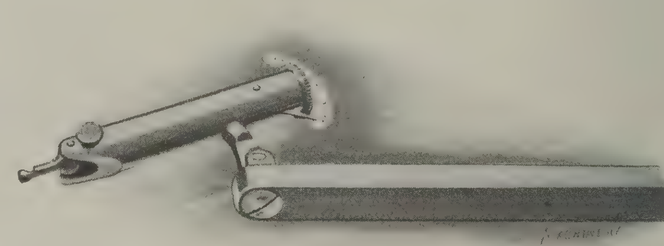
record was started and the name of the furnace or operation. This pyrometer is especially desirable when it is necessary to intrust it to the care of an unskilled workman, as there is no exposed mechanism which the operator can put out of order. There are no pens or other inking devices to look after, and when the chart is removed from the meter, it is complete and ready for use, and requires no "fixing" solution as in the case of sensitized charts. As one sheet of carbon paper is sufficient for twenty records, the cost for carbons is very small. With the exception of the clock movement, which is a Seth Thomas standard eight-day movement, every part of the pyrometer is made by the Hoskins Mfg. Co.

UNIVERSAL TEST INDICATOR

The universal test indicator illustrated below is made by the Alvan Mfg. Co., Newark, N. J. This indicator has hardened cone-pivot bearings which are kept in constant uniform adjustment by spring thrusts that prevent lost motion and consequently errors in reading. These cone bearings also



Universal Test Indicator

make the indicator very sensitive, and it is claimed that no adjustment is ever required.

The indicator proper is attached to the toolpost holder by a universal joint, which is frictionally held in any desired position. By means of this joint the indicator can be set at any angle with relation to the shank. Either side of the contact point can be used, and the spring tension is reversed by half a turn of a button on the end of the barrel. This indicator multiplies error in the ratio of 50 to 1, and has a capacity up to 0.020 inch.

NATIONAL DROP-ARM SPOT WELDER

The National Electric Welder Co., Warren, Ohio, has recently placed on the market a new electric spot-welding machine which has been designed to combine the advantages of the regular horizontal machines with those of the special swing and drop-arm types. In designing this welder, the idea was to so construct it that such work as welding the side seams of a box or tube, a well as the bottom of a box or can, could be accomplished.

The lower arm was made adjustable to adapt the welder to a wide range of work. The front face of the column is machined and carries gibs, one of which is held in place by studs and nuts. By loosening the nuts, the supporting bracket with the low tension leads and welding point can be adjusted to any convenient height with relation to the upper point. The movement is effected by the wrench shown just below the horizontal arm, which operates a pinion mounted inside the bracket. This pinion meshes with a rack on the inside of the bed-plate, and has ratchet teeth on the side which are engaged by a spring-pin on the adjusting handle.

National Drop-arm Spot Welder

The current is conducted to the lower bar and welding point by the heavy copper conductor shown. This conductor is machined to fit into the end of the movable bar, and a solid and efficient contact is made at this point. The upper overhanging arm is of cast iron and is designed to resist springing or deflection, when subjected to the pressure required for making satisfactory welds.

This welder is known as the drop-arm type, and it is built in three sizes, having distances between the center of the welding points and the face of the machine of 12, 24 and 36 inches, respectively. The movable arm on all of these sizes can be dropped 25 inches from the highest point at which it can be used.

These machines have a combination hand and foot lever control. If the work being welded is of such a nature that the operator can use both hands to advantage in holding it, the welding points and switch can be operated by the foot lever, and, if desired, the hand lever can be removed. The machine can be also hand operated, in which case the foot treadle can easily be removed.

The machines are equipped with an automatic switch which operates only after the welding points are brought firmly into contact with the work. The act of releasing the pressure, whether using the foot- or hand-lever control, causes the switch to open, which prevents injury to the work or welding points by separating them after the welding current is broken. The copper contacts are cooled by a stream of water which is conducted to within ¼ inch of the faces bearing on the heated metal. In this way the parts are kept cool and the burning or "mushrooming" of the copper points is avoided.

TOLEDO ELECTRIC WELDERS

The Toledo Electric Welder Co., Langland & Knowlton Sts., Cincinnati, Ohio, has brought out a new welding machine designed especially for welding flat tires varying from ¾ by ¼ inch up to 2 inches by ¼ inch, or 1¾ by ⅜ inch. This is

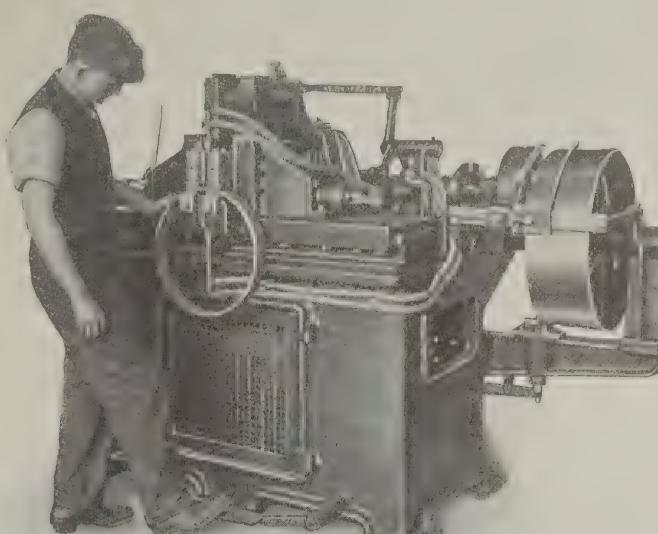


Fig. 1. Toledo Power-driven Machine for Welding Flat Tires

a power-driven machine and it will electrically weld a 1¼- by ¼-inch tire in 13 seconds.

In the operation of the machine the tire is placed in the jaws of the welder, as shown in the illustration; the workman then presses a foot lever, the clamping jaws close on the stock and the ends are brought together. The current is automatically turned on, and in a few seconds the iron is raised to the welding temperature. When the heat is just right a second pressure on the foot lever automatically turns off the current and forces the ends of the stock together. At the same time two steel dies located between the clamping

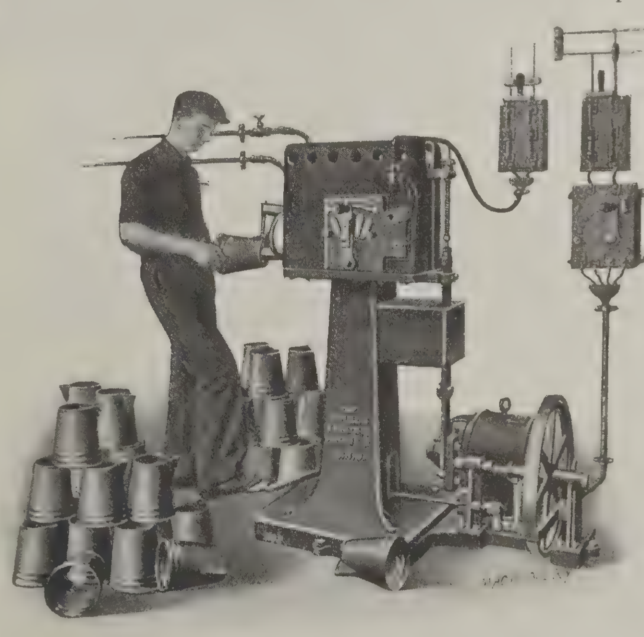

Fig. 2. Power-driven Spot Welder

jaws come together and reduce the fin or projection that is raised, thus leaving the welded portion practically the same thickness as the rest of the stock so that grinding or hammering is not necessary. At the end of this second operation the

clamping dies automatically open, after which the tire is removed and the next one is inserted. From 1800 to 2000 tires can be welded per day of 10 hours.

Alternating current is required to operate the welder, and it can be arranged for any standard voltage from 110 to 550 volts. A special transformer in the base of the welder reduces the voltage to from 3 to 5 volts, which is all that is used in the machine. This low voltage makes the machine absolutely safe, as the operator cannot get the slightest shock under any condition. A regulator is furnished to control the current, thus allowing the operator to vary the heat according to the size of stock to be welded. The dies are water cooled, and a very small amount of water is required. Adjustments are provided to vary the pressure of the welding heads, according to the size of stock to be welded.

This company has also added a new power-driven spot welder to its line. This machine is illustrated in Fig. 2, which shows an operator welding spouts on coffee pots. A small variable-speed motor furnishes the power for driving the machine, and welds are made at the rate of 80 to 150 per minute. The machine works on the same principle as the ordinary power-driven punch press. The operator presses down on a foot treadle which engages a clutch and starts the machine. When the foot pressure is released the machine stops, and when it stops the dies are open ready for the next weld. One weld or any number can be made. The welding dies move up and down like a sewing machine, as long as the treadle is held down.

When the dies are brought down on the stock the current is turned on to make the weld, and at the instant the melted metal is forced together the current is turned off. The current is controlled automatically and there is no possibility of drawing an arc and burning the stock when the die points are moved apart. The machine is easy to operate as a punch press, and there is no danger, either from the mechanical operation or the welding current. Like all welding machines, it is necessary to have a single-phase, alternating current. Where a two- or three-phase current is used, one phase of the multiphase system can be connected to the welder.

FOOTE-BURT MUD-RING AND FLUE-SHEET DRILL

The large two-head drilling machine illustrated herewith was designed primarily for drilling the mud rings and flue sheets of locomotive boilers but it is also suitable for a general line of heavy work. It is built by the Foote-Burt Co., Cleveland, Ohio. By referring to the front view, Fig. 1, it will be noted that each of the two heads is an independent and self-contained unit, thus permitting the feeds and speeds for each spindle to be regulated according to the size of the hole. The heads have an in-and-out adjustment of 8 inches on the knee, which, in combination with the 24-inch lateral adjustment of the table, makes it possible to cover a large lay-out at one setting of the work.

The saddles carrying the heads and motors are very heavy and have a four point bearing on the massive box-section cross-rail. The saddles are traversed along the rail by ratchet wrenches, and, owing to a suitable gear reduction, adjustment is easily made. The end view of the machine (Fig. 2) gives an idea of its massive construction and also shows the position of the driving motors. By mounting the motors as shown, a simple form of drive is secured. The primary drive from the motor is through a rawhide pinion and a coarse pitch spur gear to a horizontal shaft which transmits the motion through bevel and spur gearing to the spindle. The bevel gears are made of forged steel, have planed teeth and are carefully heat-treated and hardened. These gears run in extra-long bronze bushings, thus insuring alignment.

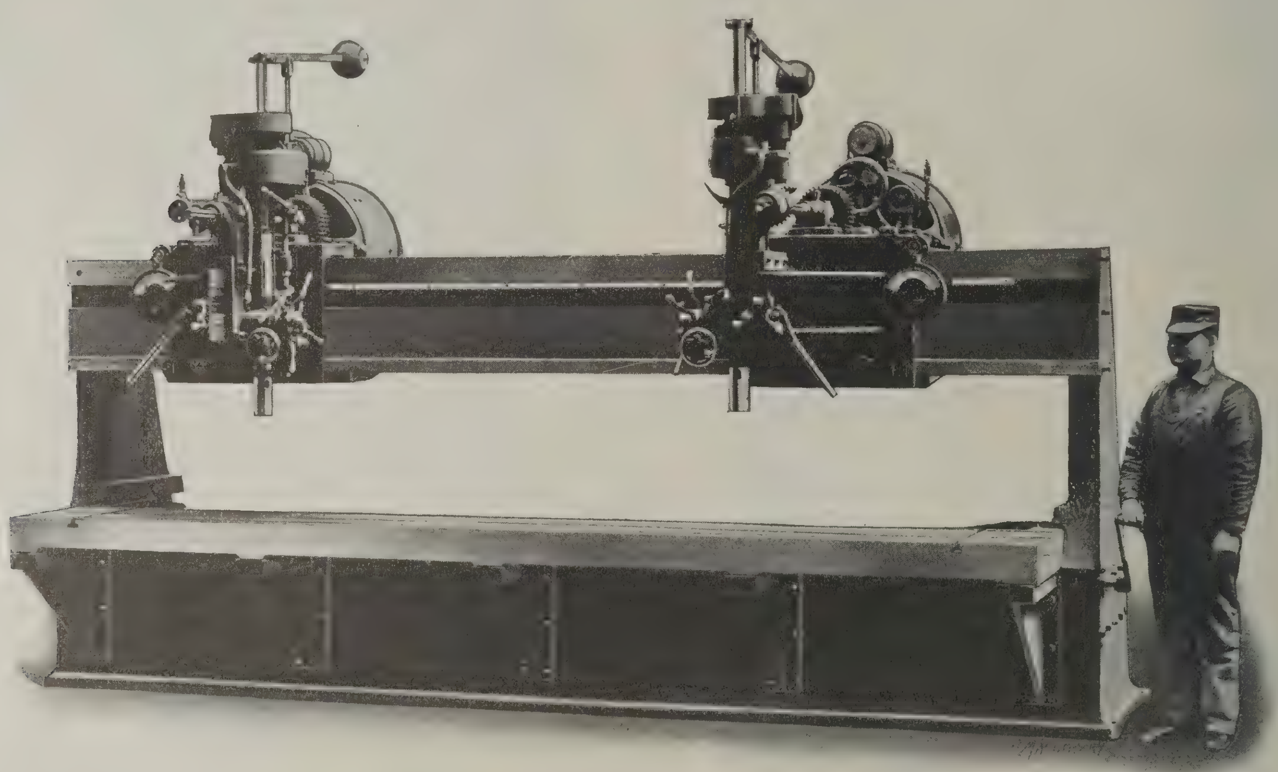

Fig. 1. Foote-Burt Mud-ring and Flue-sheet Drill with Reliance Speed Dial and Automatic Speed and Starting Control

Each spindle has an individual clutch, so that it can be started and stopped at will, without stopping the motor. With this arrangement, the motor can be adjusted for a single speed and need not be disturbed in case it is necessary to stop the spindle. The feed changes are obtained through a quick change gear device operated by a conveniently located lever. The power feed has an automatic stop, in addition to the usual hand trip and clutch, and there is a quick-return movement operated by the spider handwheel shown. The spindle and feed worms have ball thrust bearings of the company's own design. Each head is equipped with an individual oil pump and tank.

When drilling mud rings, the brackets supporting the table are removed and special mud-ring chucks are placed on the table, which is run back between the housings. The brackets are doweled in position, and can be removed and replaced readily.

The possibility of eliminating gear changes and using wide-range motors in conjunction with a direct drive is well illustrated by this equipment. Adjustable-speed, 7½-horsepower

motors of the armature-shifting type are used. These are made by the Reliance Electric & Engineering Co., and have a speed range of from 200 to 1600 R. P. M. The shifting of the armature for obtaining the speed changes is effected by a small motor which is mounted on top of the main driving motor, as shown in Fig. 2, connection being made with the shifting mechanism through a chain and sprockets. To adjust the speed, the operator simply presses the "fast" or "slow" button of a small speed control "station" conveniently located at the front of each head.

This machine is equipped with a Reliance speed dial similar in principle to the one illustrated and described in the department of New Machinery and Tools, for March, 1912. This particular dial has two scales, the upper one of which is graduated to show the cutting speeds in feet per minute, and the lower one, the various sizes of drills. The dial is first set for the cutting speed desired, by turning a small knurl in front of the case; the speed of the motor is then adjusted until the pointer is opposite the size drill to be used.

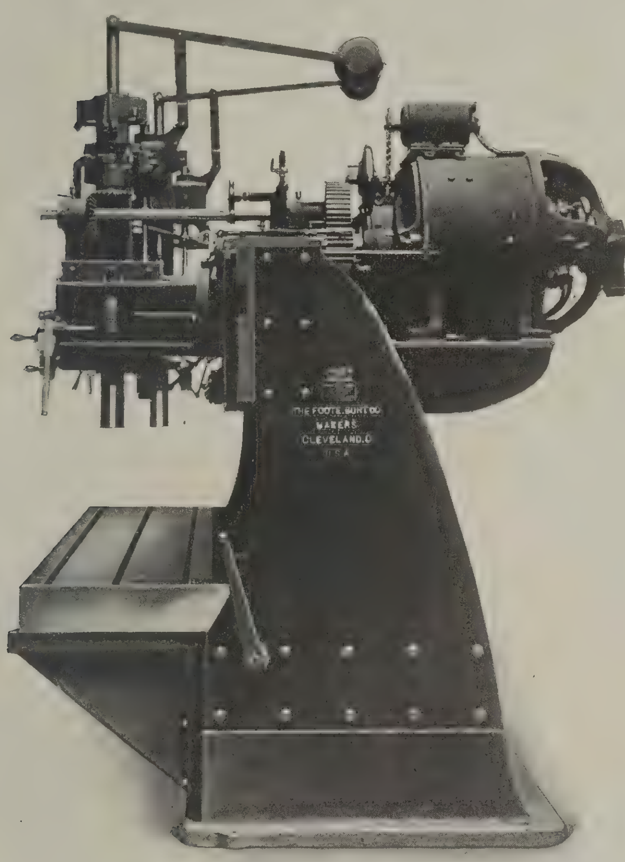

Fig. 2. End View of the Foote-Burt Machine

The starting and stopping of the motor is controlled through automatic starters operated by push buttons. These starters are located on each head close to the speed control station. This combination of automatic starting and speed control enables the operator to give his entire attention to the work in hand.

This machine has a width between the housings of 14 feet 4 inches, and the maximum distance from the end of the spindle to the table is $21\frac{1}{2}$ inches. There is a 12-inch power feed and three feed changes varying from 0.006 to 0.020 inch. The maximum and minimum center distances between the spindles are, respectively, 10 feet and 18 inches. The spindle speeds range from 37 to 347 R. P. M. The table has a working surface of 14 feet 4 inches by 24 inches, and the weight of the machine is 28,000 pounds.

WORTH WEDGE-WASHERS

There are many different ways of locking a nut on a bolt, but comparatively few of the innumerable devices designed for this purpose have come into general use. Either the expense of manufacturing the device has been prohibitive, or its application to a bolt or nut has required too much time. The Steel Specialties Co., Boston, Mass., has placed on the market a very simple device which, it is claimed, effectively prevents a nut from jarring off a bolt. This nut fastener is in the form of a washer which, as shown by the illustration, has a scalloped inner edge with projections or prongs which point outward before the washer is applied to a bolt. After the washer is placed over a bolt, it is straightened or flattened by driving it down with a punch or larger size nut, which causes the prongs to wedge tightly between the threads of the bolt and the body of the nut. A washer has been applied in this way to the bolt shown in the illustration. After a washer is in place, the nut can be screwed off with a wrench, but it will not jar off. The "wedge-washer" can be removed easily by severing one side with a chisel, and it is said to leave the thread uninjured.

Wedge-washers to prevent Nuts from Jarring Off

NEW BRITAIN PORTABLE STEEL TOOL-RACK

The portable tool-rack or work-stand shown herewith is made of steel instead of cast iron, which gives a light but strong construction. The corners of the drawn-steel trays are rounded to facilitate cleaning, and the trays are stiffened by return flanges on the edges, which also contain the corner braces. The legs are screwed into the braces attached to the upper tray and pass through the lower ones. The lower pans can be fastened to the legs at any desired height. In all trays, the holes for the brace rivets or legs are at the top edge of the pan, so that oil cannot leak through them.

These tool-racks are made in two sizes. The size illustrated is 26 by 32 inches, and there is a smaller size measuring 20 by 26 inches. The casters have ball-bearing swivels and the balls are in a retainer cage and can be handled as a unit. These racks are manufactured by the New Britain Machine Co., New Britain, Conn.

Tool-rack or Work Stand made of Steel

NEW MACHINERY AND TOOLS NOTES

Boring Tool. R. M. Clough, Tolland, Conn. Adjustable boring tool for sizing holes either to standard diameters or slightly under, when a finishing reamer is to be used. This tool has blades which are clamped in position with a square-ended wrench.

Tool Grinder. J. G. Blount Co., Everett, Mass. Wet tool grinder similar in construction to machines previously built by this company, but considerably heavier. The bearings are self-oiling, and the wheel is 30 by 3 inches. The machine is equipped with a vertical, centrifugal pump.

Toolpost Grinder. American Electric Tool Co., West Newton, Mass. Portable electric grinder carrying a 6 by ⅜-inch wheel, which operates at a speed of 3500 R. P. M. This grinder can be applied to a lathe toolpost and is applicable to the grinding of lathe centers, milling cutters, etc.

Tool Grinders. Northampton Emery Wheel Co., Leeds, Mass. Wet tool grinders having wheels 16, 20 and 24 inches in diameter, respectively. Water is thrown up against the wheel from a tank in the base, by an endless chain, and the quantity can be varied by a conveniently located lever.

Die Milling Machine. Harrington Machine Co., Erie, Pa. The spindle of this machine is at right-angles to the work-table, and clearance in the dies is obtained by using angular mills. Both the table and spindle can be tilted to an angle either to the right or left to secure better light or to suit the convenience of the operator.

Riveting Machine. C. W. Meadowcroft, Sr., 4702 Large St., (Frankford), Philadelphia, Pa. Rotary riveting machine built in the following styles: As a bench machine with foot control, as a column foot-lever type, and as a dial feed machine, the latter taking the place of the foot-lever designed for certain classes of work.

Electric Furnace. Multiple Unit Electric Co., 136 Liberty St., New York. Electric muffle-furnace with special controller built in the furnace case. Temperatures varying from 200 to 1800 degrees F. can be maintained indefinitely, and the furnace will operate on a 100 or 220 direct or alternating-current circuit, but cannot be used with both circuits, as the controller is built with reference to the voltage.

Band Finishing Machine. Gardner Machine Co., Beloit, Wis. Motor-driven band finishing machine, the wheels of which are mounted directly on the armature shaft. Adjustable, cast-iron dust-hoods nearly enclose the wheels, and there is an opening at the bottom for exhaust connection. The band wheel is so arranged that the band is kept taut under a constant spring tension. This machine is also made for a belt drive.

Tube Cleaner. Joseph T. Ryerson & Son, Chicago, Ill. Tube-cleaning attachment designed to be used in connection with this company's tube-cutting machine. The principal parts are a friction wheel, and adjustable twin-roller cleaning burrs which are built of hardened serrated steel disks. These cleaning burrs are assembled in a unit, which is readily interchanged with the roller tube support employed when the machine is used for cutting tubes.

Cylinder Boring Machine. Newton Machine Tool Works, Inc., Philadelphia, Pa. Locomotive cylinder and valve chamber boring and facing machine, so designed that the valve chamber can be bored without resetting the work. The table has a vertical adjustment and the spindle, which is 7 inches in diameter, has a rapid power traverse in either direction, in addition to the hand adjustment. The minimum distance between the center of the spindle and the top of the table is 16 inches and the maximum, 40 inches.

Gear-cutting Machine. E. J. Flather Mfg. Co., Nashua, N. H. Forty-inch automatic gear-cutting machine arranged with a bevel gear attachment and equipped with a motor drive. The power is transmitted through an endless leather belt, the tension of which is varied by adjusting the base of the motor. The indexing mechanism is enclosed and mounted in a detachable bracket. The machine is built on the unit system, and the indexing, feed, and speed mechanisms, as well as other parts, are finished and tested before being assembled.

Gang Drill. W. F. & John Barnes Co., 231 Ruby St., Rockford, Ill. 20-inch, sliding-head gang drill made with from two to six spindles. This machine can be equipped with either a plain lever feed, a combined lever and worm feed, or a self-feed and automatic stop. The automatic stop mechanism is so designed that it can be set to disengage the worm from the worm-gearing, thus permitting the drill spindle to be returned quickly, or it can be arranged to disengage the miter feed gears, which stops the feed but leaves the worm-gearing in mesh for accurate facing operations.

Drilling Machine. Langelier Mfg. Co., Providence, R. I. Special drilling machine intended for drilling and countersinking two holes on the opposite sides of jewelry beads. The machine is also applicable to many other uses. It is equipped with two vertical spindles which are opposed, one being below and the other above the part to be drilled. These spindles are actuated through rack and pinions and both move toward the work simultaneously. To cases where it is necessary to drill two holes on the same axis and part way through the work, this machine is especially adapted.

Turret Drilling Machine. Turner Machine Co., Danbury, Conn. Four-spindle turret drilling machine intended for work requiring more than one operation at one setting. The spindles are mounted in a vertical turret and are driven through spur gears. By means of an indexing device, any one of the four spindles can be quickly located and locked in the operating position. The maximum distance from the operating spindle to the table is 28 inches. The over-all height is 6 feet 2 inches, and the weight 700 pounds. This machine is also built in other styles and sizes to suit different classes of work.

Loxograph. The Loxograph Instrument Co., Wilmington, Del. The loxograph is a triangular straightedge as well as a true 45-degree angle, and the ruling edges are supported out of contact with the paper by hardened steel knife-edged wheels. As these wheels do not pick up ink, the instrument can be moved over wet ink lines without blurring or smearing them, so that the work of making ink drawings can proceed rapidly, as it is unnecessary to wait for the ink to dry. Flooding is also impossible, even though the ink wets the ruling edges. The loxograph is made in 5¾- and 10-inch sizes, respectively. The instrument has been thoroughly tested, and is said to effect a considerable saving in time.

Tool-Grinding Machine. Brown & Sharpe Mfg. Co., Providence, R. I. Universal and tool-grinding machine which will take work up to 18 inches in length and swing 12 inches. It is especially adapted to the grinding of milling cutters, straight or taper reamers, etc. This machine can also be used for straight or taper cylindrical grinding, and, by means of attachments, internal and surface grinding can also be done. The base and column are cast in one piece, thus giving a rigid support for the wheel spindle. The spindle head has a traverse adjustment of 1½ inch, a vertical adjustment of 4 inches, and a radial movement to any position. The sliding table is operated by a crank at the front of the saddle, and can be swiveled to 45 degrees either side of the central position. Sixteen changes of work speeds are obtained through a multiple, friction-disk speed mechanism. Provision is made for wet grinding.

THE TRAINING OF DRAFTSMEN

In a paper read before the American Society of Engineer Draftsmen, Mr. F. G. Higbee gave a brief summary of the particularly important subjects in which a draftsman ought to be proficient in order to fill his position in life to the best advantage to himself and his employer. Primarily, a draftsman must know how to draw; that is, he must have mastered the technique of drawing and must be able to execute a neat and clear drawing with legible letters and dimensions. This, of course, is merely a foundation upon which to build. A good draftsman must have a good grasp of shop methods and should have a fair conception, both by observation and actual practice, of patternmaking, foundry practice, forging and machining operations. Next, a good draftsman and designer must have a grasp of the theoretical principles of mechanisms. Pulleys, belting, gearing, mechanical movements, fastenings, bearings, and lubrication are the elements which he should take up in turn and study and discuss with those who could give him practical pointers.

It is also necessary in order to be a fair draftsman and designer to have some knowledge of the properties of the various materials used in engineering work and machine construction. He must also have a fair knowledge of the mathematical and mechanical principles involved in calculations of the strength of materials. Mathematics is ever an important subject and one on which many draftsmen fall short. The so-called higher mathematics are, perhaps, seldom required, but trigonometry and logarithms and a fair portion of plane and solid geometry will never fail to prove useful. The good machine designer also needs an understanding of the principles of physics and chemistry; the practical application of electricity and magnetism; the laws of vapors and gases; hydrostatics, and in general, of the fundamental physical laws which are the foundation of all engineering work. Last, but not least, the study of English should never be overlooked or neglected by one who expects to hold anything but a subordinate position. Its proper use is essential to every man who would win the respect and confidence of his associates and superiors, and no training in engineering is complete without a knowledge of how to convey ideas correctly in written form.

This outline gives the necessary foundation for any draftsman who hopes to be able to advance, and it provides a foundation upon which any man may build, no matter to what aspirations his ambition may have inspired him.

DRILLING MACHINES FOR PANAMA CANAL GATES

Sixteen electrically operated machines of special construction are being used for drilling and reaming rivet holes in

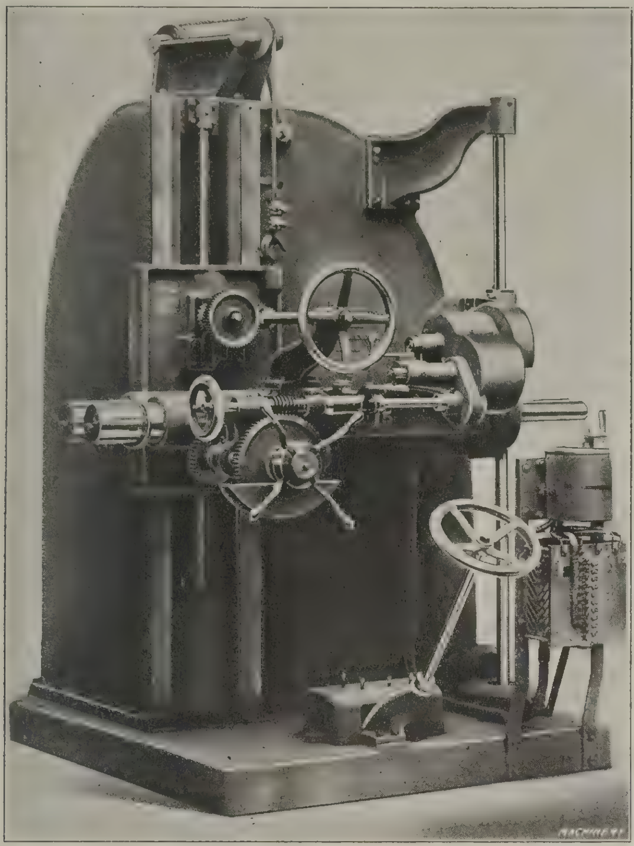

Fig. 1. Foote-Burt Special Drilling Machine for Canal Gates

the enormous lock gates of the Panama Canal. Each of these machines weighs about six tons. They are mounted on broad adjustable scaffolds which are suspended on chains attached to

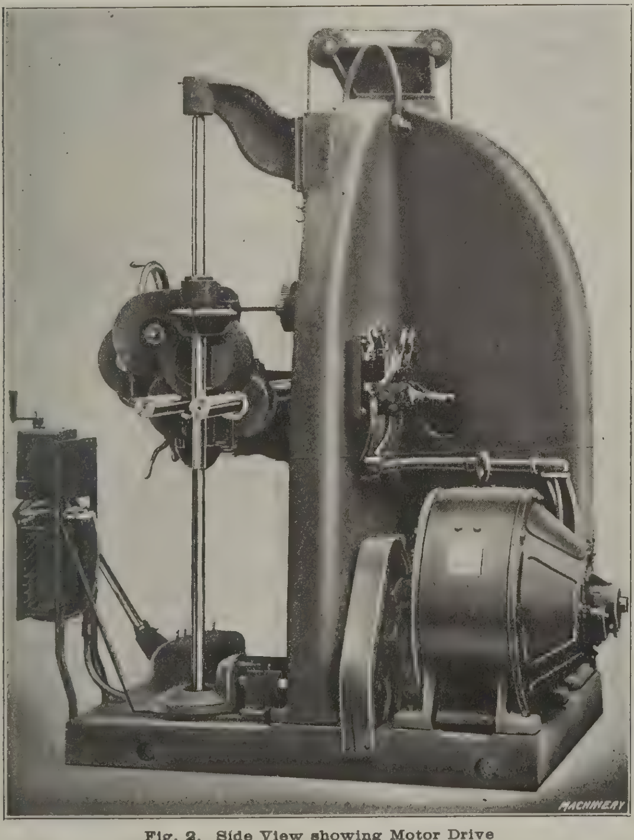

Fig. 2. Side View showing Motor Drive

brackets on top of the gate, as shown in Fig. 3. On each scaffold there is a standard gage track along which the machine is moved for drilling the horizontal rows of rivet holes. This movement is effected by the inclined handwheel seen in Fig. 1, which is a front view of one of the machines. This handwheel operates through a train of gears, and the adjustment can readily by made as roller bearings are used.

All of the controlling mechanism is centrally located as the illustration shows. The horizontal shaft and handwheel above the spindles, actuates, through suitable reduction gearing, a screw which raises and lowers the drilling head. This head is counterbalanced so that vertical adjustment is easily made. The spindles have a quick-return movement effected by any one of the four levers of the spider-wheel shown.

Each machine has four changes of power feed which are obtained through a quick change gear mechanism. The length of the power feed is 16 inches and either of the spindles can be fed independently. The clutch lever for engaging either spindle is located just above the No. 15 seen on the head of the machine, and the feed changing lever is just above this clutch lever. There are nine speeds varying from a very slow speed for heavy drilling, to very high speeds for lighter work. The

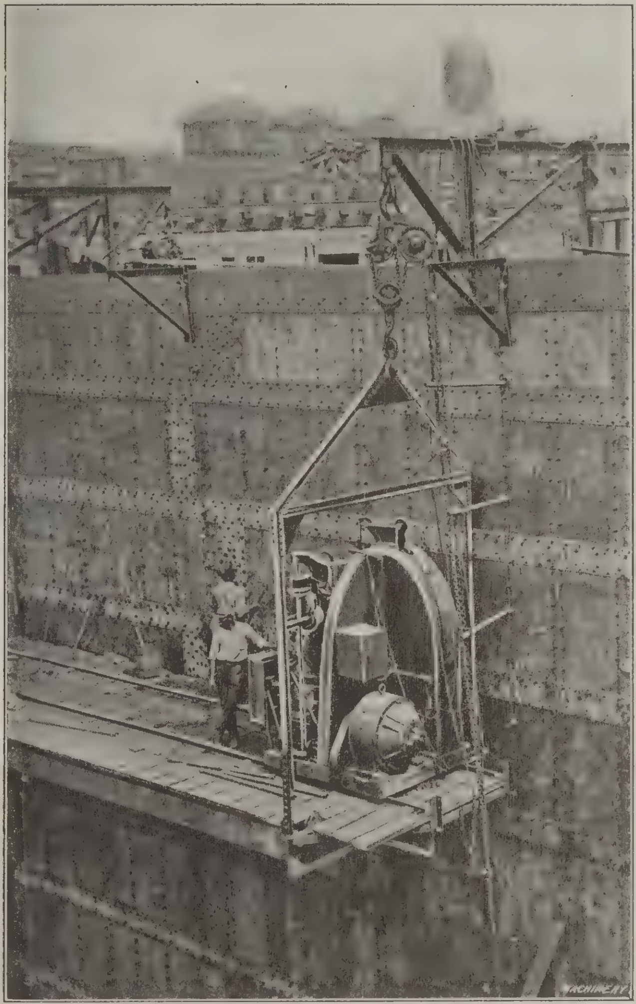

Fig. 3. Drilling Machine on Scaffold for Drilling Rivet Holes in Panama Canal Lock Gates

spindles are arranged to suit the uniform spacing of the rivet holes in the lock gates. During a test made at Gatun, one of the machines drilled 1 1-16 holes through 1-inch plates in four seconds, or at the rate of 15 inches per minute.

These machines are driven by Westinghouse direct-current, adjustable-speed, shunt-wound motors rated at 10 horsepower. The motor is mounted directly on the base, as shown in Fig. 2, and connection is made with the spindles through the gearing shafts, as shown.

These machines were placed in operation in February of this year, on the main gates at Gatun, and they are to be used on all the gates in the three locks. They were designed and built by the Foote-Burt Co., Cleveland, Ohio, especially for use on the Panama Canal.

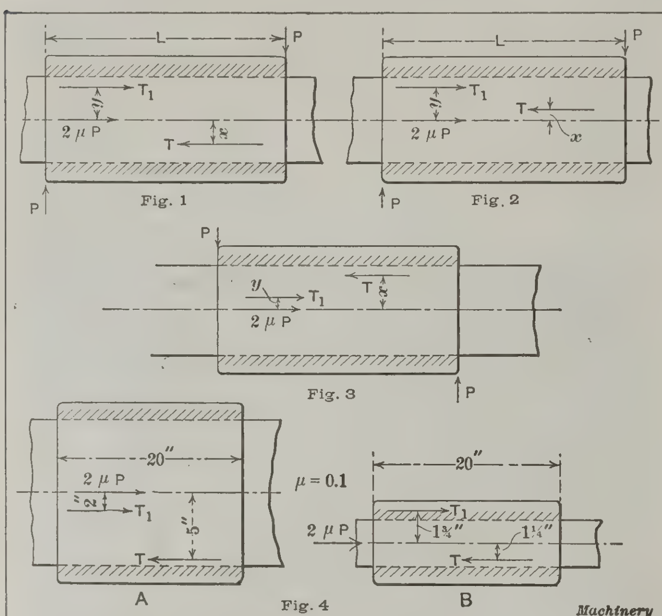
The third and last installment of "Watch Movement Manufacture" will appear in a future number.

THE ADVANTAGE OF THE NARROW GUIDE

By JOSEPH JEWSBURY*

The recent articles on the "narrow guide" which have appeared in MACHINERY have called attention to facts which have not been recognized hitherto by many designers of machinery. The writer, in common with others, had instinctively accepted as an axiom that the narrow guide did reduce "cross-wind," and had never attempted a mathematical analysis of the conditions. In the catalogues of some leading makers of machine tools, it is stated that one of the advantages of the narrow guide is that it reduces "cross-wind."

In the present article the writer intends to deal with the question of the relative locations of the guide center, feeding force, and the main resistance. This will, in a way, supplement the analysis given by Mr. H. T. Millar in the May number of MACHINERY, engineering edition. Five arrangements of positions of guide center line, feeding force, and resistance of cut are possible. Three of these are indicated in Figs. 1, 2 and 3.



Analysis of the Action of Forces involved when Moving a Slide against the Resistance of a Cut

In Fig. 1, the guide center line is located between the feeding force T and the resistance T_1. Fig. 2 shows T and T_1 on the same side of the guide center, T_1 having the greater eccentricity, and in Fig. 3, T acts at a greater distance from the guide center than T_1 and on the same side of it. The two remaining conditions are when the feeding force is in the same line as the cutting resistance, either eccentric to the guide center or on the same line.

Using the notation shown in the accompanying engraving, we have from Fig. 1:

$$P L = T x + T_1 y \qquad (1)$$

$$2 \mu P = T - T_1$$

$$\text{Hence, } P = \frac{T - T_1}{2 \mu} \qquad (2)$$

From (1) and (2):

$$\frac{L (T - T_1)}{2 \mu} = T x + T_1 y$$

$$T = \frac{T_1 (L + 2 \mu y)}{L - 2 \mu x} \qquad (3)$$

In Fig. 2, $P L = T_1 y - T x$, and by proceeding as before, we find:

$$T = \frac{T_1 (L + 2 \mu y)}{L + 2 \mu x} \qquad (4)$$

Similarly for Fig. 3, $P L = T x - T_1 y$, and

$$T = \frac{T_1 (L - 2 \mu y)}{L - 2 \mu x} \qquad (5)$$

In the other two cases T is equal to T_1, neglecting other resistances.

Comparing the results (3) and (4), and (3) and (5), it is obvious that, with the same values for L, T, x and y, the feeding force is greatest with the arrangement shown in Fig. 1. The dimensions of x and y determine whether the arrangement in Fig. 2 or Fig. 3 is more efficient. As an example, assume that $T_1 = 2000$ pounds, $L = 20$ inches, $x = 4$ inches, $y = 6$ inches, and $\mu = 0.1$.

In Fig. 1, Equation (3),

$$T = \frac{2000 (20 + 2 \times 0.1 \times 6)}{20 - 2 \times 0.1 \times 4} = 2208 \text{ pounds.}$$

In Fig. 2, Equation (4),

$$T = \frac{2000 (20 + 2 \times 0.1 \times 6)}{20 + 2 \times 0.1 \times 4} = 2038 \text{ pounds.}$$

Hence, the feeding force is 170 pounds greater in the former case.

From (3) and (4) we find that the feeding force in Fig. 1 is to that in Fig. 2 as $L + 2 \mu x$ is to $L - 2 \mu x$. From (3) and (5) we find that the feeding force of Fig. 1 is to that of Fig. 3 as $L + 2 \mu y$ is to $L - 2 \mu y$. This shows that it is best, whenever possible, to have the feeding force act on the same side of the guide center as the cutting resistance. As pointed out in the article on this subject in the May number, the advantages of the narrow guide are dependent mainly on its correct location. That this is true, and that this is in fact the deciding factor, is proved by the expressions (3), (4) and (5), and can be strikingly illustrated by an example. Comparing the relative values of the feeding forces in cases A and B, Fig. 4, it will be found that for this particular case no advantage is gained by the adoption of the narrow guide, owing to the unfavorable location of the feeding force and the resistance.

$$\text{Case A, Equation (5), } T = \frac{T_1 (20 - 2 \times 0.1 \times 2)}{20 - 2 \times 0.1 \times 5} = 1.03\, T_1$$

$$\text{Case B, Equation (3), } T = \frac{T_1 (20 + 2 \times 0.1 \times 1.75)}{20 - 2 \times 0.1 \times 1.25} = 1.03\, T_1$$

Hence, T is practically the same in both cases.

Two well-known examples from practice may be pointed out where the feeding force acts on the same side of the guide center as the main resistance, *viz.:* the cutter slide of the Brown & Sharpe gear cutter illustrated in the article referred to in the May number of MACHINERY, and the side shaper of English design when arranged with a narrow guide.

* Address: 13 Winsted Rd., Gravelly Hill, Birmingham, England.

NEW ELECTROPLATING PROCESS

Consul Horace Lee Washington, of Liverpool, England, reports that a new electroplating process has recently been developed by two Italian chemists. A description of this process recently appeared in *Chambers Journal.* The process is creating considerable interest, as it comprises a means of depositing metals of any character upon any insoluble surface by electrical energy. It is claimed that china, wood, glass, celluloid, paper and other substances which have hitherto been regarded as beyond the electroplater's art can be coated as easily as metals generally electroplated. The plating enters the fabric of the material so treated and becomes practically an integral part of it. If an attempt, for instance, is made to chip the plating from a glass vase the glass will come away with the metal coating. When plating china, the article must be in its unglazed condition, and glass which is to be treated must first be roughened by sandblasting to remove the polish, so as to enable the metal to secure a firm grip. The process, which is known as the Marino process, is also of considerable hygienic value in the household, where many articles may now be used plated with suitable metals. The possibility of being able to deposit a coating upon aluminum, for example, thus saving it from oxidation, will popularize the use of this metal in the home and in many industries where it is now excluded on account of the fact that it rapidly corrodes in the presence of acids.

M. C. B. AND A. R. M. M. ASSOCIATIONS CONVENTIONS

The forty-sixth annual convention of the Master Car Builders Association and the forty-fifth annual convention of the American Railway Master Mechanics Association were held at Atlantic City, N. J., June 12 to 19, inclusive. The Master Car Builders convention was held June 12, 13 and 14, and the Railway Master Mechanics convention June 17, 18 and 19, on Young's new pier.

The technical program of the Master Car Builders Association included the following papers and discussions:

June 12—"Train Brake and Signal Equipment"; "Brake Shoe Equipment"; "Car Wheels."

June 13—Discussion of reports on "Safety Appliances"; "Rules of Interchange"; "Prices for Labor and Materials"; "Rules for Loading Materials"; "Damage to Freight Equipment by Unloading Machines"; "Overhead Inspection"; "Coupler and Draft Equipment"; "Car Trucks"; "Springs for Car Trucks"; "Train Lighting and Equipment."

June 14—Discussion of reports on "Train Pipe and Connections for Steam Heat"; "Tank Cars"; "Specifications for Tests of Steel Truck Sides and Bolsters"; "Capacity Marking of Cars"; "Lettering Cars."

The following officers were elected for the Master Car Builders Association:

President, C. E. Fuller, Union Pacific Ry.
First vice-president, M. K. Barnum, Illinois Central R. R.
Second vice-president, D. F. Crawford, Pennsylvania Lines.
Third vice-president, D. R. MacBain, L. S. & M. S. Ry.
Treasurer, John S. Lentz, Lehigh Valley R. R.
Executive Committee—R. E. Smith, Atlantic Coast Line; C. E. Chambers, Central R. R. of New Jersey; and Henry LaRue, Chicago, Rock Island & Pacific R. R.

The program of the American Railway Master Mechanics convention was as follows:

June 17—Discussion of reports on "Mechanical Stokers"; "Revision of Standards"; "Specifications for Cast Steel"; "Locomotive Frames."

June 18—Discussion of reports on "Main and Side Rods"; "Safety Valves"; "Safety Appliances"; "Design, Construction and Maintenance of Locomotive Boilers"; "Contour of Tires"; individual paper on "Increased Power Obtained with Superheat as Compared with the Maximum Power Obtained with Saturated Steam," by Prof. C. H. Benjamin and Prof. L. E. Endsley; "Steel Tires."

"June 19—Discussion of reports on "Flange Lubrication"; "Minimum Requirements for Headlights"; "Standardization of Tinware"; "Maintenance of Superheated Locomotives"; "Engine Tender Wheels."

The following officers were elected for the American Railway Master Mechanics Association:

President, D. F. Crawford, Pennsylvania Lines.
First vice-president, T. Rumney, C. R. I. & P. R. R.
Second vice-president, D. R. MacBain, L. S. & M. S. Ry.
Third vice-president, F. F. Gaines, Central of Georgia Ry.
Executive Committee—G. W. Wildin, N. Y., N. H. & H. R. R.; C. F. Giles, L. & N. Ry.; and William Schlafge, Erie R. R.

The Railway Supply Manufacturers Association holds an annual exposition of railway car and locomotive parts, supplies, apparatus, etc., on the pier simultaneously with the conventions. The exhibit this year was larger than ever before, the space having been increased by extending the pier, thus making 7400 square feet additional space available, and increasing the total area to 83,500 square feet. Among the manufacturers exhibiting were the following:

Ajax Mfg. Co., Cleveland, Ohio. Scrap reclaiming rolls and forgings.

American Infusion Steel Process Co., New York. Compound for casehardening and converting low-grade steel into high-grade steel.

American Tool Works Co., Cincinnati, Ohio. Motor-driven machine tools comprising 24-inch geared head lathe, 16-inch relieving lathe, 2-foot geared radial drill, 6-foot plain radial drill, 16-inch shaper and 24-inch shaper.

American Vanadium Co., Pittsburg, Pa. Vanadium steel, iron, brass and bronze locomotive parts, vanadium steel forgings, etc.

Baker Bros., Toledo, Ohio. Automatic drilling machine.

Baush Machine Tool Co., Bethlehem, Pa. Hydro-pneumatic radial drill.

Bullard Machine Tool Co., Bridgeport, Conn. Forty-two-inch vertical turret lathe.

Carborundum Co., Niagara Falls, N. Y. Carborundum and Aloxite grinding wheels.

Chisholm & Moore Mfg. Co., Cleveland, Ohio. Chain hoists, and I-beam trolleys.

Davis Boring Tool Co., St. Louis, Mo. Line of Davis expansion boring tools.

Davis-Bournonville Co., New York. Oxy-acetylene welding and cutting apparatus, including the "oxygraph," a device working on the pantograph principle.

Duff Mfg. Co., Pittsburg, Pa. Track jacks and screw jacks.

Gilbert & Barker Mfg. Co., Springfield, Mass. Apparatus for storing and handling oils.

Goldschmidt Thermit Co., New York. Thermit products and exhibits showing the application of the thermit process for welding.

Gould & Eberhardt, Newark, N. J. Twenty-four-inch shaper and model showing construction of sixteen-inch shaper.

Edwin Harrington Son & Co., Inc., Philadelphia, Pa. I-beam trolleys and spur geared and screw hoists.

Higley Machine Co., New York. Cold metal saw.

International Oxygen Co., New York. I. O. C. generators for producing oxygen and hydrogen, etc.

Landis Machine Co., Waynesboro, Pa. Double head bolt cutters.

Lucas Machine Tool Co., Cleveland, Ohio. Precision horizontal, boring, drilling and milling machine.

Manning, Maxwell & Moore, Inc., New York. Hendey lathes, Gridley automatic machines, Cincinnati gear cutters, Cincinnati crank planers, Reed engine lathes, National Co.'s forging and heading machines, etc.

Newton Machine Tool Works, Philadelphia, Pa. Cold saw cutting-off machine of the internal type.

Niles-Bement-Pond Co., New York. Niles new model car wheel boring machine and Pond reversing motor drive planer.

Norton Co., Worcester, Mass. Grinding wheels and floor grinders.

Norton Grinding Co., Worcester, Mass. Ground car axles and car wheels.

Oxweld Acetylene Co., Chicago, Ill. Oxy-acetylene and oxy-hydric welding apparatus.

C. F. Pease Co., Chicago, Ill. Automatic blueprinting and washing machine.

Wm. Sellers & Co., Inc., Philadelphia, Pa. Locomotive injectors, parts of high power car wheel lathes, etc.

Standard Roller Bearing Co., Philadelphia, Pa. Roller bearings, car journal boxes and other anti-friction bearings.

Tabor Mfg. Co., Philadelphia, Pa. Inserted tooth saws.

Van Dorn & Dutton Co., Cleveland, Ohio.. Portable electric drills and reamers.

Vixen Tool Co., Philadelphia, Pa. Vixen files and machine for testing files.

Warner & Swasey Co., Cleveland, Ohio. Hollow hexagon turret lathe.

Watson-Stillman Co., New York. Hydraulic jacks.

Wilmarth & Morman Co., Grand Rapids, Mich. Surface grinders, lathe center grinders, drill grinders, etc.

Yale & Towne Mfg. Co., New York. Chain blocks, electric hoists, trolleys, locks, etc.

* * *

SPRING MEETING OF THE A. S. M. E.

The Spring meeting of the American Society of Mechanical Engineers was held in Cleveland, Ohio, May 28-31. Past president Ambrose Swasey, chairman of the executive committee, opened the meeting with a speech of welcome. Dr. A. C. Humphreys, president of the society, spoke on the economic relations of the engineer and society. The professional sessions were held in the Chamber of Commerce, as was also the membership reunion and informal reception. The registration of members of all grades was the largest of any Spring meeting in the history of the society, being nearly 600. The technical program included the following papers and lecture:

"A New Analysis of the Cylinder Performance of Reciprocating Engines," J. Paul Clayton.

"Equipment of a Modern Flour Mill on a Gradual Reduction System," John F. Harrison and W. W. Nichols.

"Design and Mechanical Features of the California Gold Dredge," Robert E. Cranston.

"Problems in Natural Gas Engineering," Thomas R. Weymouth.

"Sound Waves—How to Photograph Them and What They Mean," Dr. Dayton C. Miller of the Case School of Applied Science.

"New Processes for Chilling Cast Iron," Thomas D. West.

"Strength of Steel Tubes, Pipes and Cylinders Under Internal Flume Pressure," Reid T. Stewart.

"On the Control of Surges in Water Conduits," W. F. Durand.

"Speed Regulation in Hydro-electric Plants," Wm. F. Uhl.

"The Present State of Development of Large Steam Turbines," A. G. Christie.

"A Discussion of Certain Thermal Properties of Steam," G. A. Goodenough.

"The Reduction in Temperature of Condensing Water Reservoirs Due to Cooling Effect of Air and Evaporation," W. B. Ruggles.

"Results of Tests on the Discharge Capacity of Safety Valves," E. F. Miller and A. B. Carhart.

An informal reception for the members was held at the home of Mr. and Mrs. Ambrose Swasey, Tuesday afternoon, May 28, and a reception and dance at the Colonial Club Thursday evening, May 30.

The plants of Warner & Swasey Co., Brown Hoisting Machinery Co., Winton Motor Co., Peerless Motor Car Co., National-Acme Mfg. Co., White Co., American Steel & Wire Co., Wellman-Seaver-Morgan Co., Akron; Goodrich Rubber Co., and the Diamond Match Co., at Barberton, were open to members.

AEROPLANE EXPOSITION IN BERLIN

An International Aeroplane Exposition was held in Berlin, Germany, during the month of April. The most interesting fact brought out during the exposition was that so large a number of firms exist in Germany that are directly interested in the aeroplane industry. At the exposition there were 176 exhibitors in all, of which twenty-two were firms exhibiting aeroplanes. There are twenty-seven German firms building aeroplanes exclusively, and twelve more constructing aeroplanes in addition to other products. Many of these aeroplane factories are, of course, very small. Several, however, are organized wth a considerable capitalization—for example, one company is capitalized at $375,000, another at $150,000, another at $62,500, while three are capitalized at $25,000 each. There are between 400 and 500 aeroplanes in use at the present time in Germany. Of the forty aeroplanes shown at the exposition, thirty were monoplanes, nine biplanes, and one a triplane. The proportion of the various types, however, is somewhat misleading as regards the relative popularity of the various types, as the biplanes were exhibited by several of the German firms who had been most successful, while many of the monoplanes shown were experiments by unknown firms. For military purposes, and in general when the greatest speed is not essential, the biplane seems to have proved most satisfactory in Germany.

In general, the designs followed closely the various French types, and there was an absence of freak machines such as are generally seen at expositions of this kind. Consul General A. M. Thackara of Berlin, from whose report to the Department of Commerce and Labor the facts above are abstracted, states that, at the present time, America has little to learn from Germany as regards actual designs of aeroplanes, as the ideas in prominence at the Berlin exposition were largely of French and American origin. This condition, he states, will, however, probably not obtain much longer, as the aeroplane problem is now being attacked in Germany from every side both by the aviator in the field and the scientist in the laboratory.

The most powerful aeroplane exhibited was the Boris Loutzkoy monoplane which was fitted with two 100-horsepower "Argus" motors, each driving an independent propeller, revolving around the same axis. With both motors, the aeroplane, it is claimed, can attain a speed of ninety-three miles an hour. The machine can fly, however, with either motor alone. The weight, with pilot, one passenger, and supplies for a six-hours' flight is about 3000 pounds. The width of the machine is 62 feet, the length about 50 feet and the supporting surface, 560 square feet. The "Argus" motor used in this aeroplane is of the four-cylinder type, making 1250 revolutions per minute, and having a weight of 288 pounds or slightly less than 3 pounds per horsepower. Hilz of Dusseldorf exhibited a motor of 120 horsepower, the weight of which was only 2.2 pounds per horsepower.

* * *

PERSONALS

Frank Salomon, president of the Otto Gas Engine Works, Philadelphia, Pa., will sail on the *Cincinnati* July 4 for a six weeks' trip in Germany.

Ehrich Krell, vice-president of the Otto Gas Engine Works, Philadelphia, Pa., will return July 1 from a three months' business trip to Germany and England.

C. E. Coolidge, Western representative of the Niles-Bement-Pond Co., has resigned to take charge of the manufacturing equipment in the various plants of the U. S. Motor Co.

Frederick J. Benjamin, advertising manager of the Pawling & Harnischfeger Co., Milwaukee, Wis., has resigned to become advertising manager of the *Iron Trade Review*, Cleveland, Ohio.

W. H. Shafer, for several years superintendent of the Cincinnati-Bickford Tool Co., Cincinnati, Ohio, has resigned to take the position of general manager of the Rivett Lathe Mfg. Co., Boston, Mass.

Charles A. Moore, president of Manning, Maxwell & Moore, Inc., New York, has returned from Europe, improved in health, after an absence of nearly two years, and has resumed attention to business.

John Johannigman, for the past ten years secretary of the Oesterlein Machine Co., Cincinnati, Ohio, resigned his position April 15. Mr. Johannigman intends to enter the machine tool manufacturing business.

H. Cadwallader, Jr., recently with the Isthmian Canal Commission at Panama, is now efficiency engineer with the Continental Motor Mfg. Co., of Muskegon and Detroit, Mich., installing the Taylor planning system.

Phil A. La Brie, formerly with the Gisholt Machine Co., Madison, Wis., has taken a position as salesman for New England with the Fitchburg Machine Works, Fitchburg, Mass., manufacturers of "Lo-swing" lathes.

J. E. Fries, engineer with the Crocker-Wheeler Co., Ampere, N. J., has been transferred to the San Francisco office as Pacific Coast engineer, where he will be able to render prompter service to the rapidly growing business of the company on the Pacific Coast.

Clarence A. Hills, who was lately made superintendent of the Abbott-Detroit Motor Co., Detroit, Mich., was presented by the employes of the Hupmobile Co., with whom he had been associated for the past two years, with a gold watch and diamond stickpin upon leaving to take his new position.

Dwight N. Lane has been made superintendent of the works of the Bantam Anti-Friction Co., Bantam, Conn. Mr. Lane, who was connected for ten years with the New Departure Mfg. Co., Bristol, Conn., is well equipped with long shop experience in connection with the manufacture of ball bearings for his new position.

Marion A. Morris has been appointed superintendent of the J. H. Sessions & Sons Co.'s plant at Bristol, Conn., succeeding Mr. Frank Garrigus, resigned. Mr. Morris was formerly connected with the Scovill Mfg. Co., and was superintendent for the Blake & Johnson Mfg. Co., from which position he recently resigned.

Joseph V. Woodworth, consulting engineer at the New York office of the Taft-Peirce Mfg. Co., Woonsocket, R. I., has resigned, and taken the position of consulting engineer and New York representative of the Boston Pressed Metal Co., Worcester, Mass., with offices in the Tribune Building, 154 Nassau St., New York.

J. P. Thompson, who has been employed as general superintendent of the Van Norman Machine Tool Co., Springfield, Mass. (formerly Waltham Watch Tool Co.), assumed his duties June 5. Mr. Thompson was until lately general superintendent of the Cameron Steam Pump Co., New York, and formerly was with the Pond Machine Tool Co., Plainfield, N. J.

* * *

OBITUARIES

Gilbert Hart, inventor and patentee of safety emery wheels, in the manufacture of which he made a fortune, died May 31 in Detroit, Mich., aged eighty-four years.

Col. Francis A. Walker, the oldest employe of the E. & T. Fairbanks Co., St. Johnsbury, Vt., died April 26, aged eighty-seven years. Col. Walker entered the employ of the company at the age of twenty to learn the molders' trade, and for sixty-two years was a foreman.

Valdemar F. Lassoe died May 22 at his home, 83 Decatur St., Brooklyn, N. Y., aged seventy-six years. He was born in Copenhagen, Denmark, where he received an engineering education, and came to this country at the age of twenty-four. He was associated with Capt. John Ericsson in designing the *Monitor*, and subsequently worked with him for twenty-eight years. After Mr. Ericsson's death he became consulting engineer for the American Hawaiian Steamship Co., for which he designed twenty-eight steamships. He was also, for eighteen years, consulting engineer for the North German Lloyd Co., and was the originator of the system now employed for using oil as fuel on steamships. He was a frequent contributor of engineering articles to technical journals. Mr. Lassoe is survived by a widow and one daughter.

Wilbur Wright, who, with his brother Orville, was the first to accomplish mechanical flight, died of typhoid fever at Dayton, Ohio, May 30, aged forty-five years. Wilbur and Orville were bicycle repairers in Dayton when they became

interested in aviation. The first experiments were made with gliders, and the first flight with a motor propelled aeroplane was made at Kitty Hawk, N. C., December 7, 1903. This flight of 852 feet was made in 59 seconds. Numerous short flights followed, and on September 26, 1905, a flight of 11⅛ miles was made at Dayton in 38 minutes, 3 seconds, this one being longer than all previous flights put together. The Wright brothers were notable for modesty, reticence and perseverance. They worked under most discouraging circumstances for years before the world recognized that they had actually solved the problem of navigating the air.

* * *

COMING EVENTS

July 9.—Annual convention of the American Railway Tool Foremen's Association in Chicago. H. L. Miller, secretary of the supply association, 835 Monadnock Bldg., Chicago, Ill.

August 20.—Annual convention of the International Railroad Master Blacksmiths' Association at Hotel Sherman, Chicago, Ill. J. E. Carrigan, Rutland Railway, Rutland, Vt., chairman of the executive committee.

September 2-7.—Sixth congress of the International Association for Testing Materials at the Engineering Societies Building, 29 W. 39th St., New York. H. F. J. Porter, secretary, 1 Madison Ave., New York.

September 24-26.—Annual convention of the American Foundrymen's Association and allied bodies, in Buffalo, N. Y.; Hotel Statler, headquarters. Richard Moldenke, Watchung, N. J., secretary.

October 4-26.—International Machinery Exhibition at Olympia, London, England, organized by the Machine Tool and Engineering Association, Ltd.

October 7-11.—Annual convention of the American Electric Railway Association and allied associations in Chicago, Ill. The exhibit will be at Dexter Pavilion, 43d and Halstead Sts. H. C. Donecker, secretary-treasurer, 29 W. 39th St., New York.

SOCIETIES, SCHOOLS AND COLLEGES

Cornell University, Ithaca, N. Y., opened Rand Hall May 23 with appropriate exercises. The building, 50 by 170 feet and three stories high, is a memorial to Jasper R. Rand, Jasper R. Rand, Jr., and Addison C. Rand.

New Haven Manufacturers' Exhibit Association, New Haven, Conn., has been organized by the manufacturers of New Haven for the purpose of making a permanent industrial exposition. About eighty per cent of the manufacturers have taken space and installed exhibits in the Auditorium Bldg., 671-673 Chapel St.

National Metal Trades Association, New England Bldg., Cleveland, Ohio. Proceedings of the fourteenth annual convention of the association at the Hotel Astor, New York City, April 11, 1912. The proceedings include a number of valuable technical papers on industrial education, employers' liability and workmen's compensation laws, safeguarding machinery, etc.

University of South Carolina, Columbia, S. C. Catalogue for the year 1911-12, together with announcements for the year 1912-13. This catalogue contains the usual information relating to the courses of study, the requirements for admission, and the departments of instruction, together with a list of students. It is illustrated with unusually fine halftones showing the various buildings of the university.

American Museum of Safety, 29 W. 39th St., New York. Paper entitled "Boat Installations and other Life-saving Devices for Safety at Sea," prepared by Mr. Axel Welin, of London, England, and read at a meeting under the auspices of the museum at New York, May 9, 1912. The paper is well illustrated with halftones and line engravings showing the arrangement of life boats and davits.

Polytechnic Institute of Brooklyn, Brooklyn, N. Y. Catalogue of the college of engineering 1912-13. This catalogue gives a list of the faculty and instructors, and general information relating to the courses, admission requirements, fees, scholarships, etc. Some interesting information relating to the history of the Polytechnic Institute, its equipment, administration, regulations, and student organizations, is also given, together with a roster of students for 1911-12.

American Museum of Safety, 29 W. 39th St., New York. No. 3 of the "Manuals of Safety," covering foundry practice, by Wm. H. Tolman, director of the museum. This little book, consisting of forty 4½- by 7-inch pages, reviews especially the dangers of the foundry and the departments connected with it, and suggests a number of remedies to avoid accidents and injurious effects on the health of the workers. The book is profusely illustrated, and sells at 25 cents.

University of Wisconsin, Madison, Wis., announces that the twelfth annual six weeks' summer school of its College of Engineering opens June 24. Courses of instruction and laboratory practice are offered in electrical, hydraulic, steam and gas engineering, mechanical drawing, applied mechanics, testing of materials, machine design, shop work and surveying, in addition to which, subjects may be taken in the College of Letters and Science. Further information may be obtained from Dean F. E. Turneaure, University of Wisconsin, Madison, Wis.

NEW BOOKS AND PAMPHLETS

The Evolution of Vertical Lift Bridges. By Henry Grattan Tyrrell, bridge and structural engineer, Evanston, Ill., reprinted from *Applied Science*, 1912.

Bolts, Base Plates and Plating for Steel Stacks. By Arthur M. Green, Jr. 16 pages, 6 by 9 inches. Published by the Rensselaer Polytechnic Institute, Troy, N. Y.

An Analytical Study of the Action of the Vacuum Dashpot. By Karl Nibecker. 22 pages, 6 by 9 inches, and one folding chart. Published by the University of Pennsylvania Mechanical and Electrical Engineering Department, Philadelphia, Pa.

Twenty-third Annual Report on the Statistics of Railways in the United States, for the year ending June 30, 1910. 898 pages, 6 by 9 inches. Published by the Interstate Commerce Commission, Washington, D. C.

Proceedings of the Thirty-first Annual Convention of the American Water Works Association. Held at Rochester, N. Y., June 9-10, 1911. 490 pages, 6 by 9 inches. Published by the secretary of the society, 47 State St., Troy, N. Y.

Starting Currents of Transformers. By Trygve D. Yensen. 43 pages, 6 by 9 inches. 18 illustrations. 6 tables. Published by the University of Illinois, Urbana, Ill.

This is bulletin No. 55 issued by the Engineering Experiment Station of the University of Illinois, and deals with the starting currents of transformers with special reference to transformers with silicon steel cores, in which the current may rise to more than seven times the full load current—a phenomenon which is fully explained in the bulletin.

Constructing Concrete Porches. By A. A. Houghton. 62 pages, 5 by 7¼ inches. 18 illustrations. Published by Norman W. Henley & Son, New York. Price 50 cents.

This book is No. 9 in a series of reference books for concrete workers and contains a treatise illustrating and describing the construction of monolithic concrete and concrete block porches, taking up the molding of columns, balusters, lattice work and railings, as well as plain and reinforced types of porch floors. The book is concise and direct in the treatment of its subject.

Tests of Columns. By Arthur N. Talbot and Arthur R. Lord. 44 pages, 6 by 9 inches. 20 illustrations. Bulletin No. 56 of the University of Illinois, Urbana, Ill.

This bulletin contains an investigation of the value of concrete as reinforcement for structural steel columns. The tests recorded show that structural steel columns having a filling of concrete, if properly made, develop nearly all the strength of both the steel and concrete. The tests also show that up to the point of failure of the column, the fireproofing shell of the concrete adheres tightly to the remainder of the column.

Electrical Injuries. By Charles A. Lauffer. 77 pages, 4 by 6½ inches. Published by John Wiley & Sons, New York. Price 50 cents.

The author of this book is medical director of the relief department of the Westinghouse Electric & Mfg. Co., East Pittsburg, Pa., and is well qualified to treat the subject here dealt with. The book covers the causes, prevention and treatment of injuries with which workmen and others may meet in connection with electric currents. The book is intended to be of use to practical electrical men, and treats the subject in clear and simple language.

Concrete Bridges, Culverts, and Sewers. By A. A. Houghton. 58 pages, 5 by 7¼ inches. 14 illustrations. Published by Norman W. Henley & Son, New York. Price 50 cents.

This book is No. 8 in a series of reference books for concrete workers and contains a treatise illustrating and describing the various types of solid and reinforced arch, slab, and girder concrete bridges, and the molding of concrete culverts, drains and sewers. The book is written in a clear and concise manner and will prove useful also to persons who are not following concrete work as an occupation, but who wish to get a general idea of the methods and principles involved.

American Exporter's Export Trade Directory. Compiled by B. Olney Hough. 267 pages, 6 by 9 inches. Published by the Johnston Export Publishing Co., New York City. Price $3.00.

This book contains lists of foreign buying agencies in the United States, manufacturers' export agents, New York bankers engaged in foreign exchange business, foreign exchange dealers and brokers, marine insurance companies and export trucking companies in New York City, and foreign freight forwarders. Detailed information of steamship services to foreign parts, a list of consuls of foreign countries in the United States, and of American consulates in foreign countries are also given.

Rubber Hand Stamps and the Manipulation of Rubber. By T. O'Conor Sloane. 167 pages, 5 by 7 inches. Published by Norman W. Henley & Son, New York. Price $1.00.

This is a new, revised and enlarged edition in which chapters on the use of rubber in surgery and dentistry and the construction and repairing of rubber tires have been added. The object of the book is, in general, to present in the simplest form the subject of the manipulation of India rubber. Among other subjects the book deals with the making of rubber stamps, rubber type, sheet rubber goods, solution of India rubber, ebonite, vulcanite and gutta-percha, etc.

Brazing and Soldering. By James F. Hobart. 51 pages, 5¼ by 8 inches. 18 illustrations. Published by Norman W. Henley & Son, New York. Price, 25 cents.

This is the fifth revised and enlarged edition of Mr. Hobart's book, treating of the subject of brazing and soldering. It covers, in general, the same field as the previous editions, giving specific information regarding brazing alloys, and solders, and methods used in brazing and soldering. One chapter is devoted to special methods of soldering and covers electrical work, and tin plate, galvanized iron and zinc, lead and aluminum soldering. Compositions of various solders and fluxes are also given.

Coalfields and Collieries of Australia. By F. Danvers Power. 412 pages, 6 by 8½ inches. 231 illustrations. Published by Critchley Parker, Melbourne, Australia. Price 25s.

While coal mining plays a large part in the mining operations of Australia, this is the first work devoted to this important branch of the commercial activities of the commonwealth. The author, who is a member of the American Institute of Mining Engineers, as well as of the corresponding British and Australian societies, is well equipped to handle this subject, and the book will prove of value to those who are interested in the development of the Australian commonwealth and its mining industries.

Knots, Splices and Rope-work. By A. Hyatt Verrill. 102 pages, 4¾ by 6¾ inches. 148 illustrations. Published by Norman W. Henley & Son, New York. Price, 60 cents.

This book is a practical treatise giving complete and simple directions for making the most useful and ornamental knots commonly employed. The book is well illustrated to show the exact methods used in making knots and splices. The contents of the book will be best understood from a review of the chapter headings: Cordage; Simple Knots and Bends; Ties and Hitches; Nooses, Loops, and Mooring Knots; Shortenings, Grommets, and Selvagees; Lashings, Seizings, Splices, etc.; Fancy Knots and Rope Work.

Superheated Steam in Locomotive Service. By W. F. M. Goss. 66 pages, 6 by 9 inches. 51 illustrations. Published by the University of Illinois, Urbana, Ill.

This is bulletin No. 57 of the Engineering Experiment Station of the University of Illinois. It gives the results of a study of recent German practice in the use of superheated steam as well as of an elaborate series of tests made upon an American locomotive. The conclusions are to the effect that the use of superheated steam introduces no serious difficulties; that it brings about a material saving in the use of coal and water; and that the power capacity of American locomotives can be readily increased by this means.

Diary of a Roundhouse Foreman. By T. S. Reilly. 158 pages, 5 by 7 inches. Published by Norman W. Henley & Son, New York. Price $1.00.

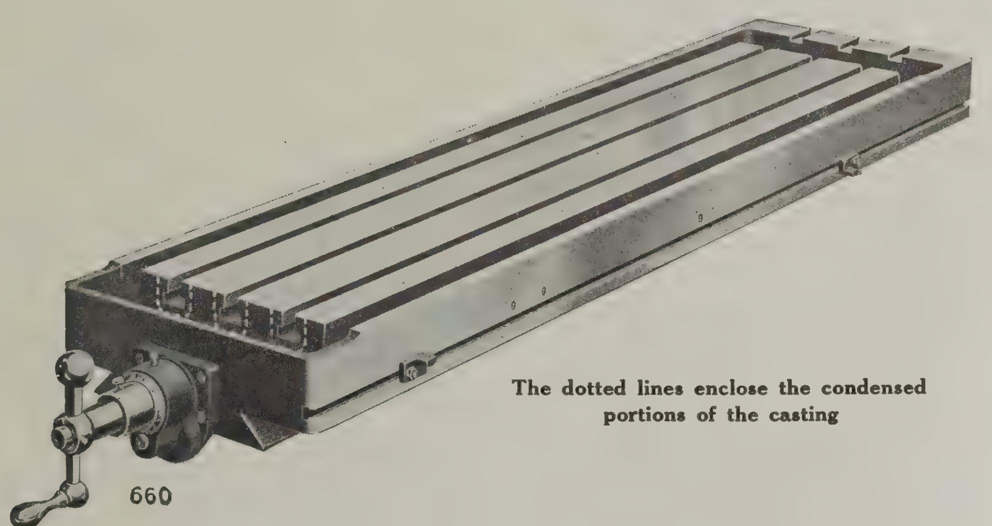
This book contains a number of articles published some years ago by the author in the *Railway and Engineering Review*, under the title "Diary of a Roundhouse Foreman." It is in compliance with many requests that these articles are now put in book form. The author has attempted to give a general idea of the nature and range of problems that a roundhouse foreman has to meet. For this purpose it has been assumed that a typical young machinist has been placed in charge of a roundhouse, and his experiences are set forth in a manner which indicates that the author is a good story teller.

House Wiring. By Thomas W. Poppe. 103 pages, 4½ by 6½ inches. 74 illustrations. Published by Norman W. Henley & Son, New York. Price, 50 cents.

The Durability and Reliability of a Machine depends largely upon the Quality of the Materials of which it is made

Our iron castings are made in our own foundry by special processes devised to produce for each important part that quality of casting best adapted for the work it has to do.

For example, the iron in our tables is condensed around the T slots making them strong and durable. There is no sponginess. The metal at the bottom of the slots is as good as at the top.



The dotted lines enclose the condensed portions of the casting

The Spindle Driving Gears of our High Power Machines are all steel forgings.

Most of them are nickel steel. These are hardened by a special heat treatment which leaves the centres soft and prevents distortion.

They are stronger than ordinary hardened gears.

We use only those that meet our exacting scleroscope inspection test.

Cincinnati Millers last longer, hold their accuracy better and cost less for maintenance than any others subjected to the same heavy duty of which ours are capable.

THE CINCINNATI MILLING MACHINE COMPANY

CINCINNATI, OHIO, U. S. A.

EUROPEAN AGENTS—Alfred H. Schutte, Cologne, Berlin, Brussels, Milan, Paris and Barcelona. Donauwerk Ernst Krause & Co., Vienna, Budapest and Prague. Sam Lagerlofs, Stockholm, Sweden. Axel Christiernsson, Abo, Finland. Chas. Churchill & Co., London, Birmingham, Manchester, Newcastle-on-Tyne and Glasgow. CANADA AGENT—H. W. Petrie, Limited, Toronto, Montreal and Vancouver. AUSTRALIAN AGENTS—Thos. McPherson & Son, Melbourne. JAPAN AGENTS—Andrews & George, Yokohama. CUBA AGENT—Krajewski-Pesant Co., Havana. ARGENTINE AGENTS—Robert Pusterla & Co., Buenos Ayres.

This book is a treatise describing and illustrating up-to-date methods of installing electric light wiring and is intended primarily for persons of limited experience who wish to obtain a practical knowledge of the installation of electric lighting systems. The subject is treated in a simple and concise manner and illustrations are used throughout the book to clearly convey the ideas presented. The book consists of seven chapters headed as follows: Showing the Plans and Layout of the Electrical Work; Flexible Metallic Wiring Systems; Installing Rigid Conduit; Combining Flexible and Rigid Conduit; Wiring and Switch Diagrams and Connections; Grounding Metallic Conduit Systems; Knob and Tube System.

Farm Gas Engines. By H. R. Brate. 195 pages, 5 by 7 inches. 37 illustrations. Published by the Gas Engine Publishing Co., Cincinnati, Ohio. Price $1.00.

This book is intended to present, in a simple way, the methods used in the successful running of gas engines. Examples are given of various troubles met with in the manipulation of these engines, the book being intended especially for persons who use small units for agricultural work on small industrial plants. Special attention has been called to the troubles met with in the ignition system. The language used is clear and simple and well adapted to the class of readers for which the book is intended. The various chapters of the book discuss two- and four-cycle gas engines, fuels, carburetion, compression, ignition, magnetos, batteries, coils, lubrication, cooling, gas tractors, portables, farm pumping plants, farm lighting plants, farm machinery operated by gas engines, and marine engines.

Primer of Scientific Management. By Frank B. Gilbreth. 108 pages, 5 by 7½ inches. Published by D. Van Nostrand Co., New York. Price $1.00.

In the early part of 1911 the *American Magazine* published a series of articles by Frederick W. Taylor, entitled "The Principles of Scientific Management." As a result of the publication of these articles, hundreds of letters were sent to the magazine requesting further information on the subject. These letters were all handed to the author of the present book and are answered in it. Hence, the book is not a complete treatise on scientific management, but gives in a catechism form a comprehensive idea of the main principles of the subject. The book is divided into five chapters headed as follows: Definitions of Terms of Scientific Management; Laws, or Principles, of Scientific Management; Application of the Laws of Scientific Management; The Effect of Scientific Management on the Worker; and Relation of Scientific Management to Other Lines of Activity.

Elementary Internal Combustion Engines. By J. W. Kershaw. 171 pages, 5¼ by 7¾ inches. 117 illustrations. Published by Longmans, Green & Co., New York. Price, 90 cents.

The author of this book, who is a lecturer in engineering at the University of Sheffield, England, states in the preface that it is intended to give an elementary account of the construction and working of internal combustion engines and power gas producers, and thus to serve as an introduction to the more advanced books dealing with the subject. The explanations have, for this reason, been made as simple as possible, but within its scope the book is thorough and comprehensive and provided with a great number of sectional illustrations showing the exact workings of the various parts of the gas engine. The contents by chapters are as follows: The Gas Engine; Large Gas Engines; Gas Engine Governing; Ignition; The Indicator and Indicator Diagrams; Calorific Power; Gas Producers; Theory of Gas Producers; Oil Engines; Petrol Engines; Oil Engines for Ships; Other Combustion Motors; Engine Efficiency.

Concrete Costs. By Frederick W. Taylor and Sanford E. Thompson. 709 pages, 5 by 8 inches. 82 illustrations. Published by John Wiley & Sons, New York. Price, $5.00.

This book is designed to meet the needs of both the contractor and the engineer and architect in making rough and approximate as well as accurate and detailed estimates. It is also intended to make possible an economical layout and a scientific management of the work in combination with task and bonus systems. The book contains an immense amount of data relating to all phases of concrete work and it is impossible in a brief review to give more than a general idea of its contents. It has twenty-three chapters which are headed as follows: Approximate Costs of Miscellaneous Concrete Work; Approximate Cost Data on Concrete Structures; Approximate Costs of Reinforced Concrete Buildings; Determination of Labor Cost; Task-work in Construction; Proportioning Concrete; Tables of Quantities of Materials for Concrete and Mortar; Cost of Concrete Materials; Excavating and Crushing Stone for Concrete; Handling and Transporting Materials; Labor of Hand Mixing; Machinery Plants for Mixing and Handling Concrete; Labor Costs of Machine Mixing; Forms for Mass Concrete; Arch Centers; Forms for Reinforced Concrete; Tables of Concrete Volumes; Tables of Steel Areas and Quantities; Tables of Times and Costs Bending and Placing Steel; Tables for Designing Forms; Tables of Quantities of Lumber for Forms; Tables of Times and Costs of Labor on Forms; Estimates for Reinforced Concrete Construction.

Practical Thermodynamics. By Forrest E. Cardullo. 411 pages, 6 by 9 inches. 224 illustrations. Published by McGraw-Hill Book Co., New York. Price $3.50.

While this book is intended primarily as a textbook for the use of classes in mechanical and electrical engineering, it is written in a manner which will appeal especially to the practical man. The author has presented his subject so that any person who would like to obtain a general understanding of thermodynamics without going into the subject deeply enough to analyze the mathematical deductions, will be able to do so without difficulty. The book has been prepared with a clear view of both practical and theoretical considerations, and the laws which underlie the action of thermodynamic apparatus are so presented that the reader will not only be able to comprehend the principles involved, but also to correctly design apparatus based upon these thermodynamic principles. The book has a pleasing and refreshing touch of originality, and as the writer himself states in the preface, he has not hesitated to present new methods whenever these methods seemed simpler and better than the older ones. Many of the definitions given, therefore, differ radically from those found in other textbooks, and the whole subject has, as a result, become more simple and also more logical. Such items as can only be fully comprehended and satisfactorily studied by more advanced students have been printed in smaller type, so as to distinguish them from the remainder of the text. In this way, it is possible for students who have advanced further to deal with the subject in a most thorough manner, while beginners may read only such parts as are especially intended for them at their present stage of development. A great number of problems for exercises are presented, these problems being given at the end of each chapter. The answers accompany the problems in each case. The general scope of the work will be best understood from a review of the headings of the chapters of the book: The Nature and Measurement of Heat; The Thermal Properties of Gases; The Expansion of Gases; Thermodynamic Processes and Cycles; The Thermal Properties of Vapors; Wet and Superheated Vapors; Mixtures of Gases and Vapors; The Steam Engine; Steam Cycles; Losses in the Steam Engine; Notes on the Design and Testing of Steam Engines; The Steam Turbine; Condensing Machinery; Combustion; The Steam Boiler; Boiler Plant Auxiliaries; Water-cooling Apparatus; Hot-air Engines; The Internal Combustion Engine; Notes on the Design and Performance of Internal Combustion Engines; Gaseous Fuels; Compressed Air; Refrigeration; Heating, Ventilation, Evaporation and Drying; Entropy Diagrams; The Kinetic Theory of Heat.

NEW CATALOGUES AND CIRCULARS

Nelson Valve Co., Chestnut Hill, Philadelphia, Pa. Catalogue S on steel valves and fittings made of acid open-hearth steel.

National Tube Co., Frick Bldg., Pittsburg, Pa. Circular describing the N. T. C. regrinding globe and angle valves with union bonnet.

Davis-Bournonville Co., 97 West St., New York. Booklet No. 4 on autogenous welding and cutting of metals by the oxy-acetylene process.

Wayne Oil Tank & Pump Co., Fort Wayne, Ind. Circular of oil storage outfits for gasoline, gasoline lubrication oils, paint oils and varnishes.

Deane Steam Pump Co., 115 Broadway, New York. Bulletin D-171 on horizontal duplex piston pumps, operated by direct-connected vertical gasoline engines.

Joseph Dixon Crucible Co., Jersey City, N. J. Booklet on Joseph Dixon, comparing his work with that of others who have made great inventions and discoveries.

McEwen Bros., Wellsville, N. Y. Booklet illustrating and describing pumps for steam turbine drive. Complete description and tables of necessary data are given.

Taylor Iron & Steel Co., High Bridge, N. J. Bulletin No. 114 briefly describing the application of "Tisco" manganese steel to crusher and pulverizer parts.

C. W. Meadowcroft, Sr., 4702 Large St., Frankford, Philadelphia, Pa. Circular illustrating the ball high-speed rotary riveting hammer, with foot lever, bench style.

O. N. Beck, 11 Queen Victoria St., London, E. C., England. Circular of elastic corrugated tubes for expansion joints, heating and smoke tubes, superheaters, condensers, etc.

Detroit Fuse & Mfg. Co., Detroit, Mich. Bulletin No. 25 descriptive of "Detroit" switches for motor-operated machinery which are "foolproof, fireproof and fumeproof."

Peters Bros. Mfg. Co., Algonquin, Ill. Circular of "Peters" abrasive metal saw for cutting high-speed steel, brass, copper, iron pipe tubing, and all metals; price, $16.50.

National Scale Co., Chicopee Falls, Mass. Folder advertising the National counting machine for parts such as bolts, screws, nuts, etc., used in quantities in manufacturing establishments.

Ingersoll-Rand Co., 11 Broadway, New York. Bulletin No. 7004 illustrating and describing Cameron steam pumps, remarkable for the small number of working parts used in their construction.

Treadwell Engineering Co., Easton, Pa. Booklet on steel castings, defining what steel castings are. The information contained will be useful to any user or prospective user of steel castings.

Bethlehem Steel Co., S. Bethlehem, Pa. Catalogue of crucible steel products comprising high-speed steel, carbon steel, die products, forged disks and blanks, special alloy steel, spring steel, etc.

Hess-Bright Mfg. Co., 2111 Fairmount Ave., Philadelphia, Pa. Catalogue on the Hess-Bright DWF ball bearing hangers for lineshafting, illustrating installations and giving data on power saving.

Wells Bros. Co., Greenfield, Mass. Circular of the "Little Giant" tap grinder which provides means for sharpening taps up to 12 inches in length and, with special arm, to 15 inches in length; price, $75.

Westinghouse Electric & Mfg. Co., East Pittsburg, Pa. Descriptive leaflet No. 2496 on Westinghouse outdoor type OISC transformers; circular No. 1194, on Westinghouse type Q direct current generators.

National Automatic Tool Co., Richmond, Ind. Catalogue of automatic adjustable multiple spindle, vertical and horizontal drilling machines with variable spindle speeds, for drilling, reaming and tapping.

Shepard Electric Crane & Hoist Co., Montour Falls, N. Y. Bulletin descriptive of the Shepard line of cage controlled monorail electric hoists for use in steel mills, foundries, machine shops and factories.

Crocker-Wheeler Co., Ampere, N. J. Bulletin No. 141, illustrating and describing alternating current motors, Form R, induction type, designed for operating from 25 cycle polyphase alternating current circuits.

Pennsylvania Railroad Co., Philadelphia, Pa. Booklet on the subject of corn culture, intended for farmers, students in agricultural schools and others interested in the promotion of higher agricultural efficiency.

Standard Pump & Engine Co., Cleveland, Ohio. Catalogue No. 12 of "Standard" pumping engines, and "Standard" water supply systems adapted to shallow wells, cisterns, lakes, rivers, etc.; also to deep wells.

S. F. Bowser & Co., Fort Wayne, Ind. Catalogue of the Bowser oil filtration and circulating systems which filter the oil, precipitate impurities, separate and automatically eject water and provide for the storage and use of refuse oil, etc.

Deane Steam Pump Co., 115 Broadway, New York. Catalogue of duplex horizontal double acting power pumps, giving brief descriptions of various types of these pumps, together with complete tabular data relating to capacity and sizes.

General Electric Co., Schenectady, N. Y. Bulletin No. 4931. "Electricity in the Shoe and Leather Industry"; bulletin No. 4939. "Electric Hoists"; bulletin No. 4947, "Edison Mazda and Gem Lamps for Standard Electric Railway Service."

Alvan Mfg. Co., Newark, N. J. Leaflet illustrating and describing the "Rex" universal test indicator for the use of toolmakers, machinists, etc., on bench lathes, engine lathes, planers, shapers or milling machines. The error is multiplied fifty times, and the capacity is 0.020 inch.

Wells Bros. Co., Greenfield, Mass. Tables of tap drill sizes for U. S. standard, S. A. E. standard and machine screw threads. The tap drill sizes are based on the formula $X = N - \frac{3}{4}(2D)$ in which X equals tap drill diameter, N, diameter of tap over top of thread, and D depth of thread.

B. F. Sturtevant Co., Hyde Park, Mass. Catalogue No. 190 of steam turbines, describing the new type Sturtevant turbine and calling attention to its advantages. Catalogue No. 200 describing the Sturtevant aeronautical motor which is of the four-cycle type with four and six cylinders arranged vertically.

Brown Hoisting Machinery Co., Cleveland, Ohio. Catalogue "J," 1912, covering pillar cranes, hand wrecking cranes, mast jib cranes, pillar jib cranes, bracket jib cranes, hand bridge cranes, and transfer tables. The catalogue is profusely illustrated, showing cranes installed in various industrial plants and for various services.

Wisconsin Engine Co., Corliss, Wis. Circular of the Adams-Wisconsin kerosene gas engines, built in sizes from 50 to 200 H. P., under the M. Rumely Co. patents. These engines use kerosene instead of gasoline, being provided with special carburetors that gasify cold kerosene the same as gasoline is gasified in an ordinary carburetor.

CONTENTS FOR JULY

The first column of page numbers applies to the Engineering and Railway Editions: the second to the Shop Edition.

Industrial Instrument Co., Foxboro, Mass. Bulletin No. 62 descriptive of Dr. Th. Horn's tachometers and tachographs, covering a great variety of styles, ranges and purposes for practically all conditions of industrial and engineering service and including precision tachographs for recording minute variations in speeds of machinery.

Stow Mfg. Co., Binghamton, N. Y. Catalogue of flexible shafts and other portable apparatus for drilling, tapping, reaming, counterboring, etc.; also center grinders, portable grinders, scratch brushes, universal joints, multi-speed electric motors, electric grinders of the floor and portable types, track drills, rail grinders, hand buffers, electric bench grinders, electric breast drills, etc.

Thomson Electric Welding Co., Lynn, Mass. Catalogue of electric welding machines operating by the resistance or Thomson process which is principally employed in butt welding, T- and angle-welding, cross welding, lap welding, seam welding, etc. A line of machines adapted to a large variety of welding operations is illustrated, and data on size, weight, capacity, etc., are given.

American Tool Works Co., Cincinnati, Ohio. Pamphlet describing methods employed in the manufacture of lathes, planers, shapers and radial drills in Cincinnati, by the company. The tests applied are shown. The pamphlet should be found of much general interest to superintendents, foremen, mechanics and all interested in any way in machine tools.

Westinghouse Electric & Mfg. Co., E. Pittsburg, Pa. Descriptive leaflet No. 2458 on Westinghouse type-T direct current turbo-generator, consisting of a steam turbine and generator mounted on a common base. The leaflet gives a description of the various characteristics and construction in detail of the steam turbine, and views of the component parts of the various elements, etc.

John M. Rogers Works, Inc., Gloucester City, N. J. Catalogue of measuring instruments of precision, manufactured after the Richards system; also solid adjustable blade reamers, solid reamers, adjustable blade hollow mills, adjustable thread cutting tools, steel mandrels, etc. The catalogue includes complete metric sizes and prices of all tools manufactured by the company.

Modern Machine Tool Co., 4657 Spring Grove Ave., Cincinnati, O. Circular of the "Modern" flat turret lathe embodying improved automatic chuck, automatic roller feed, novel belt clutch, improved friction clutch and improved feed box. The lathe has a capacity for bar stock up to 2¼ inches diameter, and 26 inches length. The swing over the bed is 20 inches and over the carriage, 14 inches.

Fahrig Metal Co., 34 Commerce St., New York. Circular of "Fahrig" anti-friction metal, composed of tin and copper combined by a special process. This metal is especially valuable for the bearings of automobiles and gas engines. It has superior anti-friction qualities and can be used in the form of die castings, sand castings or poured bearings, as may be required to suit the condition of manufacture.

Pennsylvania Railroad Co., Philadelphia, Pa. Booklet entitled "The Pennsylvania Railroad and Industrial Safety," containing extracts from the proceedings of the American Museum of Safety, New York, January 17, 1912, when the Traveler's Insurance Co's medal was awarded to the Pennsylvania Railroad, "as the American employer who, in 1911, did the most to protect the lives and limbs of its employes."

Van Dorn & Dutton Co., Cleveland, Ohio. Circular illustrating uses of the Van Dorn & Dutton Co., hard-service portable electrically-operated drills and reamers, the examples showing application to car work, structural work, manufacture of steel furniture, motor cars, drilling armor plate, erecting lineshafts, boring holes in timber, drilling staybolt holes in boilers, erecting elevators, repairing stationary engines, etc.

General Electric Co., Schenectady, N. Y. Bulletins No. 4880, on railway signal volt ammeters; 4910, on oil break switches; 4925, on combined unit-series mercury arc rectifier outfit; 4938, on Type H transformers; 4949, on direct-current portable instruments; 4950, on Washington, Baltimore & Annapolis 1200-volt direct-current railroad installation; 4951, on street lighting with Edison "Mazda" series lamps; and 4952, on series incandescent street lighting systems.

Hoskins Mfg. Co., 459 Lawton Ave., Detroit, Mich. Bulletin No. 10 descriptive of the "Hoskins" electric muffle furnaces, type FC, for the efficient heat-treatment of tool steels, made in two sizes having chamber dimensions 6½ inches wide by 5 inches high by 12 inches deep, and 12 inches wide by 8 inches high by 18 inches deep, respectively. Among the advantages claimed are even heating, accurate temperature, atmospheric control, absence of oxidizing gases, rapid heating, high thermal efficiency, etc.

Busch-Sulzer Bros.-Diesel Engine Co., St. Louis, Mo. Pamphlet entitled "The Present Status of the Diesel Engine in Europe and a Few Reminiscences of the Pioneer Work in America," by Dr. Rudolf Diesel, the contents comprising a lecture delivered before the Associated Engineering Societies of St. Louis, April 13, 1912. The growing importance of the Diesel internal combustion engine makes the pamphlet of much interest to engineers and others concerned with the economical generation of power.

American Swiss File & Tool Co., 24 John St., New York. Catalogue, fifth edition, of "American Swiss" files, fully illustrated, with price list in distinctive heavy type. A separate sheet accompanying the catalogue compares "American Swiss" list and "American Standard" list, this comparison being important to buyers of high-grade files. The inside front cover concerns trademarks, and the inside back cover briefly takes up the three epochs in file making beginning with a well-known quotation from the Bible. The engravings of files are carefully made showing the kind of cutting exactly. File users generally will find the catalogue interesting and valuable for reference.

Bristol Co., Waterbury, Conn. Catalogue No. 1000 on Bristol's recording gages for pressure and vacuum, containing 64 pages, 8 by 10½ inches. The catalogue lists all of the Bristol recording pressure and vacuum gages except round form models 50, 52 and 56. These gages are furnished with charts graduated in pounds per square inch, in ounces per square inch, in inches head of water, in feet head of water, in atmospheres, in inches head of mercury, in centimeters head of water, in decimeters head of water, in tons, in kilograms per square centimeter, in millimeters head of mercury, in millimeters head of kerosene, in centimeters head of water, in millimeters head of water, etc. The preceding partial list gives some idea of the extent of development of the recording gage, exemplified by the product of the company.

International Oxygen Co., 115 Broadway, New York. Bulletins on the I. O. C. oxy-hydrogen platinum melting processes; the Holder pressure generator for generating acetylene gas; welding torches for welding metals; high-pressure cylinders for gas, made in 100, 150 and 200 cubic feet capacities, respectively; report of tests of cells for the electrolytic production of oxygen and hydrogen made by the Electrical Testing Laboratories, New York; oxy-hydrogen and street railway construction, being extracts from paper read by Mr. Henry Mozley before the convention of the Municipal Tramways Association held at Glasgow, September 27-29, 1911; and bulletin containing tables on weights of gases, variation of pressures in cylinders with variation of temperature, quantity of gas remaining constant; quantity of gas in cylinders under various pressures, temperature constant; purity of oxygen; and calculation of thermometer readings, etc.

TRADE NOTES

Crocker-Wheeler Co., Ampere, N. J., opened an office in the Title Insurance Bldg., in Los Angeles, Cal., April 1.

Morrow Mfg. Co., Elmira, N. Y., is building a one-story brick addition, 50 by 180 feet for an automatic turret lathe department.

Superior Machine Tool Co., Kokomo, Ind., is building an addition to its plant to afford necessary facilities for its increasing business.

THE TRUTH
ABOUT
HOLLOW SET SCREWS

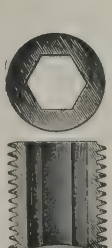
Pioneers in the promotion of new things are to be pitied. The study, the anxiety, the worry and expense of marketing anything new may bring their measure of success, but surely will bring (on any article of merit) competition, fair and unfair.

Many years ago we began the sale of Hollow Set Screws and while a Hollow Set Screw is not new, yet our method of producing them was new and produced a very much better screw than can be made from the solid bar, drilled and broached. In these solid bar screws, the surplus metal at the point at first appears to be advantageous, but in reality it is disadvantageous for the reason that the uniform thickness of our screws made from flat steel "died" out, permits a longer hold on the wrench and, therefore, a far better opportunity for tightening, while in the solid screw which is drilled and broached, it is necessary to turn in the surplus metal (resulting from the broaching) to the bottom of the hole, thereby partially filling the hole with nothing but waste material which has absolutely no holding power at all.

The H. S. & Co. Screws are made from sheet steel, stamped or "drawn up." Proper tests prove beyond a doubt that this method makes a stronger and tougher screw than one milled from the solid bar, owing to the position of the fibres of the steel. Well known proof of this is found in the comparative values of semi-finished nuts—those milled from solid rod not being as strong as the stamped goods; the same is illustrated also in wood, the plank grain being infinitely stronger than the cross grain product.

We invite comparative tests of the H. S. & Co. Hollow Set Screws with any other screws made having a hole or socket, and will supply FREE SAMPLES for this purpose, to reputable concerns.

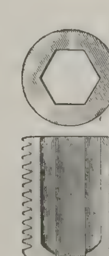
SEND FOR CIRCULAR No. 3055.



HAMMACHER, SCHLEMMER & CO.

HARDWARE, TOOLS AND SUPPLIES

New York, Since 1848 **4th Ave. and 13th St.**



Blakeslee Forging Co., Southington, Conn., will erect a new forge shop 30 by 160 feet, three stories high; also an annealing shop 32 by 72 feet, one story high.

Waterbury Farrel Foundry & Machine Co., Waterbury, Conn., has awarded the contract for the construction of a new machine shop 68 by 184 feet, one story high.

Frevert Machinery Co., 38 Vesey St., New York, the business of which has been conducted since its inception in 1906 by H. F. Frevert, has been enlarged and papers for incorporation under the laws of the State of New York have been filed.

Lumen Bearing Co., Buffalo, N. Y., is making an addition of 1800 square feet to its plant to take care of aluminum casting work. The company reports a prosperous year up to date, orders received being in excess of those reported for corresponding periods in the past.

H. W. Johns-Manville Co., Madison Ave. and 41st St., New York, has moved its Winnipeg branch offices into new quarters at 92 Arthur St. The new place is a six-story and basement building, and will be occupied throughout by the company's offices and store-rooms.

Brown & Sharpe Mfg. Co., Providence, R. I., announces that its works will be closed from August 2 to 19 for the annual vacation. During this time the offices will be open as usual and orders for machine tools, machinists' tools and cutters will receive the same attention as at any other period of the year.

Wells Bros. Co., Greenfield, Mass., manufacturer of taps and dies, has opened a store in Boston at 163 Oliver St. A comprehensive stock of all screw-cutting tools is carried, and quick deliveries will be made, thus affording better service to the trade in Boston and vicinity. Mr. John E. Chipman is manager of the new store.

Watson-Stillman Co., 192 Fulton St., New York, announces that the following officers were elected at a directors' meeting, May 15: President, E. A. Stillman; vice-president and secretary, A. F. Stillman; treasurer, J. P. Bird; chief engineer, Carl Wigtel; superintendent, Frank Lary. A new branch office is to be opened at Philadelphia soon and the shop facilities are being improved to meet increasing business.

Baldwin Chain & Mfg. Co., Worcester, Mass., has appointed Mr. Charles D. Schmidt its local representative in Greater New York City. An office and storerooms have been established at 416 Broadway, and Mr. Schmidt will give his attention to the prompt delivery of orders for the local trade. The company makes sprockets as well as chains, and Mr. Schmidt is prepared to furnish sprockets and chains for replacements on standard commercial cars.

Universal Machine Screw Co., Hartford, Conn., recently opened a New York office in charge of Mr. C. D. Schmidt, manager, corner Broadway and Canal St. (entrance 276 Canal St.) which will expand the facilities required for the increasing business of the company. The company manufactures the "Universal" five-spindle automatic screw machine and also operates a large number of these machines in its own plant, producing standard and special screw machine products from steel or brass. Mr. Schmidt, the New York manager, has been an important factor in the machine screw product field for a number of years.

E. F. Lake, Bayonne, N. J., has merged his consulting metallurgical business with the metallurgical engineering firm of Nixon & Raab under the name of Lake, Nixon & Raab, 156 Fairview Ave., South Orange, N. J. Die-casting machinery alloys and processes, and heat-treatment and carbonizing of steel will be specialized on. All kinds of physical tests and chemical analyses will be given to various metal products, and advice will be given as to the best methods and machinery used in the melting of all alloys, casting alloys, galvanizing, coloring and plating, or otherwise working and treating either ferrous or non-ferrous metals or alloys.

Van Dorn & Dutton Co., Cleveland, Ohio, has opened several new agencies for the sale of its portable tools only. Stock will be carried in the following places: 67 Main St., San Francisco, Cal., W. B. Wilson, district manager; Security Bldg., Los Angeles, Cal., J. L. Davidson, district manager; Candler Bldg., Atlanta, Ga., W. F. Davis, district manager; Alfred Herbert & Co., Ltd., England, Ireland, Scotland, Wales, France, Belgium, Spain and Portugal; Frank Saunders, Sydney, Australia. Australia and New Zealand. The company reports a largely increased business. A full line of electric grinders will be brought out in the near future.

Newark Gear Cutting Machine Co., Newark, N. J., has again found it necessary to enlarge its works, to take care of increasing business. The assembly room has been enlarged so that the main building now extends from 66-68 Union St. through to 67-69 Prospect St. The three-story brick building at 69 Prospect St. is now occupied by the offices, drawing-room, and pattern-shop; while such portions of the main building as were formerly occupied by these departments will now be given over to the machine shop. The address of the office is now 69 Prospect St., Newark, N. J. Mr. Henry E. Eberhardt, president of the company, reports that at present the plant is running at normal time, with full working force. The demand for gear-cutting machines has been increasing, especially for the Eastern trade.

MISCELLANEOUS

Advertisements in this column, 25 cents a line, ten words to a line. The money should be sent with the order. Answers addressed to our care will be forwarded. Original letters of recommendation should not be enclosed to unknown correspondents.

MACHINERY
Railway Edition for Locomotive Construction and Repair Shops
August, 1912

ASSEMBLING A LOCOMOTIVE BOILER

By RALPH E. FLANDERS*

THE construction of a locomotive boiler presents many difficulties that are not encountered in building other types, because it must be shaped to conform with the requirements of locomotive design. Some of the sheets, especially around the firebox, are so irregular in shape that considerable skill is necessary in order to properly form and rivet them together. There are also difficult joints to make, and the firebox end must be carefully braced to withstand the high steam pressures and prevent distortion or explosion. Owing to these difficulties, a high degree of skill is required in locomotive boiler construction, and, incidentally, the work is very interesting just because it is difficult.

Fig. 1. End View of the Boiler Shop, Juniata Shops, P. R. R.

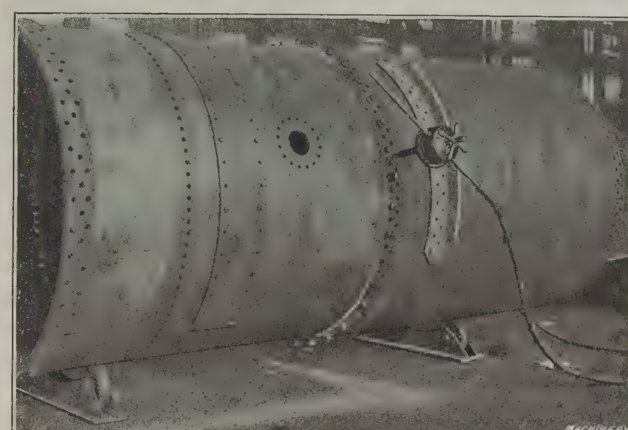


Fig. 2. Reaming Rivet Holes in Circular Seam

The method of erecting a locomotive boiler, as described in this article, represents the practice at the Juniata Shops of the Pennsylvania R. R., which, as most everyone knows, are located at Altoona, Pa. The subject will be treated in rather a general way, instead of describing in detail the exact method of assembling any one type of boiler. Special reference will be made, however, to the design having a Belpaire firebox, owing to the extensive use of this construction at the present time. The Belpaire firebox, as is well known, has a roof-sheet which is parallel with the crown-sheet, so that these members can be tied together with stays that are at right-angles to each sheet. This construction gives a flexibility which is very much needed, owing to the distortion that results from the steam pressure and the expansion due to the heat of the fire.

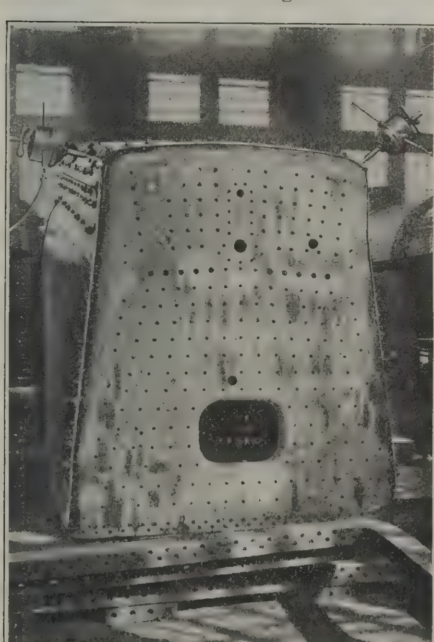

Fig. 3. Back End of Boiler bolted together prior to Riveting

Fig. 4. Back End of Boiler being riveted in Riveting Machine

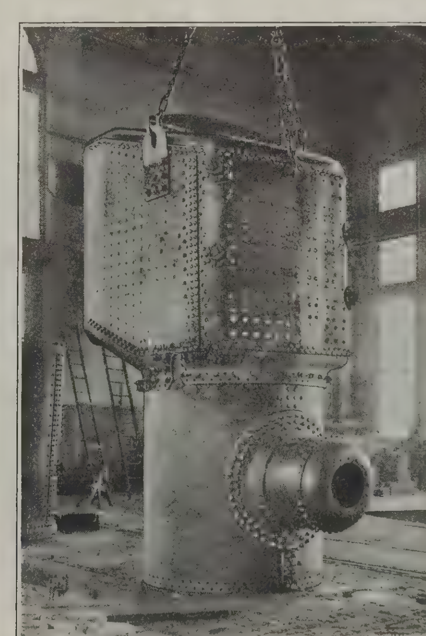

Fig. 5. Back End bolted to the Dome Course prior to Riveting

Prior to the erection of a boiler, all of the sheets are laid out and bent to the proper form. The required outline is first transferred from sheet steel templets. Practically all the rivet holes are then punched and drilled and the edges are planed or sheared to give a good surface for calking. The edges are beveled slightly, except where a butt-joint is to be made. The method of bending the sheets depends, of course, on their shape. Those for the cylindrical part of the boiler are rolled to the proper diameter, whereas the sheets of irregular shape are formed and flanged in hydraulic presses equipped with suitable dies. A detailed description of the way the different sheets are laid out, punched, trimmed, bent,

* Address: Springfield, Vt.

and flanged was previously published in the November, 1910, number of MACHINERY, railway edition.

The Riveting Machines

After the parts of the boiler have been made, we have next to consider the assembling and riveting of these parts together to form the finished structure. The riveting is done by hydraulic machines which are served by a pump and accumulator plant in the central power station. The pumping plant includes units of various capacities, so that the service can be maintained economically under varying conditions. The work

Fig. 6. Riveting the Side- and Crown-sheets of the Firebox

is presented to the riveters by a pair of special, electric cranes running on tracks provided for them in the riveting tower. Fig. 1, which is an end view of the boiler shop, shows the appearance of the riveting tower from the outside. The crane for each riveter is controlled by the operator of the riveting machine. The various hydraulic valves and electric controlling handles for the riveters and cranes are within easy reach of the riveting pit, as shown to the left in Figs. 4 and 6, so that the workman has full control of all the operations, except swinging the boiler shell about its axis, this being done by two helpers who insert short bars in the rivet holes for use as handles. Besides these two helpers, each riveting machine has its rivet furnace boy and helper for putting the rivets in the holes. It may be mentioned here, parenthetically, that to keep any or all of these men from falling into the riveter pit, an adjustable sheet-steel platform is suspended in

Fig. 7. Tube-sheet, Crown-sheet, and Firedoor-sheet being assembled

the pit with chains and can be set to any height to agree with the work in hand.

Riveting the Front Sections

The first operation on the boiler proper is that of riveting the longitudinal seams of the barrel sections. The shell to be riveted is suspended on a three-chain sling attached to a crane hook, and prior to driving the rivets, the joint is held temporarily by a few bolts. After the smokebox has been riveted on the longitudinal seam the ring for connecting it to the slope-sheet is assembled and then the flue-sheet is riveted to this ring. The smokebox with the ring and tube-sheet attached, is then lowered onto the slope-sheet to which it is temporarily bolted. These two parts are then lowered into the gap of the riveting machine and the circular seam is riveted together. In bolting up and riveting all joints, the holes that are supposed to match each other are inspected for alignment before the riveting operation, and reamed if necessary. The separate sections are also aligned with each other by means of center-lines which have previously been scribed upon them. Fig. 2 shows how the holes are reamed. An air motor is used and the two sections are mounted on rollers thus permitting the barrel to be easily turned to the most convenient position.

In designing a boiler, it is customary to have the number of rivets in the circular seams, equally spaced around the circle and divisible by 4. It is then possible, from the rivet holes, to lay out center-lines on the top, bottom, and sides of the sheets. These center-lines on each sheet, are accurately matched with each other when bolting the sections together, prior to reaming and riveting, and it is upon the accuracy of this work, that the accuracy of the finished boiler largely depends. To further preserve the accuracy of the circular joints, it is not the custom to drive first one rivet and then the next, clear around the circle, as this is likely to cause the two sections being riveted to "creep" onto each other; but instead, a rivet is driven here and there around the circle, after which the temporary holding bolts are withdrawn and the remaining rivets are driven.

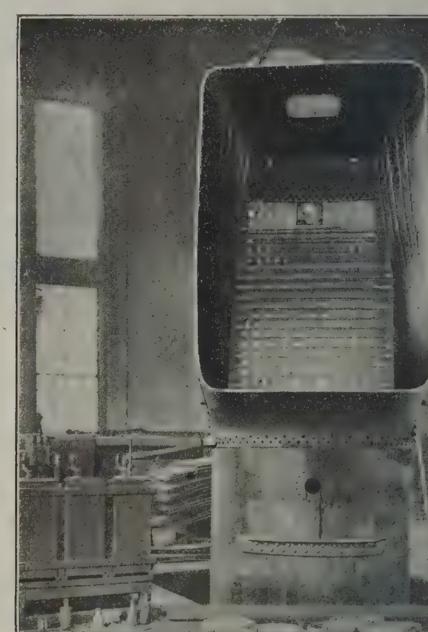

Fig. 8. Rear Half of Boiler Lowered into Pit for Riveting Throat- and Neck-sheets

Building up and Riveting the Back End

The back end of the boiler is first temporarily erected on the foundation ring or "mud ring," as it is often called. First, the side- and roof-sheets are fitted in place on the foundation ring. All of these sheets come to the boiler erecting department with the rivet holes punched, excepting a few holes that can be drilled to better advantage after the parts are assembled. The work of the riveter, prior to riveting, consists, therefore, simply in bolting the sheets together, temporarily, and then bracing them this way or that, to make the measurements correspond with those given on the drawing. When the parts have been bolted together in this way, the foundation ring is removed and whatever reaming may be necessary is done, as indicated in Fig. 3. This structure, which forms an outer shell over the firebox, is then taken to the riveter to be fastened together. It is suspended from the firedoor end, as shown in Fig. 4, so that the sides can enter the gap of the riveting machine.

Meanwhile, the foundation ring has gone back to the fitting floor to have the firebox mounted on it. The tube-sheet, firedoor sheet and crown-sheet are first fitted as shown in Fig. 7, the parts being braced in one way or the other, as may be required, to bring them to the dimensions specified on the drawing. The side-sheets of the firebox are then fitted in and all the sheets are bolted together. The holes are then reamed and the seams riveted, as indicated in Fig. 6, which shows the longitudinal seam joining the crown- and side-sheets being riveted. The firebox is suspended from the crane by the crown-sheet, and the stake of the riveter, which "backs up" the rivet, enters through the grate opening. This view also clearly shows the handles used for controlling the electric crane.

It is not possible to use the machine for all the riveting

operations on the firebox. The firedoor and flue-sheets can be riveted to the side-sheets, as well as the crown-sheet to the side-sheets, but it is not possible to rivet the crown-sheets and firedoor and tube-sheets together. This latter operation, therefore, has to be done by hand.

The outside throat-sheet is next attached to the side-sheets, and with the particular style of boiler shown in the illustrations, a neck-sheet is riveted to the crown-sheet. These two sheets, that is, the throat- and neck-sheets, are flanged at the front to form a circular opening for the dome course. The next operation is that of connecting the firebox end to the dome course, to which, in the meantime, the dome has been riveted. After these parts are bolted together, as indicated in Fig. 5, a three-chain sling is attached to the firedoor end, and the two sections are lowered into the riveting pit, as shown in Fig. 8 for riveting the circular seam. While this work has been going on, the stay gang has been putting in the various firebox stays, which are needed to hold the various members together when subjected to pressure. The location of these stays is clearly shown in Fig. 9, which is a view looking from the dome-course section, toward the firebox end.

Fig. 9. View toward the Rear showing the Stays

Assembling the Different Sections

After the different sheets have been joined, as described, the larger units thus formed are assembled. First the firebox and foundation ring are inserted in the back end of the boiler, which is turned on its side for this purpose. These parts are then bolted to the outer shell, care being taken that the water space between the inner and outer sheets conforms to the required dimensions. After the firebox has been carefully set with reference to this point, the temporary clamping bolts are tightened and the whole back end is taken to the machine to have the row of rivets around the foundation ring driven. Next, the rivet holes for the firedoor are drilled through the flanges of the inner and outer sheets, and these flanges are riveted together. This riveting is a rather difficult job as it has to be done either with hand hammers or a pneumatic hammer compact enough to enter the firedoor opening. It is also somewhat difficult to back up the rivet with a "dolly bar," but this can be done by using a special form which reaches around inside the water space.

Before the firebox end is completed, it is necessary to brace the inner and outer sheets by staybolts. A great many of these bolts are required and different forms are used. Those which tie the inner and outer sheets together are, for the most part, plain threaded bolts which have tell-tale holes drilled in the outer end as required by law. These tell-tale holes, as is well known, are drilled deep enough to extend beyond the inner side of the outer sheet, so that in case the bolt is fractured at this point (which is the place where most breaks occur) a warning will be given by the jet of steam which is allowed to escape.

In addition to these plain staybolts, what is known as the flexible type is also used in certain parts of the firebox. The position of the flexible bolts is shown in Fig. 10 by the large heads or caps. These bolts, instead of being screwed into both sheets and riveted over at the ends, are screwed into the inner sheet only, and have a spherical head at the outer end, which is seated in a bushing screwed into the sheet. A cap is also screwed over the outside of this bushing, thus forming a socket for the spherical head and preventing the escape of steam. The advantage of this construction is that when the bolt is moved by the expansion or contraction of the inner sidesheet, the bolt will turn in its socket instead of bending, as in the case of the solid type. In this way the danger of a fracture is lessened. This flexible bolt is used in parts of the firebox where the expansion is so great that solid rigid bolts would be dangerous. The taps used for threading these holes are, of course, varied to suit the different styles of bolts used. The holes for the regular solid bolts, are threaded by a long tool which is a tap and reamer combined, so that when it is pushed through by the air drill, the holes are lined up with each other as well as threaded.

The front and back sections of the boiler are now ready to be joined. The gap of the largest riveting machine would be deep enough to permit riveting this seam in the machine, were it not for the front flue-sheet. This flue-sheet might, however, be put in place last, but it has been found advisable to rivet these two sections by hand since other operations on the boiler can be performed simultaneously. Fig. 11 shows the two sections just before they are joined together. The two sections are lined up by the center-lines previously referred to, after which they are bolted together and the holes reamed. The rivets are then driven by pneumatic hammers, a man inside the boiler holding a dolly bar against the rivet, while an outside man operates the hammer.

Another important operation connected with boiler assembly is that of putting in the flues and expanding them in the front and rear tube-sheets. These flues, which have previously been reduced at one end, are inserted from the front of the boiler. They are put in by two workmen, one being in the firebox and the other at the smoxebox end. After inserting the first or bottom row, the ends of succeeding tubes slide along the top of those already in place, and the workman in the firebox has only to reach in with a bar just before the flue strikes the sheet and guide it into its hole. After the tubes are all inserted, they must be expanded and beaded to make a steam-tight joint. The well-known Prosser expander is used for this purpose. This expander consists of a set of three rollers mounted in a head and expanded outward by a taper pin, as the head is rotated by an air drill. This outward movement of the rolls, as the taper pin is forced inward, enlarges the tube until it is a tight fit in the hole, thus making a close joint all around. This rolling operation is all that is required at the smokebox end. At the firebox end, however, a copper ferrule is placed between the flue- and the tube-sheet, prior to the expanding operation. These copper ferrules are used to prevent corrosion, which might take place under the influence of the intense heat to which the rear ends of the flues are subjected. After the ferrules are in place, the tubes are

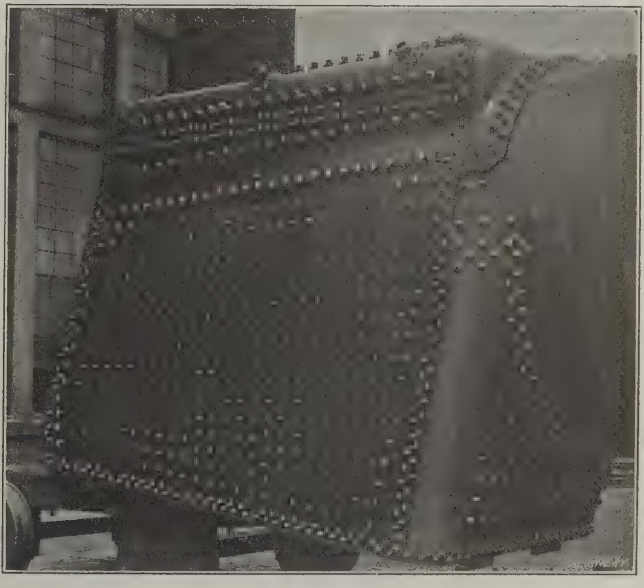

Fig. 10. Appearance of Firebox after the Staybolts have been inserted

rolled out with the Prosser expander until they form a steam-tight joint, and then the rear ends are beaded or rounded over. This beading is done by a special tool operated by the pneumatic hammer. This tool forms the bead by turning over the edge of the tube all around. In this way, an extra good joint is secured at this point and the front and back tube-sheets are firmly tied together.

While some of the operations previously referred to are being performed, the workman also calks the seams of the various riveted joints. Calking is done by a wedge shaped tool having a round nose which is driven against the beveled edge of the upper or overlapping sheet, by a pneumatic hammer. It it were not for this calking operation, the joints would leak like a sieve, because, while the rivets hold the parts together very securely, they do not take care of the unevenness in the joint. By calking, however, the edge of the overlapping sheet is compressed or driven back until a steam-tight joint is obtained. Calking is a very important part of boiler work and when it is poorly done, much trouble often results.

Miscellaneous Operations

There are, of course, a large number of miscellaneous operations on the boiler which cannot be referred to in an article of this length. These include such work as drilling and tapping openings for the washout plugs around the mud ring, and similar operations of a minor character. In addition, there is the work of mounting the fittings, such as the throttle dry-pipe, etc. This, however, is not done in the boiler shop but in the erecting shop. In connection with this work, mention should be made of the extremely accurate work done in pipe fitting. The pipes are cut to length and bent to shape within such close limits that they will go into place without further adjustment, this being the regular practice. The possibility of fitting pipes in this way, depends not only on the accuracy of the cutting and bending of the pipe itself, but also in the building of the boiler. All the pipes required for a certain design of locomotive, have corresponding wire templets of the exact length and shape required. The various pipes are bent with reference to these templets and they are not supposed to be altered afterwards. The methods employed by these pipe fitters seemed crude to the writer, at first sight, as no bending machines are used, but, instead, the open forge and hand vise. The pipes are heated and then gripped in the vise and bent by hand to conform to the templets. Upon making inquiry, it was learned that a pipe-bending machine had been tried for this work but was found to be slower than the hand method. Owing to the inconvenience of storing bent piping, and because of other considerations, it has been found unprofitable to bend the pipes in lots, the practice being to bend all of the pipes for one locomotive before proceeding with the next. On this account, the great number of changes of adjustment required when a machine is used, was found to consume all of the time saved by the machine. Probably pipe fitters less skillful and accurate than those here employed, would find that even under these conditions, they could produce work up to the required standard more rapidly by machine methods than by hand.

Fig. 11. The Boiler just before the Front and Rear Sections are riveted together

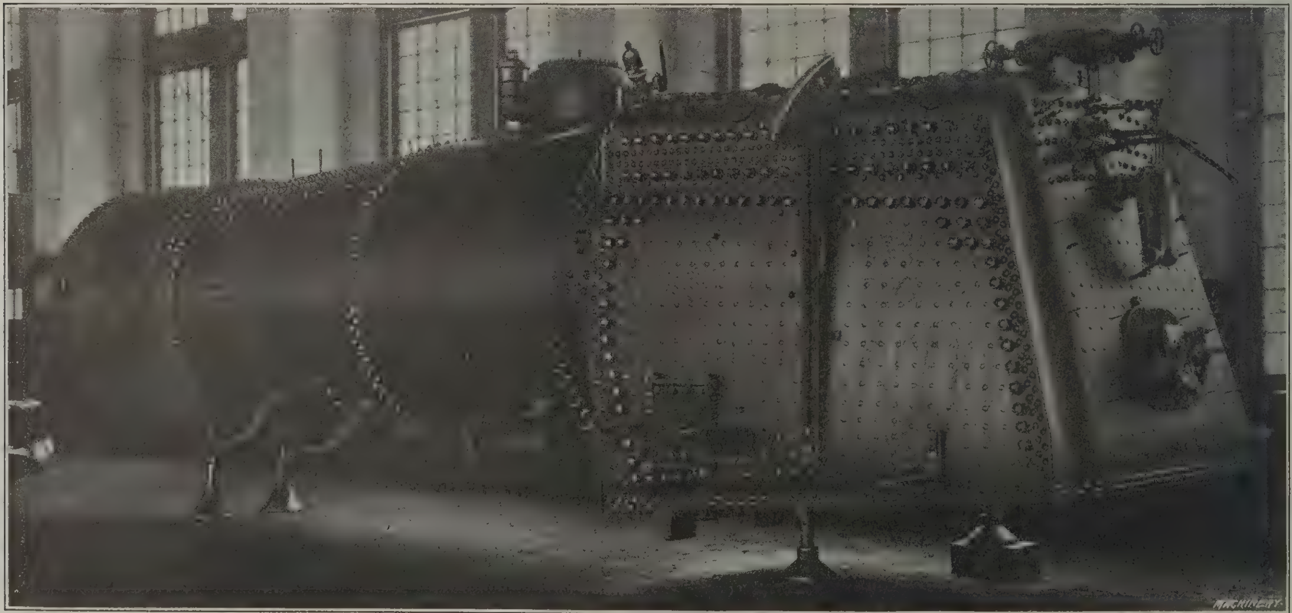

Fig. 12. The Completed Boiler ready for the Erecting Department

A Boiler Inspection Kink

In the course of this description, mention has been made two or three times of the fact that separate sections of a boiler are aligned with each other, prior to riveting, by center-lines laid off on the laying-out table. Incidentally, these center-lines

form a first-class indication of the accuracy with which the boiler has been assembled, the accuracy being checked by comparing these center-lines with those marked off on the side of the boiler at the time the locomotive was erected. When laying off these erecting shop lines, the horizontal center-line of the boiler is first located and marked on the sides of the smoke-box flange. The center of the boiler at the back end is then found, and horizontal lines are stretched along the side of the boiler. These lines are then chalked and "snapped," thus marking a center-line which extends the full length of the boiler, as shown quite clearly in Fig. 12. By comparing these center-lines with those previously made in the boiler shop on the separate sheets, the accuracy of the boiler erection can be determined.

TOOLS FOR PERFORATING LAMP BURNER PARTS

By CHARLES DOESCHER*

MANY kinds of dies have been described by the trade papers in the past, but very little has been said of the dies used for perforating the sides of cylindrical work. The punches and dies used for this work are similar to blanking punches and dies, except for the modifications occasioned by the fact that the metal fed over the face of the blanking die is flat, while that fed over the face of the perforating die is circular in form. Circular perforating tools are used in connection with this class of work because the nature of the work is such that it cannot, on account of both commercial and mechanical considerations, be carried out in any other way.

Fig. 1. Examples of Perforated Cylindrical Work, made by the Scovill Mfg. Co., Waterbury, Conn.

In describing the perforating of cylindrical work, the writer does not claim that the tools and methods in every case are the very best possible, but those in successful commercial operation at the present time are illustrated and described. The writer extends thanks to the E. W. Bliss Co., of Brooklyn, N. Y., for cooperation in the preparation of this article, and also to the Scovill Mfg. Co. of Waterbury, Conn., for the loan of the samples of perforated work shown.

Operation of the Perforating Tools

In Fig. 2 is shown a set of perforating tools together with a perforating attachment set up in a Bliss press ready for perforating a shell similar to the one shown in Fig. 4. The shell is first slipped over the die-holder (Fig. 5) in such a manner as to allow the elongated slot *A* in the bottom of the shell to engage with the projecting tongue of the driving arbor. The press is then tripped and the punches, at the first stroke of the press, cut out two of the irregular shaped perforations *B* in the shell. On the upward stroke of the press, a pawl *A*, Fig. 2, by the aid of a ratchet *B*, ratchet shaft *C* and the bevel gears, revolves the driving arbor, which rotates the shell a part of a turn. As the slot in the bottom of the shell is engaged with the tongue of the driving arbor, the shell is indexed with the arbor before the punch descends again. These operations are continued until the press, in this case, has made fourteen continuous strokes, when it is automatically stopped and the perforated shell removed. The stopping of the press is effected by cam *D*, which automatically releases the driving clutch when the required number of strokes has been made. The construction of the tools and the manner in which they are made will be treated later.

In Fig. 6 is shown another set of perforating tools for perforating the gallery fence of a lamp burner shown in Fig. 7. The gallery fence of a lamp or gas burner holds the lamp chimney or globe in place by the spring pressure exerted by the perforated part. The metal must be hard in order to impart the required spring pressure and is, therefore, on the better grade of burners, burnished before perforating, which not only hardens and toughens the metal, but also produces a brilliant finish. On the cheaper grade of burners, the shells from which the gallery fences are made are passed through an extra re-drawing operation, the shells not being annealed, but left hard. The difference in the diameter of the shell before and after re-drawing is about 1/32 inch, while the difference in the thickness of the metal is about 0.0005 inch. This treatment of the metal not only imparts the required springi-

*Address: 1029 West Main St., Waterbury, Conn.

ness, but also makes the perforating operations easier, as hard metal is more readily perforated than soft.

The tools used for perforating the gallery fence shown in Fig. 7 are somewhat different in construction from those shown in Fig. 2. The ratchet *C*, Fig. 6, is keyed to the driving arbor, and when the tools are set up in the press they are set with the face of the die-holder turned towards the right, instead of facing the operator. The perforating operation, however, is similar to the one already described. The effect of the successive strokes of the press is indicated in Fig. 7. At the first stroke of the press, the four shaded areas at *F* are punched out. At *G* can be seen the appearance of the shell after the second stroke. In order that no burr or fin may be left on the top points of the scallops, the die is made so that the punch will cut a trifle past the center of the point as shown at *H*. The shell is rotated towards the left by the driving arbor, and a simple holding device, not shown in the illustration, is used for holding the shell in place on the arbor.

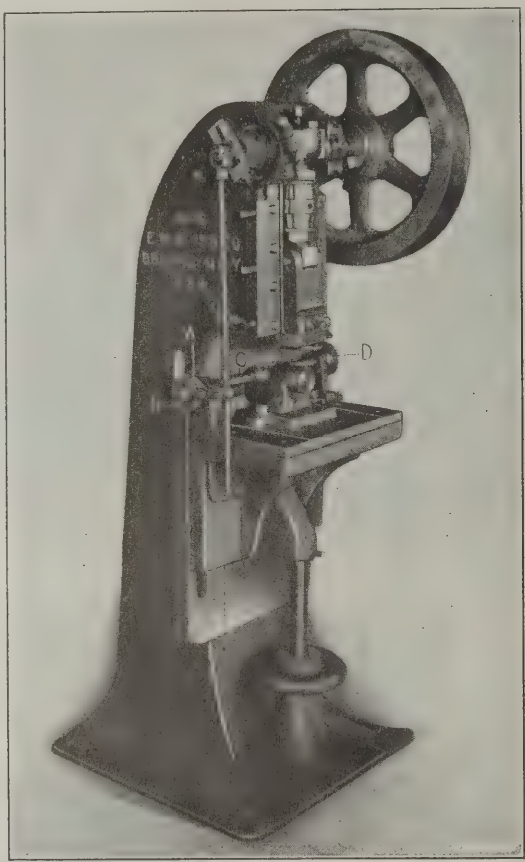

Fig. 2. Bliss Press with Attachment for Perforating Shell shown in Fig. 4

At attachment for holding work in place while it is being perforated is shown in Fig. 3. This attachment is used in connection with the tools for perforating the sides of large narrow rings. The tool equipment consists of a perforating punch *A*, and a large die-holder *B* for holding the dovetailed perforating die *C*. The die-holder is held in die-bed *D*. The perforating attachment, which rotates the shell, is placed directly back of the die-bed and is operated by the adjustable connection *E*, fastened to the gate of the press. After the ring is slipped over the die-holder, handle *F* is given part of a turn to the right which, by means of the spiral grooved arbor *G*, causes the circular disk *H* to come in contact with the ring, thus holding it in place. This circular disk rotates with the ring and is attached to arbor *G* by a pin in the hub of the disk which engages with a circular groove in the arbor.

Construction of Perforating Tools

In Fig. 8 the perforating die for the shell in Fig. 4 is shown held in a dovetail channel in the die-holder. The die-holder is preferably made of a cheap grade of tool steel, and is held in the die-bed as shown in Fig. 5. The dovetail method for holding the dies is probably the best, and is the one most commonly used. The sides of the dies are beveled at an angle of from 5 to 10 degrees. For work such as shown in Fig. 4, the die is tapered lengthwise on one side with a taper of about 1 degree, and is driven into the die-holder from the back and left flush with the shoulder of the holder, so that when in position, the die-bed prevents it from shifting back. When it is possible to do so, a pin or a fillister head screw may be used to prevent the die from shifting endwise. The shape of the shell and the design to be perforated sometimes governs the taper of the sides of the dies. This, for example, is the case where shells such as shown in Figs. 10 and 12 are perforated, when a greater angle than 1 degree must be used on account of the irregular shape of the die-holder and dies.

The longitudinal cross-section of the die-bed, die-holder and driving arbor used for the shell in Fig. 4, is shown in Fig. 5. Section *A* shows how the arbor is milled at the neck *A* in order to allow the scrap punchings to drop through. A section of the tongue of the arbor which engages the slot in the end of the shell, by means of which it is rotated, is shown at *B*. This tongue is tapered as shown, to facilitate the putting on and taking off of the work. A scrap escape hole *C* is drilled in the die-holder at an angle as shown, so as to prevent the scrap punchings from coming in contact with the shell while it is rotated around the die. An escape hole drilled in this manner can only be used on short shells and when the scrap punchings are small, or, if they are large, when they are few in number. Hole *D* in the die-bed permits the scrap punchings to readily fall out of the way.

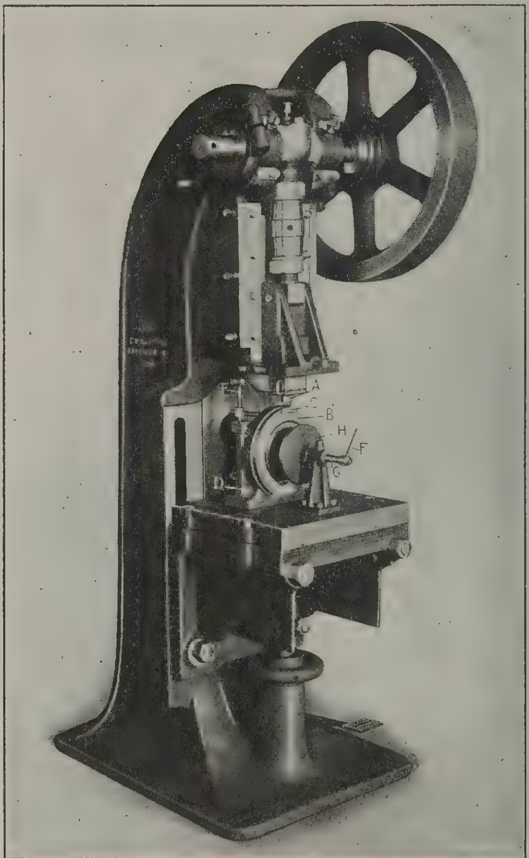

Fig. 3. Perforating Attachment with Special Device for Holding Shell in Place

The construction of the tools shown in Fig. 6 is somewhat different. Two small pins *E*, which are used in the face of the driving arbor, act as driving pins for rotating the shell. These enter into pierced holes in the bottom of the shell as shown at *B*, Fig. 7. The pawl which operates the indexing ratchet is fastened to part *B* in Fig. 6, which is made to fit the shoulder of the ratchet and works back and forth in order to provide for the required indexing. The back-and-forth motion is imparted to *B* by fastening a handle *F* to an adjustable connecting-rod which is, in turn, fastened to the crankshaft of the press. Part *D* is a brass friction which takes up the backlash of the driving arbor. This friction is fastened to the die-bed by a screw at *G*. The hole in the center of the friction fits the shoulder on one end of the

ratchet. The brake or friction effect is applied by screw *H*. Part *A* acts as a steadyrest for the driving arbor, and is fastened to the die-bed by screws *J* and *K*.

The cam fastened to the end of the driving arbor causes the press to stop automatically by coming in contact with a lever connected to the driving clutch. The driving arbor is relieved at *L* to prevent the congestion of the scrap punch-

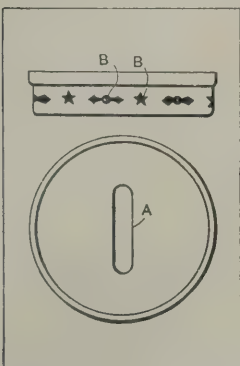

Fig. 4. Example of Shell to be perforated

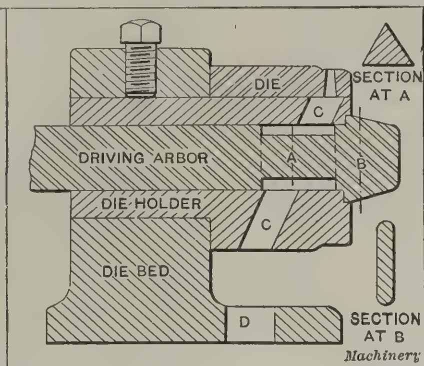

Fig. 5. Section of Die Bed, Holder and Die for Perforating Shell in Fig. 4

ings. The hole for the driving arbor in the die-holder is also recessed at this place in order to give the scrap punchings, which, in this case, are rather large, ample room to pass the arbor. When the device is in operation, a shutter *M* closes up the bottom of the scrap escape hole in the die-holder. When the shell is slipped over the latter, the shutter is forced up and thus acts as a trap, preventing the punch-

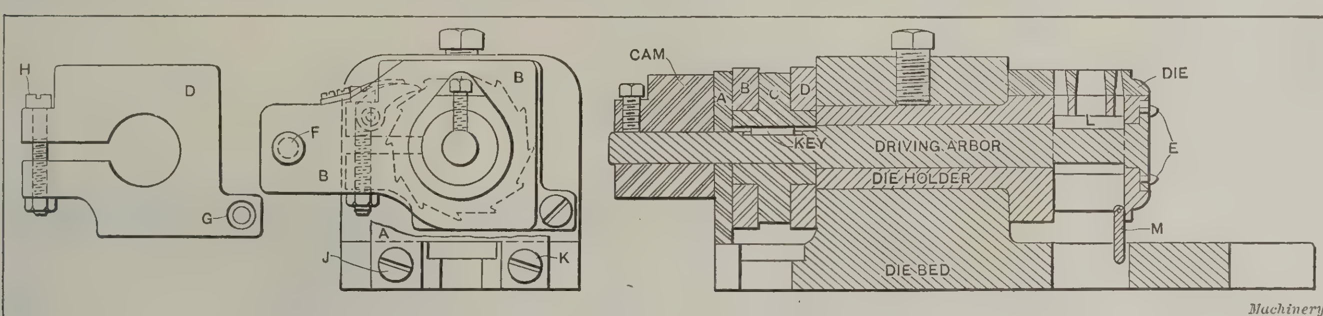

Fig. 6. Section of Die Bed, Holder and Arbor for Perforating Shell in Fig. 7

ings from dropping through into the inside of the shell. If the punchings were allowed to drop through and should cling to the perforated holes, they would cause the shell to jam and prevent it from rotating. When the perforated shell is removed from the die-holder, the shutter drops down of its own accord, thereby allowing the scrap punchings to drop out.

Perforating Shells of Tapered and Irregular Shapes

In perforating shells of tapered and irregular shapes the same general methods of procedure as already described are used, with the exception that the die-holder is held in the die-bed at an angle of 5 to 70 degrees or more with the bottom of the die-bed, the angle depending on the shape of the shell and the perforations to be made in it. In Fig. 9 is shown a die, die-holder and die-bed for work of this kind. The angle at which the die-holder is set should be such that if the outer ends of the two extreme holes in the perforating die are connected by a straight line, this line would be parallel with the bottom of the die-bed, as indicated in Fig. 10, where the points *A* and *B* are on the line which should be parallel with the base of the die-bed.

In Fig. 9 may also be seen the shell which is perforated by the die. The shell is rotated around the die by the tongue of the driving arbor engaging in an elongated hole in the bottom of the shell. The arbor is relieved at *A* in the usual manner to allow the scrap punchings to escape. No shutter is used, as the open end of the shell does not come near the scrap escape hole. The ratchet *B* which is operated by a pawl, not shown, is keyed to the driving arbor, while the friction used for controlling the backlash bears upon the shoulder of the ratchet as indicated. This shell has two rows of perforated holes, fifty-two holes in each row. Eight holes at a time are cut, or four holes in each row. The reason that four holes in each row are cut at each stroke, instead of five, six or eight, is, in the first place, that the number of holes cut at each stroke of the press must be such that the total number of holes in each row is a multiple of it. In the second place, it is not possible to get good results if the end punches are too far away from the center of the work, as these punches would strike a glancing blow. These holes would be somewhat elongated and "burry" instead of being clean, round and free from burrs. In this case, four holes in each row is as much as is practicable. Of course, if the holes are small in diameter and close together, a greater number can be cut at one time than when they are larger and further apart. If the diameter of the shells is large, a greater number of holes can also be cut at one time than with shells of smaller diameter, other conditions being equal.

In Fig. 11 is shown another set of perforating tools set up in a Bliss press. These are used for perforating the sides of the tube shown at *A* with a series of rows of small holes. These tools are of a somewhat different type from those already described. No driving arbor is used, but the shells are rotated direct from the ratchet which is placed in front of the die-bed. There may be several reasons for using this construction: When the bottom of the shell is to be left intact, no driving arbor can be used; sometimes the required shape of the shell is such as to prevent the use of a driving arbor; when the scrap punchings are so large and so numerous as to prevent them from dropping through if a driving arbor is used, or when that part of the shell that is to be perforated is very small in diameter, it may also be impossible to use a driving arbor.

Referring again to Fig. 11, it will be seen that another set of perforating tools similar to the one set up in the press is shown to the left. This is used for perforating the shell shown at *B*. The ratchet and pawl are shown at *C* and *D*.

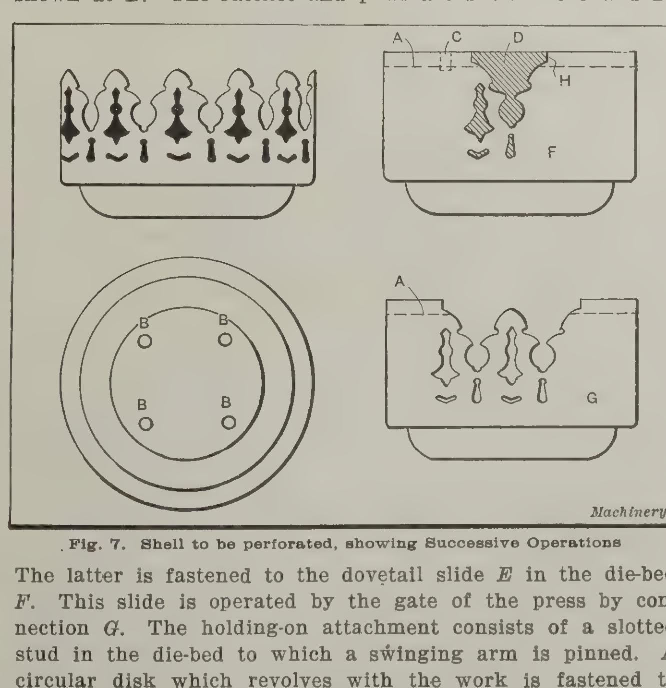

Fig. 7. Shell to be perforated, showing Successive Operations

The latter is fastened to the dovetail slide *E* in the die-bed *F*. This slide is operated by the gate of the press by connection *G*. The holding-on attachment consists of a slotted stud in the die-bed to which a swinging arm is pinned. A circular disk which revolves with the work is fastened to this arm, as is also the small handle directly in front of the

attachment. This handle is used by the operator to swing the arm up and out of the way preparatory to removing the perforated shell from the die-holder.

A method commonly used in connection with perforating tools for rotating the shell to be perforated is the dog-notch method. A dog *C*, Fig. 10, is fastened to the ratchet by screws or dowel pins. The end of this dog fits a notch *D* in the shell, called the "dog-notch." The shell is slipped over the die-holder in such a manner as to cause the dog-notch in the shell to engage with the dog on the ratchet. In this way the ratchet can index the shell directly around the die-holder.

There are also a number of other methods used for rotating shells to be perforated. Besides those already described, one may make use of an irregular shaped hole in the bottom of the shell in connection with the driving arbor. Sometimes an irregular shaped hole is required in the bottom of the shell, and in such a case the tongue of the driving arbor may be made to fit this hole, which affords a good driving means. Sometimes use is made of a coaster brake device fastened to the ratchet. The tools used in connection with this device are similar to those already described, having the ratchet in the front of the die-bed, as shown in Fig. 10, with the exception that instead of using a dog, a device working

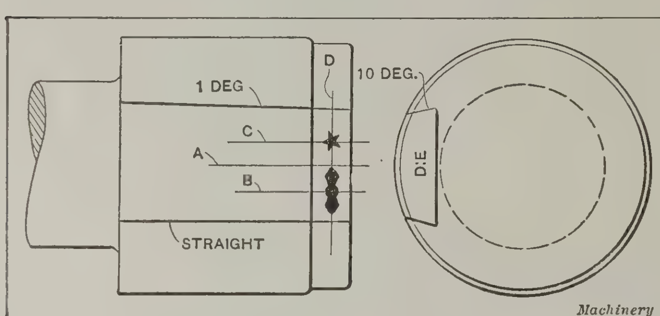

Fig. 8. Die in Position in Die Holder

on the principle of a coaster brake, such as is used on an ordinary bicycle, is fastened to the ratchet. With this device, no notch in the shell is required, as the open end of the shell is simply slipped into this device and given a part of a turn, causing it to be tightly gripped. The press is then tripped and the shell rotated around the die in the usual manner.

In cases where a dog-notch is used and where there is a tendency on the part of the shell to slip in between the dog and the die-holder, which would prevent the shell from being

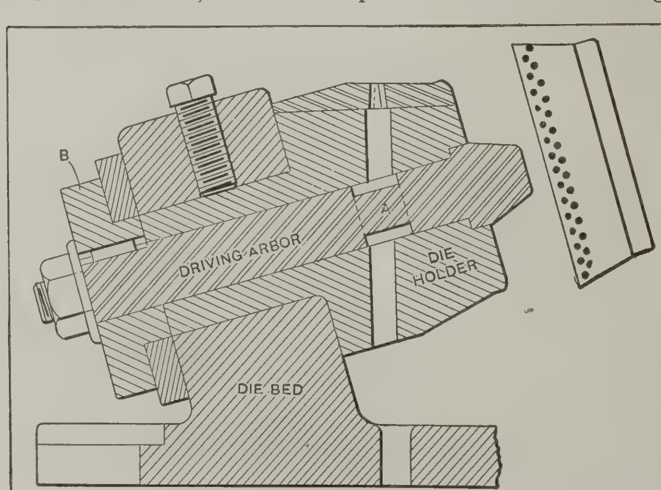

Fig. 9. Die, Die Bed and Holder for a Tapered Shell

properly rotated, the die-holder is turned down as shown in Fig. 10, and the dog is made to just clear the holder. This prevents the shell from slipping in under the dog.

The perforating die shown at *H* is held in the die-holder in the usual way, and is tapered lengthwise at a suitable angle as indicated. In order to afford a support for the die when in use, the bottom of the dovetail channel upon which the die rests is worked out so as to conform tó some extent to the shape of the bottom of the die. This is done on dies where the holes are close together, so as to support the narrow bridges that separate the irregular shaped holes in the die. The best way to do this work is to first work out an open space under the dovetail channel. This space is used for holding the scrap punchings that are prevented from dropping through by a shutter. In working out this space

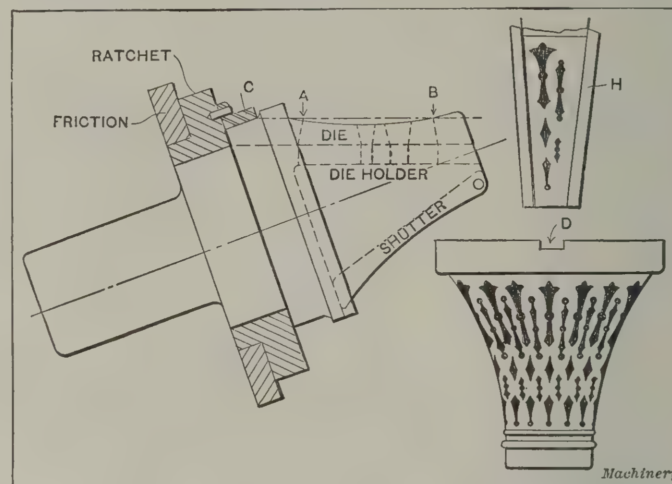

Fig. 10. Die and Holder for Perforating Shell shown to the Right

enough stock is left under the dovetail channel to support the die properly, as indicated in Figs. 10 and 12, after which the openings through which the scrap punchings from the die drop are worked out. The shutter which is shown closed in Figs. 10 and 12, swings open on the shutter pin as soon as the perforated shell is removed from the die-holder.

The construction of the tools in Fig. 12 is similar to that of those just described. At the right is a plan of the die, showing the manner in which the die is tapered lengthwise, which in this case is six degrees on each side. When

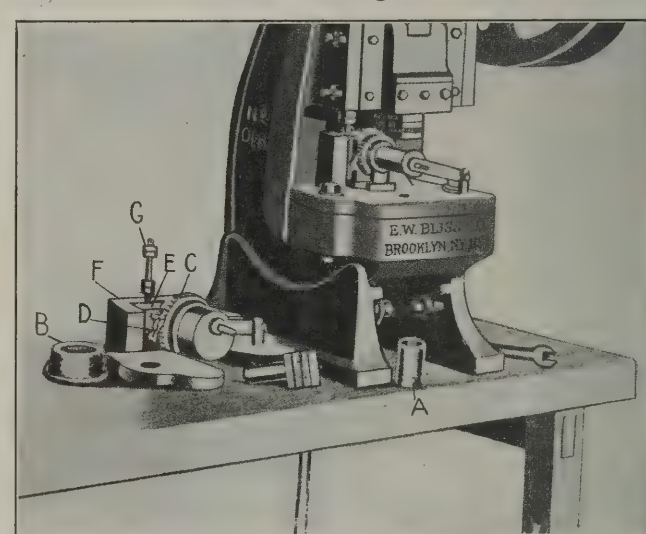

Fig. 11. Tools for Perforating Special Cylindrical Shells

the tools shown in Figs. 10 and 12 are in operation, two rows of holes are cut at every stroke of the press until the shell has completely rotated around the die and all the required rows of holes have been punched out. No device is used with these tools for holding the shells in place while they are rotating around the die, because the position of the die-holder in the die-bed makes it easy for the operator to keep the shell in place.

It sometimes happens that a perforated shell of the general type shown in Fig. 7 is required, with the exception that the bottom is left intact and therefore cannot be used in connection with a driving arbor for rotating the shell. In such a case, the shell is dog-notched and rotated in the manner already described, with the exception that the locating of the dog on the ratchet preparatory to perforating the shell forms an important part in the successful operation of the tools. The reason for this is that when cutting out the scallops of the shell, the dog-notch *C*, Fig. 7, which is used for rotating the shell must necessarily be cut away from the

shell, and must, therefore, be placed in such a position that it will come in the center of the large scrap punching which will be cut out at the last stroke of the press, completing the operation. If the shaded portion shown at *D* in Fig. 7 is the punching resulting from the first stroke of the press, and if the blank is rotating from right to left, then the dog-notch must be located at *C*, central between the two scallops completed by the last stroke of the press, after the whole shell has been perforated.

In order to prevent the punch *A*, Fig. 14, which cuts out the scrap punchings *D*, Fig. 7, from coming in contact with the dog, a short slot is milled in the center of the face of the punch at the back end near the ratchet, so that the punch will clear the dog when that part of the shell containing the dog-notch is cut out.

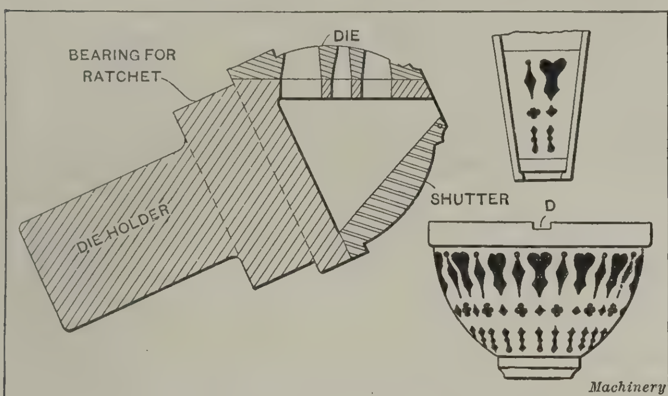

Fig. 12. Die and Holder for Perforating Shell shown

Lay-out of a Perforating Die

Preparatory to laying out the die shown in Fig. 8, the die-blank is carefully fitted to the dovetail channel in the die-holder, after which it is turned up in the lathe in place and highly polished. It is then removed from the die-holder and blued by heating, and again driven into the die-holder, after which it is ready to be laid out. The die-holder is then mounted in the milling machine, the index head in this case being set for twenty-eight divisions, as there are fourteen perforated holes of one design and fourteen of another. With a surface gage and by aid of the index head, the center lines *B* and *C* are scribed. Line *A* is merely drawn to show the center of the die, and the center of each one of the holes in the die should be an equal distance from this line. Center line *D* is next scribed the required distance from and parallel with the face of the die-holder.

In laying out the hole on the center line *B* a small circle of the exact diameter of the circular opening in the center is first scribed. The diamond-shaped ends are next laid out and scribed. The star-shaped hole on the center line *C* is laid out from a master punch which conforms to the required size and shape. In cases where the required number of shells to be perforated does not warrant the making of a master punch, the dies are laid out from the star-shaped punch that is used in connection with the die.

In working out the die, the central hole from which the star design is made is first drilled and taper-reamed from the back to the size of the teat on the master punch, which is equal to the diameter of the circle passing through the bottom of the grooves in the star. The teat of the master punch is then entered into the die and the punch set and clamped to the die so that a point of the star is on line *C*. The outline of the punch is then scribed on the face of the die, after which the die is worked out and fitted to the punch. In order to facilitate matters, the punch is used as a broach after the die is filed to shape. In working out the other hole in the die, on line *B*, a hole is first drilled and taper-reamed from the back for the circular opening in the center. Two holes are drilled and reamed in the center of the diamond-shaped ends. The surplus stock between the drilled holes is then removed and the hole filed to the desired shape.

There are two ways in which a die such as that shown in Fig. 13 may be laid out. One is to lay out the die on a milling machine in a manner similar to that already described. The other, which is most commonly used, is to lay out the die by scribing the design on its face from a master shell which is slipped over the die-holder and has the shape to be perforated upon it already worked out.

The master shell itself is laid out as follows: The shell is fastened to the die-holder by a few drops of soft solder to prevent it from moving. The die-holder is then mounted in the milling machine. The index head in this case is set for twenty-four divisions. In Fig. 13 is shown the laying-out of the die, but the same method applies to the shell. With a surface gage used in connection with the index head, the lines *A*, *B*, and *C* are scribed on the shell. Lines *A* and *C* represent the centers of two adjoining scallops, and line *A* is also the center for the two holes *I* and *H*, while line *B* is exactly in the center between two scallops and constitutes the center line for hole *G*. The lines *E* and *D* are next scribed on the shell, the former representing the height of the ears of the projecting scallops, while the latter shows the height at which the lower curved portions of the pointed scallops converge. After these construction lines are scribed on the shell, the design is readily laid out. The shape of the design is then worked out by drilling and the surplus stock is removed by means of a jewelry saw. The shell is then filed to the desired shape and when completed should be a duplicate of the portion cut out by the first stroke of the press, as shown at *F* in Fig. 7. In filing out a design, care should be taken to file out all the holes central with the center lines *A*, *B* and *C*, and also parallel with a plane passed at right angles to the center of the design, through the shell, in order that the holes may be at their exact required position on the inside of the shell.

It will be noted in Fig. 13 that the large hole *F* in the die is extended past the line *D;* this is done in order to make sure that the large scrap punching *D*, Fig. 7, will be completely cut from the shell. This is especially necessary when the shells vary in length. The dotted line *A*, Fig. 7, is drawn so as to more clearly show the length of the twelve pointed scallops, and their relation to the top of the shell.

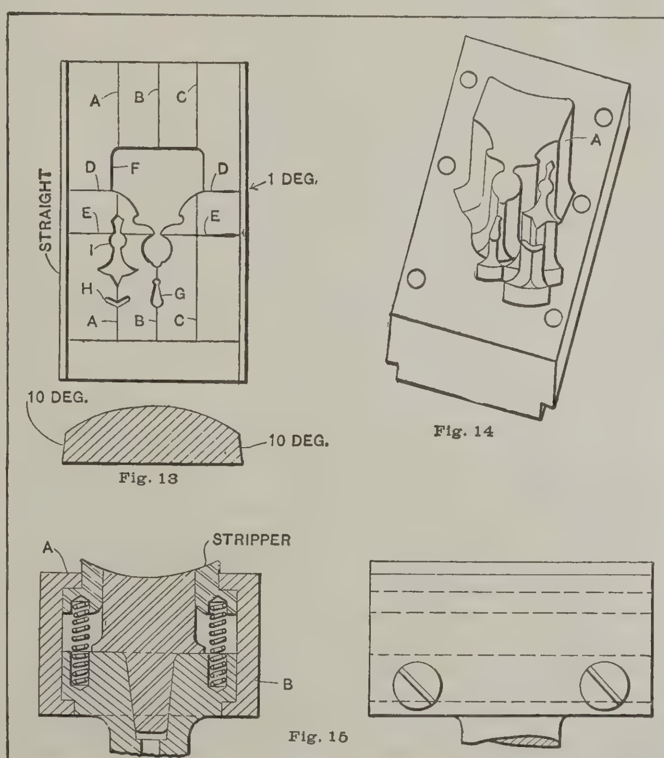

Fig. 13. Laying out a Perforating Die. Fig. 14. Perspective View of Perforating Punch. Fig. 15. Punch Holder and Stripper, showing Punch, Fig. 14, in Section

In drilling and working out the surplus stock in the die Fig. 13, the same general methods that are used for working out an irregularly shaped blanking die are used. First, remove as much of the surplus stock as possible by drilling. When drilling out the surplus stock in the hole *F*, the smaller of the two circular openings between the scallops is first drilled out and taper-reamed from the back to the finish size.

After this, the hole is plugged with a small taper pin that is filed to fit it, and the large hole is drilled and taper-bored in a lathe. The round corners at the opposite end of the hole are then drilled out. These corners are left circular in order to add to the strength of the die and to prevent cracking of the die in hardening. The remainder of the hole is drilled and worked out in the usual way. In working out the small holes G and H, the opposite ends are first drilled and taper-reamed to the finish size, after which other holes are drilled and reamed and the surplus stock is removed with a small broach or jewelry saw preparatory to filing out the die. Hole I is drilled out and the surplus stock removed in a similar manner.

Filing Out the Die Shape

A die used for perforating the sides of cylindrical work is rather awkward to hold, either in the vise or in die-clamps while being filed out, owing to the fact that the face of the die is circular in shape and the sides are dovetailed. For this reason, a die-holding fixture, shown in Fig. 16, is used to hold the die in the vise, die-clamp, or filing machine

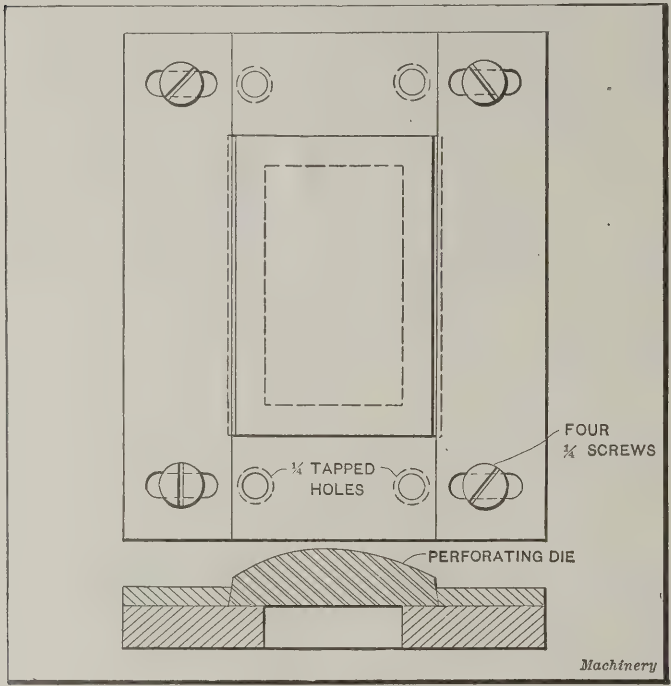

Fig. 16. Device for Holding Perforating Dies while Filing

while it is being filed out. The device shown is adjustable to accommodate various widths of dies.

The most essential points to be remembered when filing out a perforating die are: Use a coarse file for the rough filing and finish with a smooth one. Take care to have the clearance filed straight in order to prevent the congestion of scrap punchings in the die; perforating dies as a rule are not very strong and are often cracked and broken because of neglect on this point. The clearance should not be filed over 1½ degree, in order to make the die as strong as possible; in cases where the holes in the dies are close together even less clearance is necessary, and a very narrow wall that separates two holes is filed almost straight on each side, with just enough of a taper to clear. Care must be taken when filing to prevent the back or the sides of the file from running into that part of the die that has already been finished.

Making the Punch for a Perforating Die

The punch used with the die shown in Fig. 8 is comparatively simple in its construction. It consists of the usual form of punch-holder into which the two perforating punches are driven. The star-shaped punch, after it is fitted to the die and hardened, is driven into the punch-holder in such a position that when it is entered into the die the sides of the punch-holder will be in a straight line and parallel with the die-bed. The tools are then set up in a hand or foot press so that the die and star punch are in proper alignment with each other. The foot treadle of the press is then disconnected from the gate so that the gate which holds the punch-holder in place can be withdrawn from the press without disturbing the punch-holder or the ways upon which the gate slides. The other punch, in its unfinished state, is then driven into the punch-holder and the face is coated with a 1/16-inch thickness of soft solder. The gate of the press is then slipped back into place and the impression of the outline of the die is transferred to the solder on the face of the punch. The punch-holder is then removed from the press and the punch driven out and milled to conform to the soft solder outline of the die, after which the punch-holder is put back into the press, care being taken to see that the star-shaped punch is in proper alignment with the die. The milled punch is then put back in place and gradually sheared and fitted to the die. Each time after the punch has been lightly sheared into the die, the fins and surplus stock are removed and the punch is again entered and sheared a trifle deeper, until it enters the die at least ¼ inch.

The hand or foot press is very convenient to use when fitting perforating punches to their dies, because the construction of the press makes it possible to handle the gate conveniently and to keep the punches in proper alignment with the die.

In making perforating punches such as shown in Fig. 14, the punch-holder is first machined to the desired shape and size, after which the taper hole for the shank of punch A is reamed. The shank of the punch is then turned and fitted to the punch-holder and driven into place. The face of the punch is made to conform to the outside diameter of the shell and is then clamped to the face of the die and the outline scribed on it, after which it is milled to shape and sheared and fitted to the die. Before scribing the outline of the die on the face of the punch, care must be taken to see that the punch is set in the proper relation with the die, so that when the finished tools are set up in the press, there will be no necessity for elongating or widening the slots in the die-bed used for clamping the die to the bed of the press, due to the punch not being laid out central with the die.

After the first punch A has been fitted to the die, the holes for the other three punches are laid out so that the cutting part of the punches will be as nearly central with the shanks as possible. Holes are then drilled and reamed for the shanks, and when this is done punch A is hardened. The reason that this punch is hardened before the other punches are fitted to the die is that if the punches were all sheared and fitted together and then punch A should spring in hardening, it would cause great difficulties in again bringing the punches into proper alignment with the die. After punch A has been hardened and driven back into the punch-holder, the shanks of the other three punches are turned up and fitted to the respective holes into which they are afterwards driven. The shanks of these punches may be made either straight or tapered, but should be a good driving fit and should have shoulders bearing against the punch-holder.

Before the punches are driven into place, the die and punch A are set up in the foot press and properly aligned with each other. The gate of the press is then withdrawn, the three punches are driven into place, and the faces coated with soft solder. The gate of the press is then slipped back into place and the outline of the die transferred to the punches, after which they are driven out and milled separately in the milling machine. Sometimes the punches cannot be driven out from the back of the punch-holder, because if the holes for these punches were drilled through they would run into and weaken the shank of the holder. In such cases holes are drilled from the side to meet the shank holes, in order to allow a taper drift to be used for starting the punch so that it can be removed.

After the punches have been milled, they are driven back into the punch-holder and are sheared and fitted into the die, as previously described. The punches, of course, are lined up perfectly with the die so as to enter into their respective holes as one single punch. After the punches are hardened they are sharpened by holding the punch-holder in a special grinding fixture and drawing the punches back and forth across the face of a wheel of about the same diameter as the shell to be perforated. It will be seen in Fig. 14 that the base of the punches is strengthened by milling the punches so that there is a liberal fillet between the shoulder

of the punch and the milled-out shape. This also tends to prevent distortion in hardening.

The Stripper

The stripper serves three purposes: it strips the metal from the punch; it supports the small punches by preventing them from springing; and it tends to keep the perforated shell in shape by preventing it from bending or becoming "kinked up." The commonly used stripper construction is shown in Fig. 15. The face of the stripper conforms to the outside diameter of the shell. It is drilled and worked out so that it is a sliding fit on the punches. The shoulder part of the stripper bears against the bottom lugs of the side pieces *A* and *B*, which are fastened to the punch-holder and prevent the stripper from being forced off the punch. Six spiral springs exert the required pressure on the stripper. When setting up the tools in the press, the stripper is forced back about ⅛ inch and two pieces of, say, No. 31 drill rod are placed between the stripper and the bottom lugs of the side pieces, which keeps the stripper out of the way while the punch and die are aligned with each other.

In conclusion, it may be mentioned that perforating dies of the type described are sharpened on universal grinding machines. Owing to frequent sharpening it is sometimes necessary to raise them slightly by putting shims of sheet steel under the dies. These shims are drilled and filed out to conform to the holes in the dies, in order that the scrap punchings may drop through.

INTERESTING DEVELOPMENT IN HIGH-EFFICIENCY GENERATORS

In speaking before the American Society of Swedish Engineers, Brooklyn, N. Y., on "Generating Apparatus used for Wireless Telegraphy and Telephony," Mr. E. F. Alexanderson, of the General Electric Co., Schenectady, N. Y., described an interesting type of machine which he has developed for obtaining very high frequencies. In the generator described, a steel disk resembling the rotor of a steam turbine and having six hundred slots, is used. This steel disk rotates with its edge between the pole faces of the stator, at a speed of 20,000 revolutions per minute. Brass plugs are riveted into the space between the steel teeth in order to reduce the air resistance. The diameter of the steel disk is 12 inches. The generator is driven from an electric motor by gearing similar to that used for reducing the speed in De Laval steam turbines, except that in this case the gearing is used for increasing the speed. With this machine it is possible to obtain 100,000 alternations per second and with the aid of a special winding and 800 polar projections on the disk, 200,000 alternations per second have been obtained. High-frequency generators of this type will probably prove especially valuable in wireless telephony, the success of which depends largely upon the possibility of producing currents of high frequency. The development is also of great value in the wireless telegraphy field as it makes possible the sending of messages over greater distances, and also provides a means for non-interference with other wireless apparatus, as it is possible to tune the various instruments so as to receive only certain messages, in a way not possible with the lower frequencies produced by the spark system.

* * *

The discovery of means for burning explosive gases, that is, gases mixed with air just sufficient for perfect combustion, described in the May number, was, it appears, erroneously attributed to Prof. William A. Bone of Leeds University, Leeds, England. Prof. Charles E. Lucke of Columbia University, New York, described the same process, in effect, in a paper presented before the American Society of Mechanical Engineers in 1901. Prof. Bone's work, which showed the possibility of attaining temperatures from 2900 to 3600 degrees F. on the surface of porous firebrick with great economy of gas, appealed more to the popular mind as having direct application to cooking and heating. Hence the great interest in the idea.

* * *

Repeated melting of manganese bronze gradually lowers the ultimate strength and elastic limit as well as the hardness of the metal.

SOME TOOLS USED IN THE MANUFACTURE OF SMALL STEEL BALLS*

By A. G. BLACK†

Very small steel balls—say of from 1/32 to 1/16 inch in diameter—are handled in a somewhat different manner when being manufactured than are the larger sizes. The reason for this is simply that more delicate machinery is required on account of the small sizes dealt with. The best idea of how small a 1/16-inch ball really is may be gathered from the fact that there are 28,840 balls of this size to a pound, or about 1800 balls to an ounce. Comparing this with 1/2-inch balls, we find that there are only fifty-five in a pound, or less than four in an ounce.

In the following will be described the methods that were used in a factory with which the writer was connected several years ago, for making balls of small sizes.

The forgings were made from annealed crucible steel wire, the diameter of which was about 0.002 inch smaller than the diameter of the finished ball. The stock was upset enough in the forging operation to make the blank about 0.010 inch

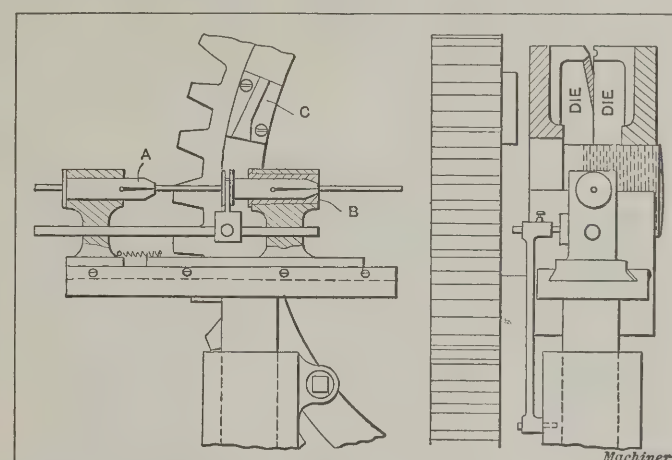

Fig. 1. Diagrammatical Outline of the Main Features of the Ball Blank Rolling Machine

larger than the finished ball. The forgings were made in a Simonds forging machine, of the same general type as described by Mr. Grant in the February number of MACHINERY, in the article entitled "The Manufacture of Steel Balls." The machine was remodeled, however, to use the platen style of die as shown in Fig. 1, this being accomplished by cutting off the extending projection on the large driving gear and mounting one-half of the circular die on the hub of the gear, the other half being mounted on the shaft that projected through the center of the hub and revolved in the opposite direction. A gas jet was located near the point on the dies where the stock entered. In this way the stock was heated to the required heat for rolling.

The wire was furnished in a coil and fed off from a reel, an automatic feeding device being provided having one stationary, spring chuck *A*, Fig. 1, and one sliding spring chuck *B*, similar to those used on automatic screw machines. A cam *C* was provided on the side of the main driving gear to open and close the sliding chuck. When the stock fed into the dies, the cam opened the chuck and also carried it back against the action of a spring for another feed, and locked it ready for the next cycle. The stationary spring chuck held the stock from moving while the rolling operation took place. The machine could cut off and roll 75,000 blanks per day.

After the forgings were made, the blanks were passed between two large hardened revolving plates in order to remove any fins or inequalities in the blank. They were then hardened before grinding, which latter operation was done in a machine similar to the dry grinder described by Mr. Grant, except that the machine was smaller. The writer also added an improvement which consisted of a spring suspension of the upper ring which rotated the balls as indicated in Fig. 2. Four coil springs *A* were mounted between the upper ring

* See "The Manufacture of Steel Balls," MACHINERY, February, March, and April, 1912.
† Address: 53 Westford Ave., Springfield, Mass.

and a plate above it as shown, the upper ring being driven from this plate by four stud bolts. In this way it was possible to place any amount of pressure required upon the balls. With this arrangement the emery wheel and the rings would last much longer, because of the reduction of wear, as the upper ring was allowed to spring away from the wheel when a new set of blanks, which were not absolutely round, were first put into the grinder.

Another improvement consisted in making an adjustable emery wheel fastening for preventing the emery wheel from running out of balance, due partly to the inequalities of the wheel itself and partly to the wear of the spindle bearings.

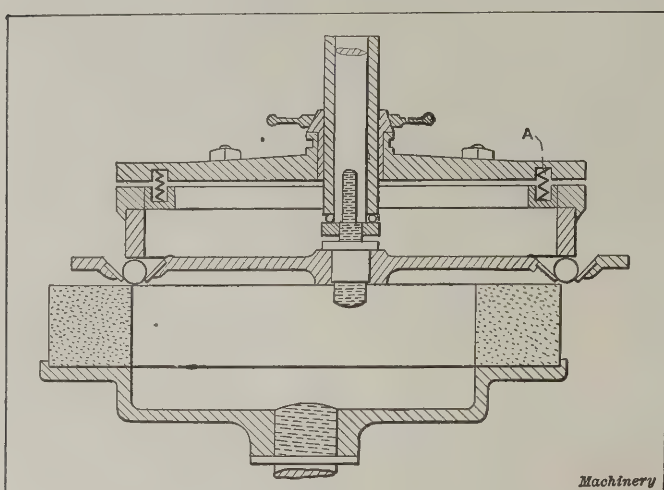

Fig. 2. Spring Balanced Dry Grinding Machine

An arrangement was introduced consisting of four wide jaws in the wheel plate, as shown in Fig. 3, which gripped the edge of the wheel in a manner similar to that of a lathe chuck, but which had surface enough to cover a fair portion of the wheel diameter. In this way, the wheel could be adjusted and balanced every time a new wheel was mounted.

The balls were dry ground to within 0.002 inch of the finished size, after which they were lapped with emery and oil, using a set of cast-iron rings. These were fitted to sensitive bench drill presses arranged in banks of six, attended by one operator. After the oil finishing grinding, the balls were polished and inspected. This last operation was done by an auto-

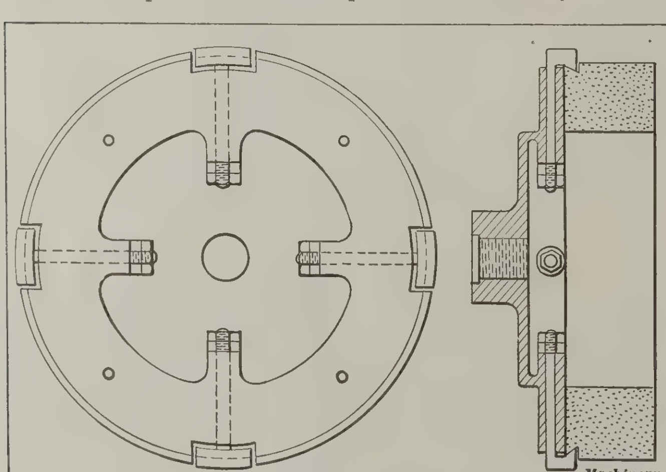

Fig. 3. Faceplate and Chuck-jaws for Holding Grinding Wheel

matic device which the writer designed and built, the outlines of which are shown in Fig. 4.

The principle of this machine was to feed the balls from a hopper under a fixed magnifying glass about 2¾ inches in diameter, focused to suit the operator. The balls would then remain under the glass for six seconds. The operator held a steel magnet in each hand, and with her elbows or arms resting on the table at each side of the glass lens, was ready to pick out any balls which appeared defective to her. If they were all perfect, she would merely wait until the balls turned half a revolution, exposing the other half for six seconds more. Then, in order to expose the periphery whch had not yet been directly under the inspector's view, the balls were turned one-quarter of a revolution so as to bring the part but imperfectly seen in the two previous operations squarely under the glass; then another half turn was made and in that way all the parts of the balls were exposed and could be carefully inspected. After this, the feeding plate would draw out from under the glass and the balls would fall into a drawer, after which the plate would be returned to the hopper, bringing out another lot of balls ready to be inspected. This last operation required also six seconds, which gave the operator an opportunity to temporarily rest her eyes.

The various movements were timed by a cam. When changing from one size of ball to another it was only necessary to slip off one cam and put in another adapted for the desired size, and also to change the feed plate. The device permitted of inspecting balls ranging in size from 1/16 to 1/2 inch diameter. The method was very efficient and six girls were able, in this way, to handle the work which required twenty inspectors to do in the old way. The method was also more positive, and the chances of defects slipping by the inspector were not as great, as each ball was fully exposed to view from all sides.

Some of the cam motions mentioned, as, for instance, that for feeding the balls from under the hopper, were constant

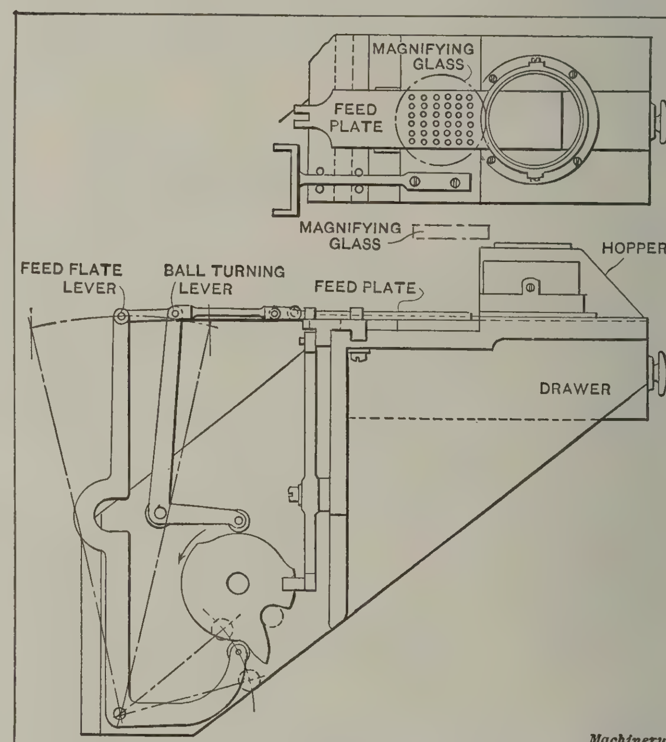

Fig. 4. Main Features of Ball Inspecting Machine

for all sizes of balls, but the cam operating the sliding plate that rolled the balls over was different for different sizes, as the plate had to travel further for the larger balls than for the smaller. The lens of the magnifying glass was large enough so that one could see 64 one-quarter-inch balls conveniently, and as there were often but one or two of these balls to be picked out at each movement, the operator had plenty of time, and with both hands free could pick them out very rapidly. A lever was also provided to throw out a clutch mounted on the driving pulley hub, so that the operator could stop the machine immediately, if necessary.

One difficulty that had to be overcome consisted in the balls clogging and refusing to roll out from a small opening. This difficulty was overcome by bridging over the outlet by a partial baffle; then the balls would easily feed out in the shallow depth under the bridge where they were always free to roll out and drop down an incline. This prevented clogging and no agitator was found necessary. The device was never patented because the president of the concern with which the writer was employed believed that if a patent was applied for the principle would become known to all ball manufacturers, and they would work out the same idea in a somewhat different manner. The gaging was done by a machine similar to that illustrated by Mr. Grant.

WATCH CASE MANUFACTURE—2

Before a watch case is fitted up, that is, on a hinged case, before the cap, back and bezel are joined, it is necessary to fit and solder the pendant into the case center. The majority of pendants on watch cases are made from rolled-plate in two pieces, but some are made in one piece by a number of successive press operations. The pendant is used for holding the bow and the stem setting mechanism.

The crown *b* shown in Fig. 8, which is used for operating the setting mechanism, is also made from rolled plate. The press operations on this part have previously been described in the December, 1909, number of MACHINERY, so that a short summary of the most important operations will be sufficient. The first operation is to make a blank and draw it up into a

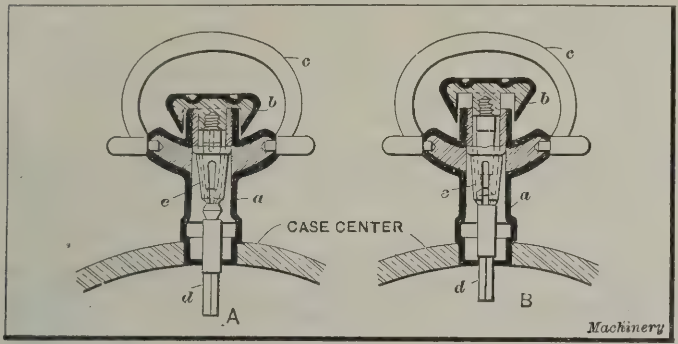

Fig. 8. Pendant Set in the "Up" and "Down" Positions

cup, both operations being accomplished at the same time in a double-action press. This cup is then cut to the desired length in a small sawing machine, after which it is passed through a corrugating die. A core of the required shape, which has been made in an automatic screw machine and corrugated in a die in the punch press, is then inserted and the two parts—cup and core—are placed in a swaging die. The upper part of the die is so formed as to shape one end of the crown, while the lower die forms the other end.

After the crown is completely formed, it is taken to an automatic screw machine where it is counterbored, drilled and tapped to fit the pendant and pendant set. This machine is equipped with a magazine attachment which was illustrated in an article entitled "Magazine Attachments—1," in the February, 1912, number of MACHINERY. This, with the exception of polishing, completes the operations on the crown.

The bow *c*, Fig. 8, or ring, as it is sometimes called, is made from either solid gold or gold-plated stock, drawn out into wire. Bows made from solid gold are used on solid gold watch cases, and also on some filled cases. The operations followed in making the solid bow are simple and need no description. It might be well, however, to state that it is first blanked from the flat sheet about 1/16 inch thick to approximately the desired shape, then the center is pierced out, and finally, it is completely formed in an embossing die held in a hydraulic press. The flash is then trimmed in a trimming die and the inside ends of the bow milled on a milling machine to fit into the holes in the pendant.

The operations for making the bow from drawn wires are a little more difficult. The material from which the bow is made is first blanked out and drawn up into a cup, and then by successive drawing operations, it is extended to such a length that it can be completely drawn in a draw bench. The drawn wire is then cut up into pieces of the desired length and drawn up in dies. After this operation, the bow is bent around to the desired shape in a simple bending fixture. As bows are generally plain and have no small crevices to polish out, the polishing is very easy.

Construction and Operation of the Pendant Set

On watch cases provided with a pendant set, it is necessary to pull out the crown before the hands can be rotated independently of the motion transmitted to them by the gear train. Some means, however, has to be provided so that the crown cannot be easily pulled out, or the utility of this simple device would be destroyed. This is accomplished by screwing a stem *d*, Fig. 8, provided with a cone shoulder into the crown, and also screwing a split "chuck" *e* into the pendant *a*. Now before the crown, which is shown "down" at *A* can be pulled out, the split chuck *e* has to be expanded as at *B*, by the cone shoulder on stem *d*, the necessary pull being sufficient to prevent the setting mechanism from being operated accidentally.

The stem *d* presses on another squared stem which is used in operating the setting mechanism (see "Setting Mechanisms" in the May number of MACHINERY), and when stem *d* is pulled out by the crown as shown at *B* it allows the setting mechanism to operate the hands.

Polishing Watch Cases

A watch case, as a rule, is given a very high polish and is free from scratches and imperfections. The methods employed in polishing a watch case are interesting, and as they differ slightly from other polishing work, it might be well to give a short description of the materials used and the order of the operations. After the case is jointed and assembled, it is rough polished on a rag wheel with dry tripoli, also called "rottenstone," on it. For additional rough polishing, a hair brush is used and lard oil and tripoli are applied as an abrasive. The second polishing of the inside of the cases is accomplished with an elk skin polishing buff supplied with rouge and alcohol. The outside of the case is polished with a rag wheel and rouge. The center of the case is brushed with a hair brush and hard rouge.

The third polishing is done after the case has been pinned and fitted. The inside of the back and cap are polished with elk skin, soft rouge and alcohol, the outside of the case being

Fig. 9. Hand-operated Engine Turning Machine

polished with a rag wheel and hard rouge. All plain parts and shields are polished with rouge and elk skin, after which an additional polishing is accomplished with soft rouge; then the cases are washed in ammonia water and soap and dried. The drying is done in a heated drying box. After being dried the cases are cleaned with chamois and then sent to the inspector who examines them to see that everything is perfect. The case also passes through numerous other inspections during the course of its manufacture.

Engine Turning

Engine turning, another name for engraving by machinery, consists in cutting various designs or patterns on the backs of a watch case or bezel. Thousands of patterns are cut, and the designs vary considerably. Some types of patterns, of course, require slightly different methods for their production

and in many cases patterns can only be cut on certain types of machines, or hand engraved. There are at least six distinct types of engine turning machines employed on this work. Three of them, the most interesting ones, will be described in the following.

Hand-operated Engine Turning Machine

The engine turning of the straight-line variety cut in the backs of watch cases is accomplished in the hand-operated machine shown in Fig. 9. The back or bezel, whichever it may be, is held in a chuck *A*, which, if desired, can be rotated by hand or can be indexed by thumb-screw *B*. The screw on which thumb-screw *B* works, has a worm formed on its lower end meshing with a worm-wheel on the head. This device is brought into play when it is desired to cut lines crossing each other at right angles or any other angle.

For producing straight-line work on this machine, the vertical slide carrying chuck *A* is simply moved up and down by the operator, by means of the hand-crank *C*. The motion from this crank is transmitted by grooved pulleys, belting and chains to the vertical slide *E*. This slide is kept in the "up" position by a weight attached to a string *F*, which runs over the grooved pulleys *G*.

The table *H*, carrying the tool-slide *I* in which the tool *J* is held, has a circular adjustment, so that the center line passing through the point of the tool is always at right angles to the face of the back being operated upon. This adjustment is controlled by the knurled thumb-screw *K*, which is rotated by the operator a slight amount after each cut. The tool-slide *I* is advanced to bring the tool in contact with the work by hand, the operator gripping the spring "handle" *L* by the first finger and thumb. The depth to which the tool advances into the work is governed entirely by the pressure given to this slide; and it requires considerable experience before an engine turner can produce lines of a uniform depth. It is simply a matter of "fine touch," as no stop is provided for the forward movement of the slide. The slide is returned by a spring which is compressed when the slide is advanced. The work is viewed while under progress through the magnifying glass *M*.

Various patterns are secured by irregular faced strips *N* held vertically in the slide *O*. This slide can be moved to bring any desired pattern into operation by means of a hand-wheel, not shown. The patterns impart an oscillating movement to the head (which is also equipped with a horizontal slide) at the same time that it is moved up and down by the hand-crank *C*. The spacing of the lines is effected by a pawl and ratchet, not shown, which move the slide carrying tool *J* along, giving any desired width of spacing.

Electrically-operated Engine Turning Machine

The engine turning machine illustrated in Fig. 10 is electrically operated and is used for producing the "barley corn" engine turning, as it is called. The back that is being engine turned is held in a split chuck *A* which is tightened on the work by a knurled nut. The entire mechanism is driven from a shaft under the machine, which, in turn, derives power from the countershaft through belting.

The spindle *B*, which carries the work and is rotated by spur gears from the lower shaft, is mounted in an oscillating head *C* called a "cradle." This head receives its oscillating motion from a cam held on the lower shaft, which is provided with a series of projections and depressions that impart the oscillations to the head. The "electric pattern" *D*, as it is called, is driven by spur gears from spindle *B*. The tool-slide *E* that carries the holder in which a cutter is retained is also operated from spindle *B* through spur gears, a universal joint and bevel gearing.

The electric pattern *D* is made by engravers who cut out the portion to be "barley-corned" and fill the depression with a non-conductor of the electric current. A steel needle *F*, under spring tension, runs or is pressed against this pattern and is fed in from the outer circumference towards the center at the same rate of travel that the tool makes across the face of the work, the latter also being traversed in the same direction.

The tool-slide *E* which is operated in the manner previously described, carries a taper guide which through a roll, lever and crank, forces up the rod *G* carrying needle *F*, at the same time as the tool is fed from the outside circumference to the center of the work. This system of levers and cranks constitutes a pantograph arrangement which can be changed to reduce the pattern for any size of watch case. The roll is kept in contact with the pantograph form, so that the motion transmitted to the cutting tool will conform to the shape of the back, by means of a string *H* to which a weight is attached.

In operation, as the needle *F* passes over the non-conductor on the pattern *D*, the electric circuit passing through the armature *I* is broken so that plate *J* flies back, and in so doing operates the tool-slide *K* through lever and crank connections, thus forcing the tool into the work. When the needle *F* passes over the brass portion of the pattern the circuit is closed and the reverse action is imparted to the tool-slide *K*, that is, the tool is withdrawn from the work. This

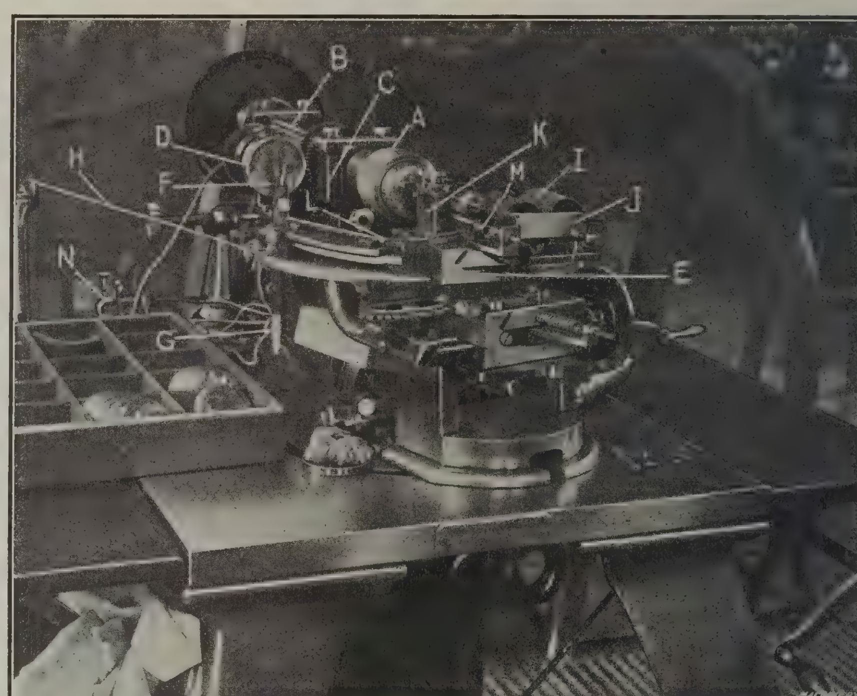

Fig. 10. Electrically-operated Engine Turning Machine

action is repeated until the engine turning is completed, when the machine is automatically stopped.

The tool-slide *K* is withdrawn to remove the work by a handle *L* which, when pulled back, brings back the slide and releases it from the tension of the spring *M*. This spring has sufficient strength to keep the tool in contact with the work, when the electric circuit is broken. The barley-corn effect is governed, of course, entirely by the cam on the shaft under the machine, but the pattern can be made either coarse or fine as desired, by altering the change gears that transmit motion from the spindle *B* to the main tool-slide *E*.

Swiss Brocade Machine

The interesting machine shown in Fig. 11 is for "brocade" or "Swiss machine" work, as it is called, which is simply a special class of engine turning resembling in appearance the regular work on currency bills, which is produced by a geometric lathe. This brocade machine was designed and built in Switzerland and is a marvel of mechanical ingenuity. As an engine turning machine its possibilities are practically unlimited, and it is doing away with a large amount of the work previously accomplished by skilled engravers. The work, when being operated on, is held in a split chuck *A* by a knurled nut. The power for operating the entire mechanism is transmitted from a countershaft by round belting running over grooved

pulleys C, D and E, up to the main driving shaft at the rear, not shown. This shaft drives the front shaft F, which through change gears G operates the spindle carrying the work. This spindle can be centered, that is, located in the desired relation to the other mechanism when starting a pattern, by means of the screw and worm-wheel H; this turns around the sleeve or spindle carrying the work.

This machine is supplied with two pattern plates I and J. Plate I is made of hard rubber and is called the outline pattern plate, while plate J is made of cast brass and is called the filling-in pattern plate. Plate I is rotated by a spur gear held on a shaft at right angles to the rear driving shaft, and is driven from the latter by bevel gears. Plate J is also driven from the shaft which is at right angles to the rear driving shaft, through bevel gears and change gears K.

The faces of plates I and J are provided with the desired patterns and transmit up-and-down oscillating movements to the tool carrier M. The movement is transmitted by steel points held in vertical brackets N (only one can be seen), which are fastened to a dovetail-shaped bar operated by a pantograph arrangement. From this bar, motion is transmitted through a universal joint and a shaft running parallel with and under the tool-slide M. As tool-slide M is fulcrumed at a point directly under the point of the cutting tool, it is consequently given an up-and-down oscillating movement by means of this shaft and levers connected to it. By changing the position of the ends of the universal joint, the tool O can be put into the work to any desired depth.

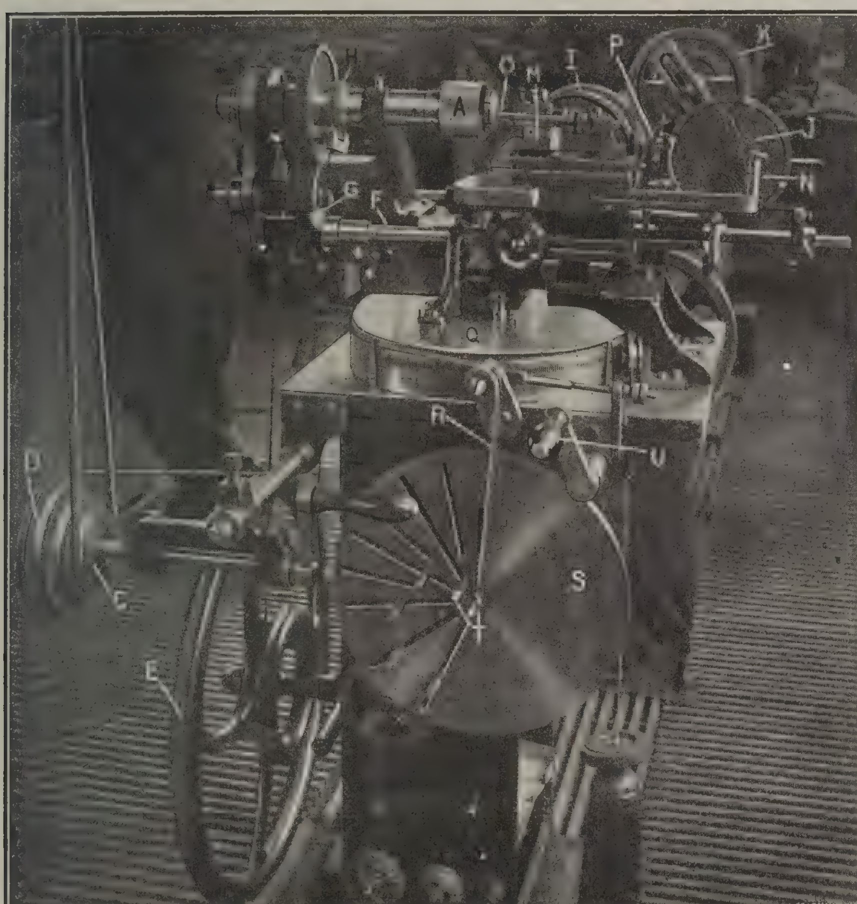

Fig. 11. Swiss "Brocade" Machine, which produces Special Designs of Engine Turning

The ratio of the gears driving the filling-in pattern, to those operating pattern I, can be changed so as to alter the pattern of the work. Barley-corn filling-in cams P are also provided which have a series of indentations and projections distributed around their peripheries. These cams have slightly different patterns, and any one of them can be brought into operation as desired. The cams are held on a shaft which is driven from the holder carrying plate I, by bevel gears, the rear face of the plate-holder being formed into a bevel gear. Through a steel pointer, not shown, these cams P also give a slight oscillating movement to the tool-holder M carrying the cutting tool O, which produces a neat barley-corn pattern in the bottom of the depressions, where neither of the other two patterns act.

The work-holder head is mounted on a circular table Q, which is rotated to swing the head to conform to the shape of the back by a wire rope R. This rope is wound partly around the table and is fastened to it by a dog, and is also fastened to dogs T held on the faceplate S. This faceplate is provided with a series of radial slots in which dogs T are located, the latter being adjustable to any position. It is also provided with a spur gear at the rear, and is driven through change gears from the main driving shaft. As the faceplate rotates, it unwinds the wire rope from table Q, and consequently pulls the latter around, which action swings the head carrying the work. The table is graduated and a pointer is provided so that it can always be started from the same point, after it has been swung around by the hand-crank U to insert a new piece of work in the chuck. The unwinding of this wire R imparts a movement to the head which approximates closely an involute curve.

The principle employed in driving the front shaft F for rotating the work is both interesting and novel. From the preceding description, it will be seen that the work-holder must swivel through an arc, and also be rotated at a constant speed irrespective of its position. This is accomplished by double-face miter gears called "A gears." These gears roll on each other and the center of contact is always directly in a vertical line passing through the cutting point of the tool O. If this were not the case the pattern would not be accurately reproduced.

A pantograph arrangement of levers compensates for the size of the case being brocaded, and the position of the dogs T is altered to provide for the changes in the shape of the back. The slide on which the pantograph arrangement of levers, tool-slide M and pattern plates I and J are held is traversed by a worm and worm-wheel from the rear driving shaft. The cutting tool starts at the outside circumference of the case and works in towards the center. The machine is automatically stopped when the work is completed by a bracket held on the slide carrying the pantograph arrangement, which comes in contact with an adjustable stop screw in a lever held under a latch. This bracket pushes the lever from beneath the latch and shifts the belt on the countershaft, thus stopping the machine.

Special Designs and Colored Gold

Many watch cases are furnished with elaborate designs such as plated work of colored gold, and gilded. The gold-plated patterns are cut out in punch presses and soldered onto the back of the watch. The patterns are made in all sorts of color, which is accomplished by alloying coloring matter with the gold when melting. Most of the designs cut on the Swiss brocade machine are gilded in an electric bath, colored gold being used as the annode. The part of the back not to be gilded is coated with shellac, which is removed in hot water after the work has been gilded.

* * *

Some time ago there was exhibited before the French Academy of Science a small dynamo, the total weight of which is claimed to have been only one-fifth ounce. This machine measured about 0.6 inch in height and length. The diameter of the armature was about one-quarter inch, and the magnet was wound with silk-spun wire 0.002 inch in diameter. The total length of the field wire was about five feet. The collectors and brushes were constructed exactly as in large dynamos. When run as a motor, the machine consumes about two amperes at two and a half volts and runs at a very high speed, making a humming noise like a large insect.

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit contributions from practical men on subjects pertaining to machine shop practice and machine design. All contributed matter published exclusively in MACHINERY is paid for at our regular space rates unless other terms are agreed on.

AUGUST, 1912

PAID CIRCULATION FOR JULY, 1912, 24,575 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 700 reading pages. The Engineering Edition—$2.00 a year, coated paper, $2.50—contains all the matter in the Shop Edition, about 300 pages a year of additional matter and forty-eight 6 x 9 Data Sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. The Railway Edition, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of Data Sheets.

MECHANICALLY-GUIDED WELDING AND CUTTING MACHINES

The mechanically-actuated oxy-acetylene torch for cutting shapes from iron and steel plates, described in the July number, is one of the most interesting developments in metal working apparatus brought out in the past decade. The oxy-acetylene torch fed with an excess of oxygen becomes a cutting tool of extraordinary efficiency, making a narrow clean "saw" cut of any desired pattern at a speed in thick plates that cannot be equalled by any existing machine tool. Mounted on a pantograph frame, the torch is made to follow a pattern traced on a drawing, and the rate of traverse is fixed by an electrically driven feed wheel. Being capable of cutting steel three inches thick, the apparatus should obviously be of great value in die making.

The use of a gas flame as a cutting tool evidently is capable of still greater development when the torch is guided and traversed mechanically. The flame is used at its highest efficiency, and the shapes produced require a minimum of finish to meet the requirements of many lines of metal-working. The process can be regarded as another of the auxiliary processes of which grinding, drawing, extrusion and swaging are examples, that extend the economical possibilities of metal working, and thus directly promote the usefulness of the so-called "standard" machine tools in those fields for which they are best adapted.

* * *

TOOLMAKING AND EFFICIENCY

In these days of interchangeable manufacturing, when the tool designer and toolmaker are chief factors in determining the kind and quality of accessory equipment provided for manufacturing, and, therefore, to a large extent in determining the efficiency of the production departments, their attitude toward efficiency assumes great importance. The production of fine tools, jigs and fixtures is to some degree an artistic job, requiring men who love the work and exercise their ingenuity because they love it rather than for the wages paid for the work. To men of this disposition some of the principles of higher efficiency in shop management as applied by enthusiastic organizers are very distasteful. This mental attitude of the expert toolmaker, as expressed in the following paragraph, taken from a recent letter, is important:

"I have been through the mill—made master plates, and all classes of tools for the finest and most accurate instruments.

* * * * * * * * *

Too much is said by most writers regarding speeds, cuts, angles of tools, etc., for their articles to be of value to a toolmaker. A toolmaker is not working on a premium basis, nor is the nature of the work such that a table of speeds could be compiled that would be worth a row of pins, and a table of angles, etc., simply confuses a young toolmaker and especially one who is endeavoring to get the rudiments of toolmaking by study."

While it is undoubtedly true that the data so useful to the machine shop in promoting efficiency have little direct application to the toolroom, we believe that toolmakers generally should have a clear idea of shop conditions and the importance of speeds, feeds, cuts, cutting angles, etc. A toolmaker who has been a machinist and has developed the artistic quality and skill of the toolmaker is likely to be more practical and efficient from the production standpoint than one who has been a toolmaker all his life. Toolmakers should guard themselves from becoming absorbed in their specialty to the exclusion of the practicalities of the shop. Too much concentration on one thing makes for narrowness, and the narrow man is not a desirable development in any walk of life.

* * *

SAFETY APPLIANCES AND THE WORKMAN

Some years ago, when the agitation for safety devices in work-shops began to be carried on in a systematic manner, it was directed mainly towards the manufacturer, exhorting him to install devices to safeguard his workmen, and this agitation has in the last few years produced the desired effect with many large concerns. But as these devices became more numerous it was found that in many instances the problem was not solved, for a second difficulty arose—that of inducing the workmen to make proper use of the safeguards installed. Men who have been accustomed for years to working around dangerous machinery not provided with adequate protective devices, are liable to develop a spirit of bravado and ridicule new devices intended to safeguard them. Instances are recorded where workmen have deliberately removed the safeguards, claiming that they were unhandy and hindered them in their work. In some cases, no doubt, safeguards may have been improperly designed and caused inconvenience to the workmen, but it is probable that in the majority of cases the objections of the workmen have been due to prejudice towards innovations.

In order to counteract this opposition of the workmen towards safety devices, it is necessary that the management should educate them in the proper use of such appliances. A notice such as the following does not reflect credit upon its originator: "Use the accident guards; if any workman does not intend to use these wherever possible, he will please report to the office for his pay." Instead of securing the cooperation of the workman in preventing accidents, such a notice will merely arouse his antagonism. One firm that has been remarkably successful in reducing the number of accidents in its shops has made use of an entirely different method. When new safeguards were placed on the machinery, their men were thoroughly instructed how to work without being inconvenienced by the appliance. They were given an opportunity to complain if they found that the safeguards interfered with their work; and, if practicable, the design was altered to suit the conditions. In this way, the cooperation of the worker was secured, and security against accidents was increased. There is, perhaps, no condition where cooperation between the management and the workmen is more necessary, nor where it results in a better understanding between employer and employes, than when they meet on common ground, in an endeavor to prevent accidents in the shops.

ELIMINATE THE HUMAN FACTOR

On July 4 forty people were killed outright and many injured by a rear-end collision on the Lackawanna Railroad at Gibson near Corning, N. Y., where an express running at full speed crashed through the rear cars of a passenger train. This train was protected by a flagman and by automatic block signals, but these were not seen by the engineer of the express, probably because of a fog which prevailed at the time. The present "safety" system is reasonably safe, so long as the employes are alert and watchful, but it is not proof against carelessness or negligence. The block signal may be set for danger, but so long as the engineer stands between it and the throttle, there will be wrecks and loss of life. To prevent them, the elimination of the human factor is necessary.

There are various inventions for automatically stopping a locomotive in case of danger, and if none of them are perfect they can probably be made as nearly so as the semaphore, by experiment and use. An expression of public opinion may overcome the indifference of railroad managers to this improvement.

* * *

A NEGLECTED FUNCTION OF ENGINEERING SOCIETIES

In another part of this number a brief review of the history and activities of the British Engineering Standards committee is given, from which it appears that the British engineering societies recognize as one of their most important functions, the compilation of data for the standardization of specifications for engineering work, machine details, etc. Very little of this kind of work has been done by the engineering societies in the United States. The American Society of Mechanical Engineers has done very useful service in bringing about the standardization of machine screws; but important as this work has been, it is insignificant when compared with the great need and the unlimited opportunity for the standardization of hundreds of details in the mechanical engineering fields.

The British engineering societies have set a fine example, and by the successful accomplishment of their work have proved that it is possible to formulate certain standards upon which all manufacturers can agree. Our engineering societies are neglecting a great opportunity by not devoting themselves to work of this character. No other body is so well fitted to render this important service as a national engineering society and it should be considered a duty by all of them. The important work of the national engineering bodies can never be done at the conventions, because these are, and probably always will be, largely social functions; but a vast amount of matter of permanent value would be available to the engineering profession if the papers presented at these meetings were crystallized into permanent records by being used as an aid in preparing standards for mechanical practice. In addition, the engineering societies would then become a kind of clearing house for mechanical information, where data relating to standards of all kinds could be readily obtained, and where the reason for the adoption of these standards could be ascertained.

At the present time, there seems to be no one subject to which the engineering societies could devote themselves with greater profit than to the establishment of engineering standards. There is in the mechanical engineering field, at least, a hopeless confusion as to the established practice with relation to many details of machine design and shop practice. No other body is better fitted than the national engineering societies to clear away this confusion.

* * *

At one of the busy machine shops in the heart of the city of Boston where the machinists prefer to take but one-half hour for their luncheon and thus make their day one-half hour shorter, the management allows the men to go to luncheon at 11:45 returning to work at 12:15; thus the men are enabled to get into the luncheon rooms and restaurants just before the rush hour commences, which insures them prompt service and good lunches.

INDUSTRIAL ADMINISTRATION AND SCIENTIFIC MANAGEMENT—2

CAUSES OF INDUSTRIAL INEFFICIENCY

By FORREST E. CARDULLO*

So far this article has considered only the broad aspects of industrial administration. In order to get a better idea of the objects of scientific management, the methods which it is likely to adopt, and the obstacles which it must overcome, I propose to classify and describe some of the causes of inefficiency in our industrial life. In studying the causes of inefficiency we will discover the remedies which a proper system of administration should apply, and develop some of the principles underlying scientific management. I do not claim that all the faults which I will describe are prevalent in every industrial plant not under scientific management. I will admit that most of them can be eliminated without the complete adoption of scientific management. I do know, however, that they are astonishingly prevalent in our industrial life, and that neither conventional nor systematic management has succeeded in uprooting them.

The causes of inefficiency may be divided into three classes: The first are those causes which are chargeable primarily to the employer, the second those which are chargeable primarily to the workmen, and the third those which are chargeable primarily to our political and industrial system.

Those causes of inefficiency which are chargeable primarily to the employer may, in turn, be divided into two classes. Those of the first class arise from a lack of knowledge. They can be remedied by showing the management the possibilities of better methods. Those of the second class arise out of moral defects on the part of the employer, and will require more than a change in the system of management or full information of the conditions of the plant in order to eliminate them.

Mental Laziness

The first and most prolific source of inefficiency is mental laziness. Most of us dislike to think. While a good many of us will devote a spare hour now and then to the consideration of some interesting subject, no man will, if he can avoid it, devote two hours a day, not to mention eight hours a day, to the task of devising and comparing methods of work. That kind of thing is entirely too strenuous to suit the average officer of administration. In the average plant, each officer places upon the shoulders of his underlings the burden of detail for which he himself ought to be responsible. When work is to be done, the manager "puts it up" to the superintendent. The superintendent, in turn, puts it up to the foreman, the foreman to the gang boss, and the gang boss to the workman. Upon the workman devolves the task of devising the methods and of planning the details of the work. Now as I will show later, the workman is no fonder of thinking than the management, and performs his task in that way which involves a minimum of mental effort. He is not to be blamed for so doing, because he has merely followed the example of the management. It is the duty of the management and not of the men to study the work, to discover the most efficient methods, and instruct the men in those methods. When, because of lack of instruction, the men fail to perform their work in the most efficient manner, it is the fault of the management and not of the workmen. Conventional management is fundamentally wrong, in that it compels the workmen to originate the methods, and leaves to the management only the task of criticism.

When the management of an industry is reproached for laziness in not properly directing the workmen, the officers of administration will usually reply to this effect: "These workmen which we hire are supposed to be competent men. They are experts in machine molding, tool dressing, lathe work, or whatever it is that we hire them to do. They have devoted their lives to these lines of work, and know a great deal more about it than we do. When a man receives a job, he can devote his entire attention to that one job. His task is easy, because he has to think of but one thing at a time. If we

*Address: Department of Mechanical Engineering, New Hampshire College of Agriculture and the Mechanic Arts, Durham, N. H.

devised the methods of work, we would have a thousand jobs to figure on each day. They could not receive the same amount of attention that they get now, nor would that attention be as satisfactory, since we are not experts, and the men are. When you ask us to direct the workmen in the details of their work, you are demanding of us an overwhelming and impossible task."

In answer to this argument, it is only necessary to say: First, while the workmen are usually much more capable than the management, this is due to the lamentable ignorance of the management, and not to the extraordinary knowledge of the workmen. It is practicable for the management to acquire and apply knowledge which it is impossible for the workman to have. Second, many shops that are eminently successful do direct all of the acts of their workmen. Third, when the workmen devise the methods of doing work, they are handicapped by being obliged to use such tools and machines as the management provides, while, when the management devises the methods, they can and will secure the proper tools and machines for doing the work.

Prejudice against So-called Non-productive Labor

A second source of inefficiency is a dislike on the part of most managers to employ a considerable executive staff to direct the efforts of their workmen. The management balks at such a staff, and claims that "non productive" labor is a necessary evil if you have to employ it, and an unnecessary evil if you can do without it. In the old days draftsmen were regarded as an unnecessary evil, and the designing was done by rule of thumb and the head patternmaker. Experience has shown that Johnny Pencilpusher is not an evil, nor is he unnecessary, and that it pays to employ him. Accordingly he is now classed as "productive" and not as "non-productive" labor. The men who direct the work of the shop are just as necessary as the men who make the designs, yet it is difficult to persuade the average manager that a large executive staff is desirable even when you can show him that a gain will result from its employment. The attitude toward such a staff is well shown by the name "non-productive," so often applied to this class of labor. The labor of the planning department is just as truly productive as the labor of the drafting department, the machine department, or the erecting department. A new attitude in regard to the employment of indirect labor is a pre-requisite to greater efficiency in many of our shops.

Timidity of Capital

A third fault of management is timidity. Capital seems to be ruled by fear quite as often as by judgment. Men dislike to risk their money in something which they feel is not absolutely sure to bring adequate returns. They especially dislike to risk money in any investment which is of such a character that they cannot recover the principal in case they decide to give up the enterprise, even though adequate returns are almost certain. Managers often hesitate to spend money for new tools or equipment until other firms have tried the tools or equipment and found them to be successful.

Probably one of the best examples of this is the difficulty which Mr. George Corliss had in selling his engines at a reasonable price, when they were first brought out. It will be remembered that in some cases he had to take for his pay the value of the coal which his engine could save in a given period of time, and was under bonds to take out his engine and reinstall the old one in case the purchaser decided that the new engine was unsatisfactory. Just as Mr. Corliss' customers were fearful of spending money for an improved type of engine, and insisted on making a contract which was, in reality, unfavorable to themselves, so the present-day employer is fearful of assuming the expense incident to proper management, even though it can be shown that great gains ought to be realized from proper administration.

Lack of Foresight

This brings us to a fourth fault of management, which is lack of foresight. The management, in performing the work of today, fails to make allowance for the needs of next week, or the growth of next year. Plants grow in haphazard fashion. Equipment is added without making plans for the future. No attempt is made to insure that there will always be a corps of trained workmen and a staff of able foremen. The lack of definite and far-reaching plans for future work is not felt at the time that such plans should be made, but is felt later.

Mental Inertia and Lack of Adaptability

A fifth fault of management is one which may best be described as "mental inertia." Managers tend to follow methods which have been satisfactory in the past, but which changing conditions have made unsatisfactory for present requirements. Whenever a new invention of any importance is introduced into a shop the conditions of work are greatly altered. The introduction of high-speed steel is a case in point. When the time required for machining work is cut down to a third of that formerly required, the amount of crane service for a given number of machines is trebled. The foundry and forge shops must be made very much larger in order to furnish the stock required by the machine shop. The amount of storage room required for stock and for finished product is greatly increased. The relative importance of different items of cost is radically altered, and the nature of the problems of administration are greatly changed. Notwithstanding these changes, we will find that in most cases the management will attempt to get along with the least possible change in equipment, and in methods of work and administration. Many men resist change simply because it is change, in spite of the fact that the change may be desirable.

One of the best examples that comes to mind of the mental inertia that prevents the adoption of new ideas is the general disregard of Mr. Taylor's discovery that the use of a heavy stream of water at the cutting point of a roughing tool, increases the permissible speed of cutting by forty per cent. If the machines of a shop are engaged on roughing work for one-third of the time, by the use of such a stream of water their output will be increased by thirteen per cent. In a shop in which 100 men are employed on machine work, this will mean a reduction in the cost of machining of about $20,000 per year. To install a system for distributing soda water to all the machines in such a shop, and for returning and purifying the water, will certainly not cost more than $20,000, yet, so far as the writer is aware, there is only one shop in which such a system has been installed, even though it would unquestionably pay one hundred per cent on the investment. This is an example of bad management arising from mental inertia, which occurs in almost every shop. When the subject is brought up in any plant, the management fortifies itself in its obstinate attitude, by advancing as arguments statements which are untrue, for instance, that the system costs more than it is worth, that the soda water destroys the machines, or that it is always giving trouble. Were the management to give the matter proper study however, it would find that practical experience has demonstrated that the benefits realized are so great that their shops cannot afford to operate in any other way.

Lack of Study of the Industry

A sixth and probably one of the greatest of all causes of inefficiency is the fact that the management very seldom makes a careful study of the industry. In the few cases where a careful study is made, it is usually done for the purpose of improving the materials used or the quality of the output, or increasing the amount of work turned out by the use of a given method.

It is of equal or even greater importance that the methods themselves should receive the same careful study. Probably the best example of a scientific study of methods of manufacture is the work of Mr. Taylor on the art of cutting metals, to which reference has already been made. It is probable that a similar study of methods would result in equally important developments in other lines of industry. Such studies are not made for three reasons. In the first place, managers do not realize the need of such studies nor the advances which are possible. In the second place, very few men are capable of making such studies. In the third place, inertia opposes the changes which would result from such studies, and timidity hesitates to expend the money necessary to carry them out. Very few managers would have the courage to commence an investigation whose final cost would be $800,000 and which would take twenty-six years for its completion, and while the management of some very large industries might be willing to

take a chance on an investigation of this kind, even the most sanguine would deride the possibility of such an investigation producing such valuable and far-reaching results as have followed from Mr. Taylor's experiments. When all is said and done, it will be found that most managers want someone else to do the experimenting, feeling that by so doing they can participate in the profits of such work without sharing its expenses.

Systems of Rewarding Labor

A seventh source of inefficiency in many industrial plants is the system of wage payment adopted. It would be hard to devise wage systems better calculated to limit efficiency than the two which are in most common use; namely, the day wage plan, and the piece-work plan with frequent cuts. Under the day work plan, the man receives no reward for his efficiency, he is instead punished for inefficiency. This is a method which is fundamentally wrong, and only to be employed when no other method is possible. When a man receives day wages, he is paid for the time which he spends at his work. The first question which arises in connection with this system of wage payment is: What wages ought a man to get? The answer is he ought to get all he can. He is selling a commodity, labor. He asks for it the highest price he can get, and is justified in so doing. His labor is measured by time and the value of the labor performed in a given time has nothing to do with the payment which he receives. The only thing which limits him is the fact that if he does not do a satisfactory amount of work, he will be discharged. What constitutes a satisfactory amount of work, neither he nor anybody else knows. The whole thing works out very much as it would if a man when buying a quart of milk, were to insist simply that there be some milk in the quart measure, and the matter of how much milk there was to be in the measure, should be left with the milk-man, with the understanding that the milk-man would lose his customer in case the amount of milk was not satisfactory to the purchaser.

When you discuss with the average workman the question of proper wages and the proper amount of work to be done in a day, he will tell you that his motto is "a fair day's work for a fair day's pay." Different men, however, have very different ideas as to the amount of work which constitutes a fair day's work. Some employers think that it is all the workmen can possibly accomplish. Some workmen think it is the least that they can accomplish and still not get fired. Most workmen think it is work they can do when working steadily at the gait that habit and temperament have fixed in their cases. Most employers think it is the amount of work which their most honest and industrious employe normally does. When there is such a great diversity of opinion as to what constitutes a fair day's work, it will naturally be seen that there will be great diversities in the efficiencies of different men and different shops.

When a piece-work plan is adopted, the management usually knows very little about the possibilities of the work. If the management fixes what the men think to be a reasonable piece-rate, the men will soon so increase their output that they will be making exorbitant wages. The management will then cut the piece-rate, and after the men have experienced a series of cuts as a result of successive increases in efficiency, they will discover that the management does not propose to pay them more than a certain amount of money, and will work just hard enough to secure a trifle less than the maximum amount they can secure without experiencing a cut.

If, on the other hand, a proper piece-rate is established in the first place (*i. e.*, one by which the men can earn fifty per cent to one hundred per cent more than a regular day's wages when they have reached their best efficiency), the men will believe that it is impossible to earn reasonable wages under the proposed piece-rate, and will decline to accept it.

"Holier than Thou" Spirit of Some Employers

An eighth cause of inefficiency is one which is happily becoming less frequent. It is a disposition on the part of some employers to regard their workmen as being of a lower order of humanity than themselves. I have talked with such men on more than one occasion. Among their associates they were highly regarded for their kindness of heart, but I have heard them speak of their workmen as "beasts" and "ignorant brutes." No man who regards his employes in that light can be persuaded to adopt scientific management nor can he bring the efficiency of his plant to a high standard, because such feelings will unconsciously affect his attitude in dealing with his employes, arouse their antagonism, and destroy that feeling of cooperation which is the essential basis of high efficiency.

On the other hand, even though the employes of such a man are ready and anxious to cooperate with him, his attitude will prevent him from doing many things which would utilize such potential cooperation to advantage.

Avarice of the Management

The last source of inefficency of which I will speak is avarice on the part of the management. Avarice reduces wages, cuts piece-rates, purchases inferior materials and equipment, employs unskilled labor, skimps on supplies and makes unjust exactions of its employes. Avarice refuses to expend money for the collection of information, for increasing the facilities of work, and for improving the efficiency of administration. Avarice hampers the administrative staff at every point. Avarice is the sin of the board of directors and the stockholders, and not of the superintendent and his staff. Scientific management often requires a large staff of clerks and costly experiments when it is being introduced into a new line of work, and this effectually prevents its adoption by the avaricious employer.

Not only will avarice prevent the adoption of scientific management in a great many cases, but it is also very likely to give scientific management a black eye by adopting some of its methods, without adopting its spirit. An avaricious employer finds himself coming out second best in competition with one who utilizes scientific management. He attempts to appropriate the experience of his competitor in the same spirit in which he imitates his trademarks, copies his designs, and steals his methods of work. Now while it is possible to imitate a trademark or steal a method, it is not possible to imitate or to steal the scientific habit of mind or the spirit of fair play, which lie at the basis of scientific management. The reward and instruction are just as essential to scientific management as the discovery of a method of work, but the avaricious employer cannot be made to see this. When his neighbor has discovered a method of work better than that which his workmen employ, he will attempt to force his workmen to accomplish the same results without teaching them the new method and without offering them the reward to which they should be entitled, and his attempts will therefore always end in failure. While there is no question but that scientific management will continually discover new and improved methods, processes and materials, and while these improvements will gradually find their way into shops which do not employ scientific management, the extraordinary performances possible under scientific management will never be achieved in the shops of the avaricious employer because knowledge alone will not lead workmen to increase their efficiency.

I have not by any means exhausted the list of causes for inefficiency which arise from faults of the management. It would be as easy to name a hundred as to name nine, but the task is not agreeable. I have endeavored merely to point out the fact that such faults exist, that they can be remedied, and that before scientific management can be applied to an industry, they must be remedied.

Causes of Industrial Inefficiency due to the Workmen

While most of the causes which lead to inefficiency are chargeable to bad management, I would not have it inferred that the workmen are free from blame in the matter. I know of many shops in which the blame rests almost wholly on the workmen. In one that I have particularly in mind, the management is keenly alive to the possibilities of improvement. They could today increase their output fifty per cent, and would gladly increase their wages in the same proportion, if the workmen would cooperate with them. Time and again they have attempted to make changes leading to higher efficiency, but in every case the opposition of the workmen was so strenuous that they were convinced that it was the part of wisdom to accept the inevitable and to permit the inefficiency which they deplored. Were they to insist on a change of

methods, it is quite likely that labor troubles would force their plant into bankruptcy on account of their limited capital.

The Natural Pace of Workmen

The first source of inefficiency chargeable to the workmen is their disinclination to work at any other than their natural pace. If a man is allowed to work as he pleases he will soon settle down into a certain pace which suits his temperament and nervous organization, and will keep to that pace without very much variation from day to day. I may call this his natural pace. It is perfectly possible for such a man to work very much faster without tiring himself, and if he is properly trained and given adequate inducement, he will adopt the faster pace, and make it his habit to work at that faster rate. I may call this faster pace his proper pace. In order to illustrate the relation of the natural to the proper pace, I would like to compare them to the natural gait which a horse takes when his driver allows him to go at his own free will, and the proper gait which an experienced driver will set for the horse, in order that he may accomplish the best results. A careful and experienced driver will get a great deal more work out of a horse if he urges him to travel at the proper gait. Notwithstanding this, the horse will be no more tired at the end of the day when driven at the proper gait, than he would be had he traveled at his natural gait. The faster gait does not mean undue wear and tear, and the horse will maintain good health and vigor just as long when working for a careful driver who makes him work, as he will if he works for an indifferent driver who allows him to do as he pleases.

A man differs from a horse in two ways. In the first place he cannot be driven, and in the second place, a reward offered him for extra labor must seem to him to be reasonable. It is not difficult to get a man to change his pace if you offer him an adequate reward. If, however, he finds that the reward is not always forthcoming, *i e.*, if he finds a piece-rate being cut or a premium reduced, or if he feels that the reward is inadequate, he will not respond. He cannot be driven by threats of discharge or by fines, and he cannot be coaxed by broken promises or gold bricks.

Lack of Ambition

A second source of inefficiency is lack of ambition. While most men will be stimulated by a proper reward, there are some classes of labor which cannot be reached in this way. Some workmen do not accomplish as much or as good work when well paid as they do when poorly paid. In certain sections of the South contractors find that when negro laborers are paid seventy-five cents a day they will work a full week, when paid $1 a day they will lay off one day in the week, and when paid $1.50 a day they will lay off half the time. The reason is that these men are not ambitious. Four dollars and a half a week supplies their needs, and when they have earned that amount they do not care to work any more. It is needless to remark, however, that the average artisan is not of that character. He is ambitious, and invariably responds to a suitable reward, unless he believes that in so doing he is acting against the best interests of himself or his fellow workmen.

Mental Laziness of Workmen

A third source of inefficiency lies in the fact that the workman does not like to think any more than the superintendent, the foreman, the manager, or the board of directors. He prefers to work without thinking when it is possible. Few men are physically lazy, but nearly all men are mentally lazy. The only way that a man can work without thinking is to do the job the way in which he or someone else has done it before. When he has to do a new job, he must do some thinking, but usually it will be found that the workman will adopt the method which requires on his part the least mental effort for its origination. Very seldom is the method adopted the best one. In the course of his work, ideas will come to the workman. Sometimes these ideas are good. If the ideas make it easier for him to perform the work, that is, if the new method is in accord with his temperament and habits, the idea is put into practice. If the idea makes it harder for him to work, that is, if it requires him to do something disagreeable or not in accord with his habit, the idea will be rejected. An investigation of methods of work will usually show that men who are physically restless will often adopt difficult and tiresome methods of work on account of their temperament. Men who are physically lazy will adopt easy-going and slipshod methods of doing work. In every case the workman seeks to conform the method to his temperament, in order that the mental and nervous effort which he must make in accomplishing the work shall be a minimum.

Fallacy of the Arguments against a Good Day's Work

A fourth, and possibly the most prolific source of inefficiency is the belief held by many workmen, and unfortunately, taught by many union officials, that in doing efficient work men are displacing other workmen and lowering wages. There can be no greater economic fallacy than this. One illustration alone will serve to make clear the falsity of the argument that a man who works efficiently reduces wages and the opportunities for labor. Let us suppose that on account of the increased efficiency of the workmen, the cost of making cement is materially reduced, and the output greatly increased. Of course, if the demand for cement were fixed at so many barrels per year, some cement makers would be thrown out of employment, but with the increased output and diminished cost there will come an increased demand for cement, and there will be a greater amount of concrete construction. Instead of reducing the number of men employed, it is quite possible that a larger number of men will be employed in manufacturing cement, and it is certain that a very much larger number of men will be employed in concrete work. If these concrete workers, in turn, become more efficient, cheapening the cost of concrete construction, the use of concrete will be stimulated, more cement makers will be employed, new factories, warehouses and bridges will arise, and finally every branch of industry will be stimulated by the improvement. The workman who increases his output is a benefactor, not alone to his employer, but to every man in the community. His increased efficiency will result in higher wages, and more general prosperity.

The facts in the case are so simple and so easily understood that it is strange to me that every workman does not understand and appreciate them. If all workmen were twice as efficient, the annual value of the products of labor would be twice as great as at present. The products of labor are distributed among the community (somewhat inequitably it is true), and the share which each member of the community can get will be proportional to the total amount to be distributed. Any increase in efficiency means that there will be more goods to be divided, that every one will get a larger share, and that the community will be benefited. It is impossible in an article of this character to go into the subject of economics, but the more the subject is studied, the more clearly the advantages of increased efficiency will be seen. As a matter of fact we can only reach that millenium when poverty, disease and unhappiness will disappear, by the straight and narrow path of increased industrial efficiency, and anything which impedes that efficiency is in reality as great a crime against humanity as the poisoning of a well, or the adulteration of drugs.

Enmity to Employers

A fifth source of inefficiency chargeable to workmen is a feeling of enmity against their employers. A great many workmen are unable to see the community of interest between the workman and the employer. Some workmen act as if they believed that the two were at war, and that anything done to injure the employer was a benefit to labor.

Now there will always be discussion and bickering between capital and labor as to how the wealth created by their joint effort should be divided. There can, however, be no discussion over the point that each must have a share, and that the amount of wealth which they can divide between them, and the size of the share to which each is entitled, will be great or small according as they are more or less efficient.

Any sensible man can see that the more efficient the workmen are, the more prosperous their employer will be, the better able he will be to extend his works and employ more labor, and the higher wages he will be able to pay. Until all feeling of enmity between capital and labor is replaced

by a knowledge of mutual need and appreciation of mutual interest, and a desire for mutual success, not only efficiency, but also prosperity, must suffer.

Causes due to Political and Industrial Systems

Those sources of inefficiency which arise out of the imperfections of our political and industrial system are just as important as are those due to faults of management or of workmen. Unlike the latter, however, it is impossible for either the management or the workmen to correct the faults we are about to consider. It is not usual to discuss such matters in a technical paper and on that account this phase of industrial administration will be dealt with in the briefest possible manner, confining the discussion to a description of the causes, and not to a discussion of legal remedies. Everyone studying the industrial history of this country will be struck with the fact that we have alternate periods of feverish activity and of deadly dullness. In so-called "boom times" factories are run twenty-four hours a day, efficiency and quality of workmanship are sacrificed to output, our railroads are crowded to the limits of their capacity, untrained and inefficient men find ready employment in all trades, ill-considered plans for industrial expansion are hastily carried into effect, inferior and unsatisfactory equipment is eagerly purchased and installed because no other kind is available, and the general efficiency of our industrial system suffers a severe decline.

As a result of this inefficiency a "period of business depression" sets in, men are discharged, plants lie idle, wages fall, men are forced to move at great expense, and to seek new employment for which they are not trained, and again inefficiency is the order of the day. Now there is no reason why these alternations of activity and dullness should occur, except that our methods of conducting business are wrong. Proper laws, proper methods of banking, improved business customs, and a rational development of our natural resources and methods of communication will very nearly eliminate such conditions.

Certain industries, however, are subject to seasonal variations of opportunities for work. Agriculture and the canning industries are examples. Other industries are subject to seasonal variations in the demand for their products. The automobile industry and the manufacture of Christmas goods are examples. Where the supply of raw materials for an industry is subject to seasonal variations, nothing can be done except that such an industry may be operated in connection with another industry so that the workers and possibly a portion of the plant may be efficiently employed, practically all the time. Where the demand for the products of an industry is subject to seasonal variations, the industry may run steadily throughout the year if an accumulation of stock is permitted. The amount of capital tied up in the stock will usually, in such a case, be less than the capital otherwise tied up in the plant, since a plant which turns out a given product in three months will have to be four times as large as one which turns out the same product in a year, working the same number of hours per day. There is also the possibility of operating such an industry in connection with another industry, possibly of a like character, in such a way that both the plant and the workmen may be efficiently employed throughout the year.

We must all recognize that one of the causes of inefficiency at the present time is the struggle which is going on in the business and political world over the question of whether capital shall be used for the benefit of those who nominally own it, or whether it shall be used for the benefit of the community. Originally the position sanctioned by law was that capital belonged absolutely to the one owning it, and that he might use this capital in any way that he saw fit, except that he might not employ it in levying war on the sovereign, or in committing a criminal act. We are gradually coming to the view that capital must be used for the benefit of the community, and while we believe that the nominal ownership and the detailed administration of industrial enterprise should be left to individuals, we are coming to insist that a business shall be conducted efficiently, that in case the business is not regulated by competition the profits shall be reasonable, and that the methods of making and marketing the products shall be those which will further the well-being and efficiency of the community as a whole, rather than the profits and self-satisfaction of the owner of the business. While we are engaged in this process of changing the fundamental principles of law and of business, we must expect that inefficiency will be more or less the order of the day.

One of the economic sins of the present day which is very effective in destroying efficiency, is foolish and wasteful competition. The construction of parallel and competing lines of railway when one line is adequate to serve the traffic is a case in point. The installation of two telephone companies in the same city, of competing street car and electric railway lines, the duplication of generation and distribution plants by two electric power companies, and competition in other so-called "natural monopolies" are other examples. There are certain kinds of industrial work in which competition is undesirable and inevitably leads to inefficiency, and laws which permit or encourage such competition place a premium upon such inefficiency.

Another cause of inefficiency is frequent and sudden changes in laws, customs, fashions, and social conditions. For instance, a bounty, subsidy, or extraordinarily high tariff may cause the factories and workmen of an industry to be transferred from Europe to America. This transfer means a considerable temporary loss, and in case American conditions are not naturally favorable to the development of the industry, it causes a permanent loss. A few years later the abolition of the tariff or the bounty may cause the plant to be re-transferred to Europe and the workmen to be thrown out of employment, with a further loss. Similarly, a change in the direction or amount of traffic in a given district, the development of new resources, the sudden growth or decline of a transient industry and many similar things may affect the efficiency of a given plant, or even a whole industry. Often these changes are entirely beyond human control, or are incident to increased efficiencies in other and more important lines.

SHERMAN LAW HELD TO APPLY TO RESTRAINT OF TRADE BY PATENTS

The Supreme Court of Massachusetts, in an opinion of the full bench handed down July 3, advanced the application of the Sherman law to embrace combinations in restraint of trade by reason of patent rights held by corporations. In a suit of the United Shoe Machinery Co. against Euclid I. Chappelle, an inventor who worked for the corporation for $12 a week, the corporation endeavored to force Chappelle to transfer certain patent rights under a contract of employment. Chappelle offered to show that the company was a monopoly and doing business in restraint of trade and contrary to the provisions of the Sherman act, but Judge Hardy refused to admit the testimony. Counsel for Cnappelle took exceptions to his rulings and appealed to the Supreme Court. The decision holds that the lower court erred in not admitting such evidence. Chief Justice Rugg, who wrote the opinion, finds that the question of whether the United Shoe Machinery Co. is an illegal combination in restraint of trade and had monopolized trade and commerce between the several States must be governed ultimately by the Supreme Court of the United States. The opinion states, however, "that no word or phrase in the Sherman anti-trust act reveals an intent to exempt the owners of patents from its sweeping provisions against monopolistic combination."

"We are unable to perceive," stated the court, "any underlying reason for supposing that by implication growing out of economic or business conditions such an exemption was intended. There appears to be no inherent natural distinction between owners of patents and owners of oil which would justify the application of the statute to one and not to the other. The conclusion seems to follow that the comprehensive condemnation of the act against every person who monopolizes interstate commerce by combination with others includes holders of patents as well as others."

CHARTS FOR HORSEPOWER TRANSMITTED BY GEARING AND BELTING*†

By CHARLES E. EVANS‡

The accompanying illustration and the Data Sheet Supplement show a number of charts which the writer has found convenient and useful. Two of the charts in the Data Sheet Supplement give the horsepower transmitted by spur gearing, one of them being used for circular-pitch gears and the other for diametral-pitch gears. When using these charts one can choose the fiber stress most suitable for the material and work in question. The charts do not give values directly proportional to the pitch line speed, but values that are relatively lower for high speeds as compared with low speeds. The light upper dotted line in the charts shows the form the upper curve would take if the horsepower were taken as directly proportional to the pitch line speed.

Gears having a large number of teeth have a stronger tooth form than gears with a small number of teeth, and provision has been made in these charts to cover this point, but if it is not desired to determine the results with such refinement as this arrangement makes possible, the values for a 12-tooth pinion can be used for gears of any number of teeth, thus reading straight across the chart at the right-hand side. The horsepower transmitted by gears of different width of face from that specified can be obtained by proportion.

The following examples are traced in dotted lines on Charts I and II in the Data Sheet Supplement:

A 12-tooth pinion of 4-inch face and 3 diametral pitch, running at a pitch line speed of 100 feet per minute, will transmit 2.3 horsepower with a fiber stress of 3000 pounds per square inch.

A 20-tooth pinion of 4-inch face and 3 diametral pitch, running at a pitch line speed of 100 feet per minute, will transmit 4.1 horsepower with a fiber stress of 4000 pounds per square inch.

A 12-tooth pinion of 1½-inch circular pitch and 4-inch face, running at a pitch line speed of 100 feet per minute, will transmit 3.3 horsepower with a fiber stress of 3000 pounds per square inch.

A 20-tooth pinion of 1½-inch circular pitch and 4-inch face, running at a pitch line speed of 100 feet per minute, will transmit 5.8 horsepower with a fiber stress of 4000 pounds per square inch.

The chart contained in the accompanying engraving gives the horsepower transmitted by belts or friction gears. When using this chart one can choose a tractive force per inch of width consistent with the problem in question. An example traced on the chart in dotted lines indicates that a 6-inch belt running at a speed of 3000 feet per minute will transmit 33 horsepower at a stress of 60 pounds per inch of width of belt.

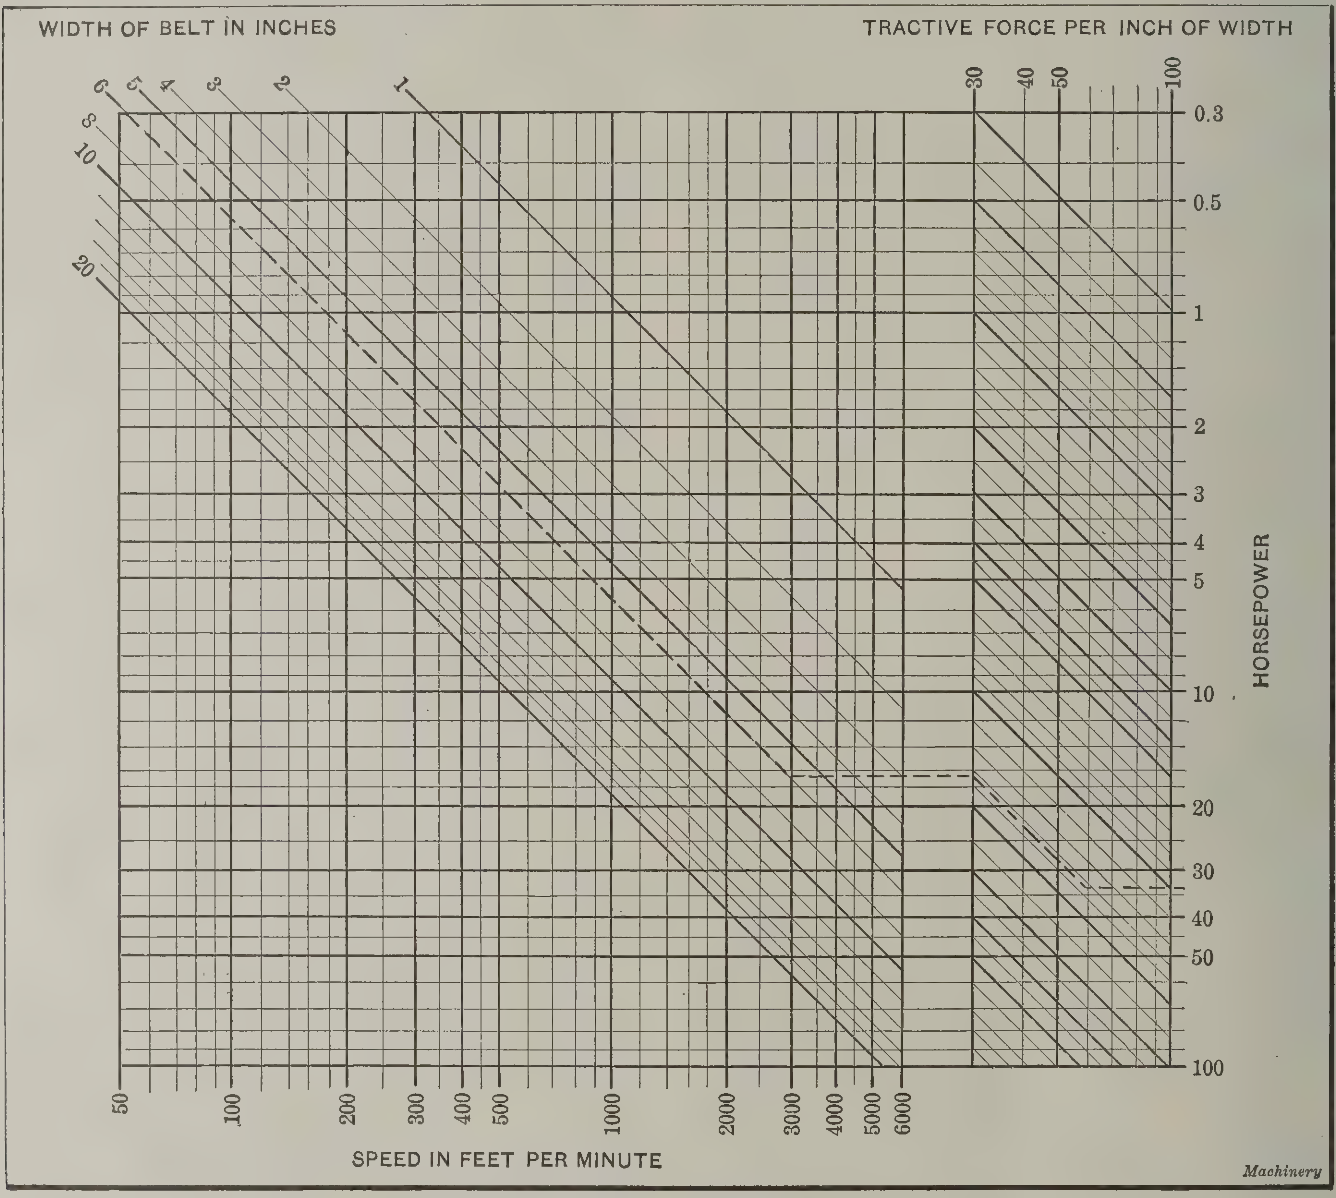

Chart for Finding the Horsepower transmitted by Belting

*With Data Sheet Supplement.
†For additional information on this and kindred subjects previously published in MACHINERY, see "A New Gear Chart," December, 1911, engineering edition; "Horsepower Transmitted by Leather Belts per Inch of Width," September, 1906; "Horsepower Transmitted by Belts," July, 1906, engineering edition. See also MACHINERY'S Data Sheet Book No. 5, "Spur Gearing," pages 21 to 23, and 26 to 29; Data Sheet Book No. 19, "Belt, Rope and Chain Drive," pages 14 to 16; Reference Book No. 15, "Spur Gearing," Chapter IV, "Strength and Durability of Spur Gears"; and Reference Book No. 52, "Advanced Shop Arithmetic for the Machinist," Chapter VI, "Horsepower of Belting."
‡Address: Fifth Ave., near Ohio St., Aurora, Ill.

Charts III and IV in the accompanying Data Sheet Supplement are auxiliary diagrams for finding the pitch line or rim speed in feet per minute. Chart III gives this when the diameter and the revolutions per minute are known. The example traced on the chart in dotted lines indicates that a gear or pulley having a diameter of 3.4 inches and running at 500 revolutions per minute has a pitch line or circumferential speed of 445 feet per minute; or if the diameter is 34 inches and the speed 50 R. P. M., the pitch line speed is 445 feet per minute; in other words, the chart can be used for other dimensions than those actually given if proper care is taken with regard to the position of the decimal point.

Chart IV gives the pitch line speed of a gear when the pitch, the number of teeth and the number of revolutions per minute are known. The example traced on the chart by dotted lines indicates that a 13-tooth pinion of 3-inch circular pitch, running at 100 R. P. M., has a pitch line speed of 325 feet per minute.

HINTS TO EXPORTERS

By ERNST VOEGELI*

From time to time American journals have published instructions relating to the proper crating of machines for export. This is a very important subject, but there are some other points almost as important which are frequently overlooked. Details, which at first sight may seem to be of little or no importance, sometimes cause considerable trouble and damage. With the present-day competition between different firms and different industrial nations, every reasonable precaution should be observed in order to avoid inconvenience to the customer.

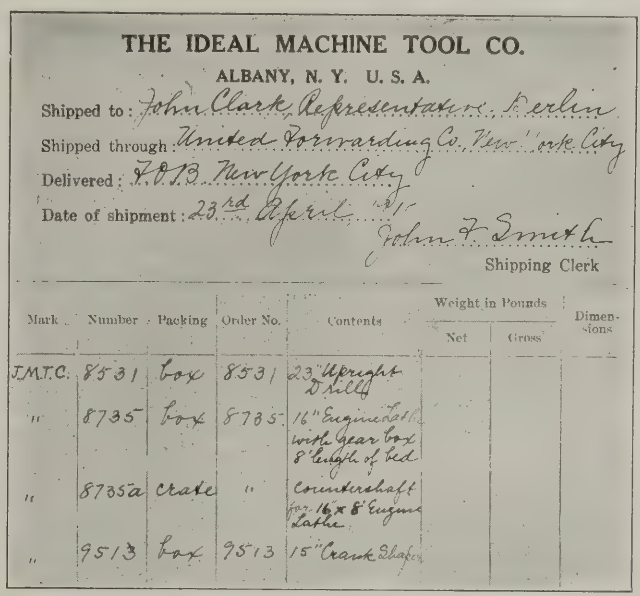
A very important point is that machines should be carefully greased before shipping. Solid crating will prevent breakage, and careful greasing will prevent rusting. The machines are often exposed for several days to the mist or fog at the harbors, and sometimes sea water may come into direct contact with them. The boxes may lie for some time in the open air, not even protected against rain. Hence, if not carefully greased, the machines will rust, and it is extremely unpleasant for the customer to receive high-priced and high-class machines in this condition. When badly rusted, the polishing and cleaning almost always injures the accuracy of the machines to some extent, and this may be detrimental to the reputation of the manufacturer of the machine. It is a fact that a good many machines arrive in Italy badly rusted.

Another important point is to have the boxes distinctly marked. Having almost daily had to do with the forwarding of American, German and English machines, the writer has observed that many American firms make mistakes in this direction. They place the address of their customer in large black letters on the box or crate. However, the customer is not always also the receiver. The customers of American manufacturers, on the other hand, are mostly agents and dealers, but the machines ordered by them are sometimes sold in advance and are to be shipped direct to the user's factory. Thus only a small part of the machines ordered are delivered to the address printed on the box, the larger part being forwarded to the ultimate buyer by the customer's forwarding agent. In that case, the addresses on the box are useless.

Difficulties are met with especially when different machines are arriving at the same time for the same machine dealer. Of these machines some are already sold and are to be forwarded direct to the buyers' addresses. The machines may originally have been shipped by different manufacturers in America, but they are all delivered to the forwarding agent at an American harbor, generally in New York City or Boston, and this forwarding agent sends all the machines at approximately the same time to the European forwarding agent. This agent, therefore, only knows that the American agent has shipped a number of machines, but he does not know who are the original shippers. The machine tool dealer gives the European forwarding agent instructions to ship some machines to one firm, others to another firm, and, perhaps, a third lot to still another destination, while a small part of them will be delivered to his own address.

How, now, is the forwarding agent to distinguish the different machines? There is no way to do it if all the crates are sent to one address. It is not possible to risk having the forwarding agent open the cases and distribute the machines according to the machine tool dealers' descriptions. Some machines might seem very much alike to one not familiar with them, and mistakes would easily be made. The writer knows from his own experience that such mistakes have occurred, simply for the reason that the box bore nothing but the address of the machine tool agent. In one case, where two machines were thus substituted for each other, the agent had to pay a penalty for delay in delivery, as well as the additional freight charges, to straighten matters out. In another case, the delay very nearly caused the customer to refuse the machine and to buy another from an agent who had it in stock for immediate delivery, but this latter machine was made by a competing firm in another country.

In order to avoid such inconveniences, it is suggested that the crates be marked in some way to avoid mistakes. This method is already followed by some of the American firms



THE IDEAL MACHINE TOOL CO.

ALBANY, N. Y. U. S. A.

List sent by Manufacturer to Agent for Identifying Shipment

familiar with the export business, and is generally followed by German and other European firms. In place of the machine tool agent's address, it would be advisable to print on the box some distinctive marks and numbers, preferably the initials of the firm which ships the machine and the number of the order. If, however, the order comprises more than one machine, each crate should have a separate number so that every crate bears a distinctive mark. The Jones & Smith Mfg. Co., for example, may use the marks J. S. M. C. with a number. The probability that two or more boxes would bear the same identification marks is very small. These marks and numbers are to be repeated in the invoices, possibly together with the net and gross weights and the dimensions of every crate. This will allow the machine tool agent to give precise instructions to the forwarding agent for the delivery of the machines, and mistakes will be avoided. The writer would recommend a shipping list to be sent to the machine tool agent together with the invoices as soon as the machines are shipped, this shipping list being made up about as shown in the accompanying illustration. Of course this illustration only shows an example, and special conditions may require modifications; but the principle is illustrated.

Another thing worth mentioning is that very small packages containing small tools, catalogues or circulars are frequently sent by express to European countries. This is a slow and expensive way and should be avoided whenever possible. It is preferable to make, if necessary, a number of parcels and to send them by parcels post, or, in the case of catalogues and circulars, as printed matter. It will cost much less and the packages will arrive much earlier.

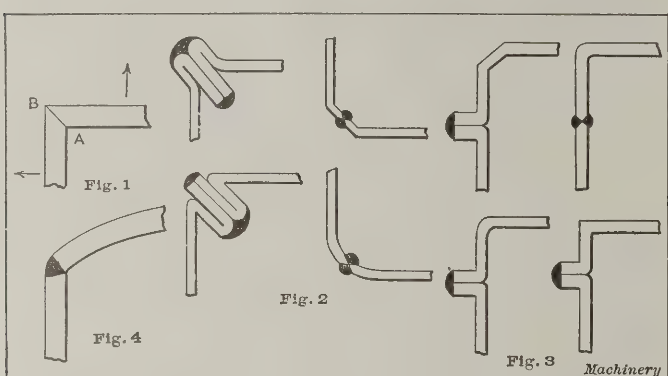
OXY-ACETYLENE WELDING OF TANKS AND RETORTS*†

By J. F. SPRINGER‡

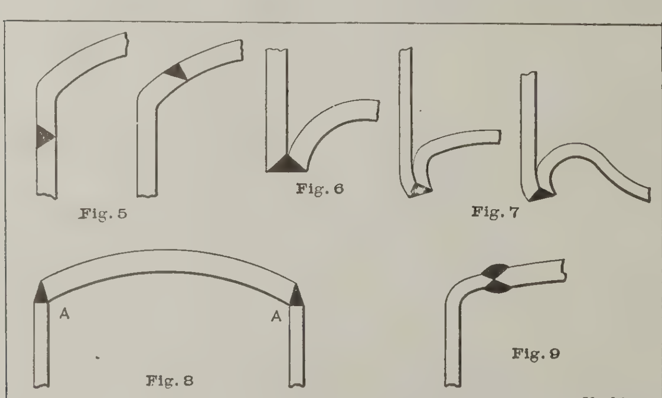
One of the most important applications of the oxy-acetylene welding process is in connection with the manufacture of tanks and cylinders from sheet metal. In this field the new process promises to supersede soldering and riveting to a very large extent. The advantage over soldering consists principally in the increased strength of the joint and the equality of the expansion and contraction of the metal in the seam and in the work. There is also much less likelihood of the occurrence of poisonous corrosions.

In constructing vessels of sheet metal which are subjected to alternations of high and low internal pressures, it is generally advisable to use special forms of joints at the corners or to avoid corner joints entirely. The stresses on the corner joints become very severe if the corners are of right-angled shape. If the corner is rounded, the effect of the internal pressure at the joint is reduced. In Fig. 1, for example, if the welded joint is made at the square corner *AB*, it will be located at the point where the stresses on it, acting as indicated by the arrows, will be most severe. By forming the joint in the various ways shown in Fig. 2, the weld will be



Figs. 1 to 4. Illustrations showing Various Methods of Making Welded Joints

considerably strengthened as compared with a weld that merely joins the two sides at the corner *AB* in Fig. 1. It is still better, however, to remove the joint from the corner altogether. In Fig. 3 are shown the methods used for doing this. The best method of all to relieve the welds of the excessive



Figs. 5 to 9. Methods of Welding Tops and Bottoms to Cylindrical Shells

corner stresses is, of course, to change the horizontal section to that of a circle.

Tops and Bottoms of Sheet-metal Vessels

One of the most difficult operations in the welding of tanks and retorts is the attaching of the tops and bottoms to cylindrical vessels. One of the first methods employed was that of making a joint as shown in Fig. 4. The welding was done from the outside and could be well finished. However, when the vessel was subjected to pressures from within, a combination of compressive and tensional stresses was produced at the weld, thus causing cracks. To overcome this difficulty, joints as indicated in Fig. 5, were made. Where the metal is quite thin, sufficient contact of the surface can be secured by bending the metal outward to form a kind of a flange. By using more welding material than necessary to produce a joint flush with the adjoining surfaces, a stronger weld can also be made.

In all these cases, the top or bottom is assumed to be convex on the exterior. Another method, shown in Fig. 6, is to make it concave on the outside. Such forms are especially suitable for bottoms. In Fig. 6 the rim of the bottom is bent and the edges of the bottom and of the cylinder are both beveled to provide a welding groove. Another method which does not necessarily include concaving is to bend up the rim of the bottom for a short distance, the dimensions of the piece being such that this rim snugly envelops the cylinder; the two may then be welded together.

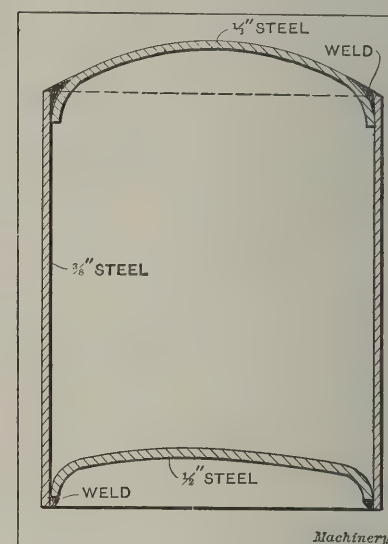


Fig. 10. Example of Tank welded by the Oxy-acetylene Process

The use of flat tops and bottoms should, of course, be avoided. The expansion and contraction of these during welding are different from those of the cylinder. The flat piece does not yield to the cylinder, and, hence, the work is likely to be distorted. The convexing and concaving of the tops and bottoms provides a suitable margin for yield. Two forms of bottoms are shown in Fig. 7, in both of which elasticity in the diameter is provided for. The bending in of the edges enables the cylinder wall to support the bottom when the latter is under pressure from within. In some cases it may be necessary to prevent diametral expansion of the cylinder when welding. A heavy removable band of metal in the form of a hoop may be used for this purpose. It is placed close up to the location of the seam. Most of the heat from the cylinder will then be absorbed and dissipated by this hoop.

An interesting example of the application of the foregoing principles is afforded by a large containing vessel constructed by Munk & Schmitz, Cologne-Bayenthal, Germany. This vessel is a cylindrical shell, closed at top and bottom, and is formed of sheets 0.40 inch thick in the cylindrical portion and 0.83 inch thick in the end portions. The vessel is 15 feet high and over 9 feet in diameter. All joints were made by the oxy-acetylene torch and the vessel successfully withstood, when tested, a pressure of 90 pounds per square inch.

General Considerations in Welding Tops and Bottoms to Cylindrical Vessels

If the joining of the top to the cylindrical shell were made at the precise point where geometrically the side of the wall joins the top, as shown in Fig. 8, an outward pressure exerted from within and tending to produce a spherical shaped bottom, would tend to make the angles at *A* more obtuse and would thus produce a tensional stress on the inner portion and a compressive stress on the outer portion of the weld. Hence, it should be carefully noted that this method of joining ends to cylindrical shells is objectionable, and that the methods shown in Fig. 5 should, in general, be adopted.

It is also very important in forming welds of the type described not to forget the effects of expansion and contraction. It is recommended that the weld be hammered during the cooling-off process. The hammering should be discontinued while the metal is still quite hot, and should not be continued below the point where a horse-shoe magnet attracts the iron; in fact, at this point, one has perhaps gone a little too far. Subsequent to the cooling, the region that has been exposed to the high temperature should also be well annealed. This

* For further information on autogenous welding, see "Modern Welding Methods," MACHINERY, December, 1911, and the previously published articles there referred to.

† This article was prepared with the cooperation of the Davis-Bournonville Co., N. Y., and is a chapter from a forthcoming book: "Oxy-acetylene Torch Practice."

‡ Address: 608 West 140th St., New York.

may be done by using two oil torches for gradual re-heating, one from the inside and one from the outside. Incidentally it might be mentioned that in performing the welding operation it is also often advisable to use two welding torches, in which case a weld of the double-V character, as shown in Fig. 9, will be produced. The bottom of such a vessel should be so arranged that the weld is not located where the weight of the vessel itself comes upon it.

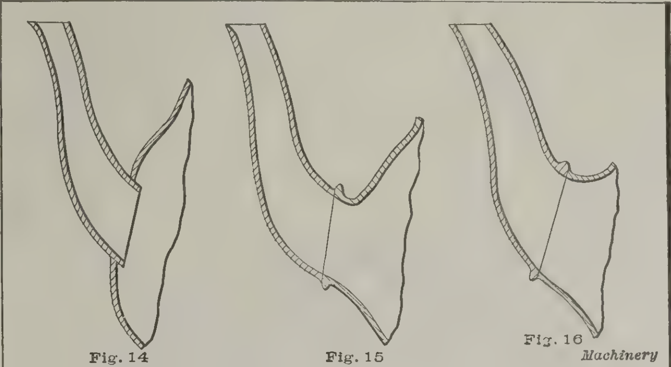
As an interesting practical example, the illustrations Figs. 11, 12 and 13 are shown, indicating the progressive steps in welding a cylindrical shell, as well as the welding of a top and bottom to it. A diagrammatical view of a section of the welded container is shown in Fig. 10, the work being done by the Vilter Mfg. Co., Milwaukee, Wis. It will be seen that the top is convex and the bottom concave, as viewed from the outside. The shell is of ⅜-inch boiler iron; the metal in the heads is ½ inch thick. The tank is 20 inches in diameter and 24 inches long. Both heads fit the inside of the shell as indicated.

After welding, this tank was tested at a pressure of 1200 pounds per square inch. For carrying out the test, a hole was drilled on one side of the shell and a nipple inserted after tapping. The tank was then connected with a hydraulic press pump. At 1100 pounds pressure the nipple started to leak, but there was no leak at the welded joints. A No. 7 Davis-Bournonville tip was employed in making the straight weld in the shell, and a No. 8 tip was used for the ends. The straight weld was made in 45 minutes at a cost of $1.62 (exclusive of labor, but including depreciation); the circular weld at the convex end required 2.67 hours and cost $6.99; the circular weld at the concave end required two hours and cost $5.24. At thirty cents per hour, the labor cost would be about $1.63, making a total cost of $15.48. These tanks are used at a maximum working pressure of three hundred pounds per square inch. A water cooled torch was employed in part of this work.

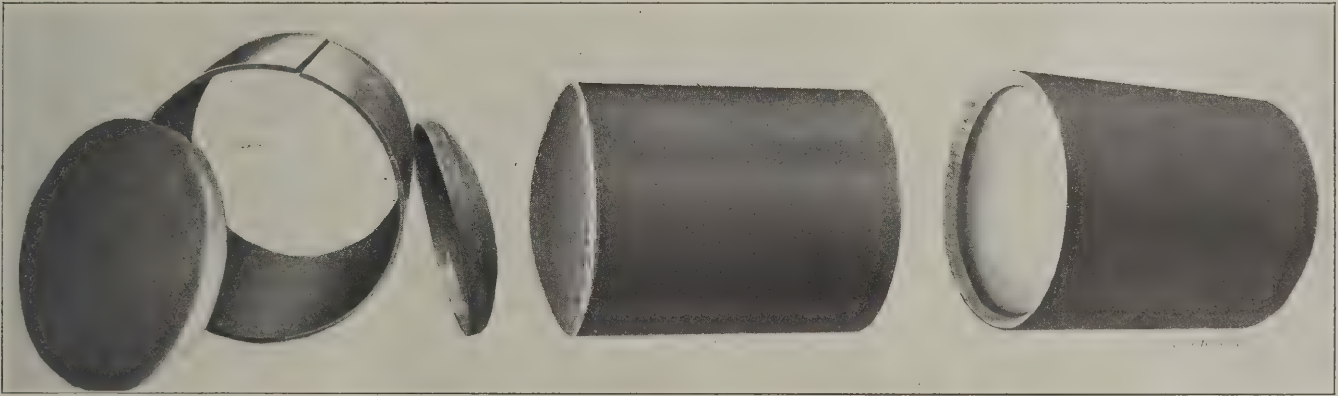
Autogenous Welding of Copper

While copper is normally tough and ductile, it enters a brittle stage when heated to about 1650 degrees F. This brittleness continues up to the melting point (at about 1930 degrees F). In order to weld copper it must be heated to this critical stage. At these high temperatures copper possesses a remarkable capacity for absorbing certain gases. If exposed to the atmosphere while at a white heat it absorbs oxygen. Another peculiar quality of copper is that when heated to a high temperature, quenching in water has a softening or annealing effect. Copper that has been highly heated and oxidized will, however, begin to fracture when one commences to hammer it, even if it has been annealed; hence, it is very important to prevent oxidation when welding, and by proper management of the outer flame of the oxy-acetylene torch the operator may succeed in preserving the new copper in the weld from oxidation. To make perfect work, however, it is necessary also to preserve the old copper, and here is where difficulties are met with. On account of the great heat conductivity of copper, a high temperature will be found for some distance on either side of the joint to be welded. Unless the operator can protect this outlying region, the results will not be satisfactory.

It is well known that phosphorus has a great avidity for oxygen. If, then, instead of a very pure copper we use a phosphor-copper alloy when welding, good results may be expected. A welding powder containing a percentage of phosphorus may also be used to secure a de-oxidation. Investigations along these lines are now being carried on in Germany, the exact results of which are not yet known, but it can be stated, in a general way, that good welding powders for copper can be made of such mixtures as borax, phosphor-natrium and prussiate of potash. The borax is not commercial borax, but that which has been subjected to a high temperature in a crucible and has then been pulverized. Boracic acid may be used instead of borax. The powder is prepared by mixing the boracic acid and the phosphor-natrium. Welding powders of this description form a film over the work and thus exclude the atmosphere. It is recommended when welding copper sheeting to spread the powder containing phosphorus for about 1½ inch on either side of the joint. This powder is then melted before the welding operation proper is begun. As there is some possibility of blowing away some of the powder when used in this way, it would seem desirable to apply it in the form of a paste.



Figs. 14, 15 and 16. Methods of Welding Spouts to Household Utensils



Figs. 11, 12 and 13. Progressive Steps in Making the Tank shown in Fig. 10

The Welding of Aluminum

The coefficient of expansion of aluminum is equal to twice that of steel and its melting point compared with that of copper and steel is rather low, being about 1215 degrees F. It is also comparatively weak in tension. Cast aluminum resists a tensional stress of about 10,000 pounds per square inch. Because of this weakness, and on account of its high rate of expansion and contraction, it is a difficult material to weld. As its heat conductivity is high, it is also difficult to localize the region of the high temperature. Oxidation of aluminum, however, can be avoided by the use of a proper flux.

While the total expansion and contraction from 100 degrees F. to the fusion point or welding temperature is about the same for cast iron and aluminum, because of the fact that the fusion point of cast iron is at a temperature about twice that of the fusion point of aluminum, the expansion and contraction, due to temperature changes, take place much more rapidly with aluminum, and the operator must use special care on this account. The low temperatures dealt with when welding aluminum make the pre-heating easier, but the operator must guard against not exceeding the fusion temperature. It is sometimes possible to make slight saw cuts here and there, and thus assist in making the effects of expansion and con-

traction harmless. These cuts, of course, must be repaired when the main operation is completed. Aluminum should never be welded without a flux. If welding is attempted without a flux, little globules consisting of aluminum within and a coating of alumina (oxide of aluminum) will appear. In order to eliminate these by heat, it would be necessary to raise the temperature to the melting point of the oxide of aluminum, which is about 5400 degrees F. A flux consisting of the following ingredients has been recommended: chloride of sodium, 30 parts; chloride of potassium, 45 parts; chloride of lithium, 15 parts; fluoride of potassium, 7 parts; and bisulphate of sodium, 3 parts.

When melting new metal from a rod, it is good practice to keep the rod constantly submerged in the molten bath of the metal in the welding groove, which for aluminum should be much larger than usual. If no powder is used, the oxidation is then confined to the upper surface. The main point to remember when welding aluminum is that the fusion point of this metal is very low; hence, the working flame should be kept further away from the metal than is usually the case

Fig. 17. Example of Welding Copper. Kettle is 5 feet 6 Inches in Diameter, 31 inches deep and used under Pressure. All Seams are welded on Both Sides

when welding cast iron and steel. The torch should be so adjusted as to furnish an excess of acetylene. There need be but little fear of carbonizing the metal, for the reason that the temperature of the work is comparatively low.

The Welding of Household Utensils

Some forms of household utensils, such as, for example, coffee and tea pots, cause considerable difficulties in their manufacture, particularly in connection with the attachment of the spout. Soldering has been used to a great extent in making these joints. However, the basic material of the solder is altogether different from the material united. The uses to which the vessels are put expose the joints to the action of acids, and galvanic currents are set up which injure the joint. Aluminum vessels are especially exposed to the action of these currents, because this metal is electro-positive to nearly all of the common metals. One means to obviate the difficulty is to bend the metal of the main vessel or body inwards at the hole for the spout. The material of both body and spout is then bent into a fold on the interior, no soldering material being used. The presence of this fold on the inside, however, is very objectionable. Even though it is closed when the vessel is new, the effect of repeated heatings is liable to open it, and the crevice becomes a trap for various small particles, which prevents effective cleaning. The oxy-acetylene welding presents the best solution of the foregoing difficulties.

When seeking to unite the spout and body by the oxy-acetylene torch, the worker is, however, confronted with several difficulties, especially if the sheet metal be aluminum. The expansion and contraction of aluminum, due to temperature changes, as already mentioned, is very rapid, so that the operator must guard against distortions of the work. The melting point of the metal is low, so that holes are apt to be made in thin metal. Heated aluminum is very readily oxidized with the result that a proper intermingling of the material is difficult. In view of these facts, it is recommended that the joint be placed away from the main body, that welding wire be dispensed with, and that a suitable flux be employed. In Fig. 14 is shown a joint which eliminates the necessity for the welding wire; the spout fits closely into the hole and is introduced far enough to protrude about 1/8 inch into the interior, the projection thus furnishing the welding material. There is considerable advantage, of course, in thus eliminating the handling of the wire as far as the worker is concerned, and another advantage is that the welding material is precisely the same as the material of the work. It is difficult, however, to operate on the interior, but this difficulty may be reduced by using a tip of special form. The appearance of the exterior, however, is good.

Another form of joint is shown in Fig. 15. Here the diameter of the hole is first made smaller than the interior diameter of the lower end of the spout. The material is then bent outwards to form a ridge of the same diameter as that of the spout end. The body and spout can then be butt-welded by using welding wire. It is preferable, however, to bend the edge of the projection from the vessel outward, thus supplying the needed welding metal, or the auxiliary metal may be provided by bending the edge of the spout outwards, a joint of this kind being shown in Fig. 16. In either case, the ring of metal protruding at the joint will not be thicker than 1/8 inch in a radial direction. In both cases, the interior is smooth.

COST OF MAINTENANCE OF GASOLINE MOTOR TRUCKS

An interesting paper was presented by Mr. Louis Ruprecht, before the summer meeting of the Society of Automobile Engineers, at Detroit, June 27-29, 1912, on the "Cost of Work with Gasoline Motor Trucks." It may be of interest to quote a few of the figures given, as the motor truck is now looked upon with considerable interest by many manufacturers. The depreciation may be figured at from 10 to 15 per cent per year, the tire value being deducted from the cost of the complete vehicle and the tires considered independently. The drivers' wages on a half-a-ton delivery wagon may be assumed to be about $2.75 per day, and on larger trucks from $3.00 to $4.00 per day. The garage charges, including only the washing and storing of the vehicle, are on an average from $240 to $300 per year, according to the size. The tire cost should be figured on the basis of a life of 8000 running miles, as guaranteed by the makers. The gasoline cost may be taken as about 11 cents per gallon, although at times it may be somewhat higher. Oil may be assumed to be 30 cents per gallon, and one gallon of oil will be sufficient for 50 to 125 running miles according to the size of the vehicle. The insurance will come from $100 to $250 per year according to the size. Repairs and replacements should be figured up to 3 cents per mile in the case of heavy trucks. This figure is based on extensive records.

Based on these figures a table has been compiled which gives, in the first place, the fixed charges per day for different sizes of vehicles, and in the second the additional running cost per mile. For example, the cost of operating a six-ton truck, all charges included, 45 miles per day, will be $\$6 + (0.1540 \times 45) = \$12.93$. The figures presented by the author also show conclusively that wherever a large tonnage is to be handled it is of the highest importance to use a few large units instead of many small ones.

Size of Vehicle	Fixed Charges	Increment Per Mile
1000-pound	$5.07	$0.0686
3-ton	5.33	0.0860
5-ton	5.60	0.1253
6-ton	6.00	0.1540
7-ton	6.15	0.1718
12½-ton train	7.40	0.2070

The data on the effect of vanadium in high-speed steel, given in the July number, was erroneously attributed to a publication issued by the American Vanadium Co., Pittsburg, Pa. The data should have been credited to the Vanadium-Alloys Steel Co., Latrobe, Pa.

THE STURTEVANT AERONAUTICAL MOTOR*

By CHESTER L. LUCAS†

Although the past few years have witnessed remarkable achievements in mechanical flight, it is evident, from the constantly recurring accidents, that, at best, aerial navigation is still extremely hazardous. Many of these accidents have been due to motor troubles of some form, and it is generally admitted that the majority of the present-day motors are inadequate, either through faulty design, poor workmanship or both. In the mad race for a light-weight motor, safety seems to have been almost entirely disregarded by introducing freaky designs and employing unsuitable light-weight materials; moreover, some of the workmanship displayed has been unmechanical, to say the least. The really reliable motors are few in number.

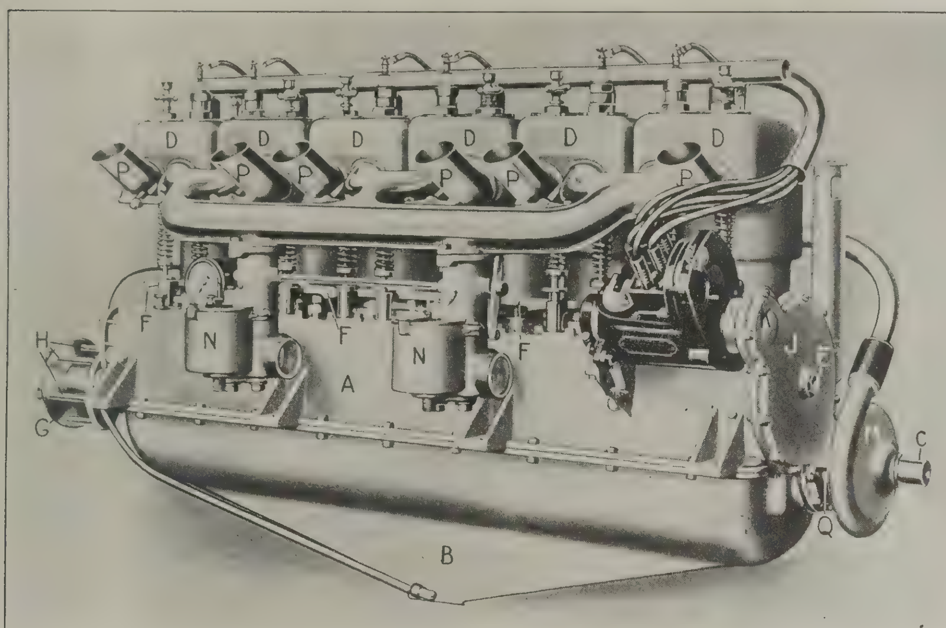

Fig. 1. The Sturtevant Aeronautical Motor, Six-cylinder

The ideal aeronautical motor should possess certain fundamental qualifications; these qualifications may be briefly summed up in the order of their importance: First it should be capable of continuous satisfactory performance at various angles over long periods; second, it should produce the maximum amount of power for a given weight, at the same time being economical in consumption of gasoline and lubricating oil; and third, it should be refined in appearance and operation, being hooded and muffled so as to be as small a source of distraction to the aviator as possible. This latter consideration is not, perhaps, as important at the present time as it will be in the future of aviation when the use of aeroplanes in war will necessitate that the motors employed be as nearly noiseless as possible, and when aeroplanes become more common it does not seem fanciful to state that there will be active legislation to silence aeronautical motors.

Distinctive Types of Aeronautical Motors

Generally speaking, aeronautical motors may be divided into two distinct classes: namely, those of the rotary type, in which the cylinders are arranged radially and constitute a revolving member about a stationary hollow shaft fitted with an inlet valve, and those of the stationary type in which the cylinders do not revolve. Under this latter head may be included those motors in which the cylinders are arranged vertically and in tandem; those in which the cylinders are placed in the form of a V, commonly known as the V-type; and those in which there are but two cylinders which are sometimes placed directly opposite each other as in the opposed type. Some motors operate on the four-cycle principle, while others are of the two-cycle type. Each of these different forms of motors has qualifications more or less important in its favor, but most of them have objectionable features to offset these qualifications.

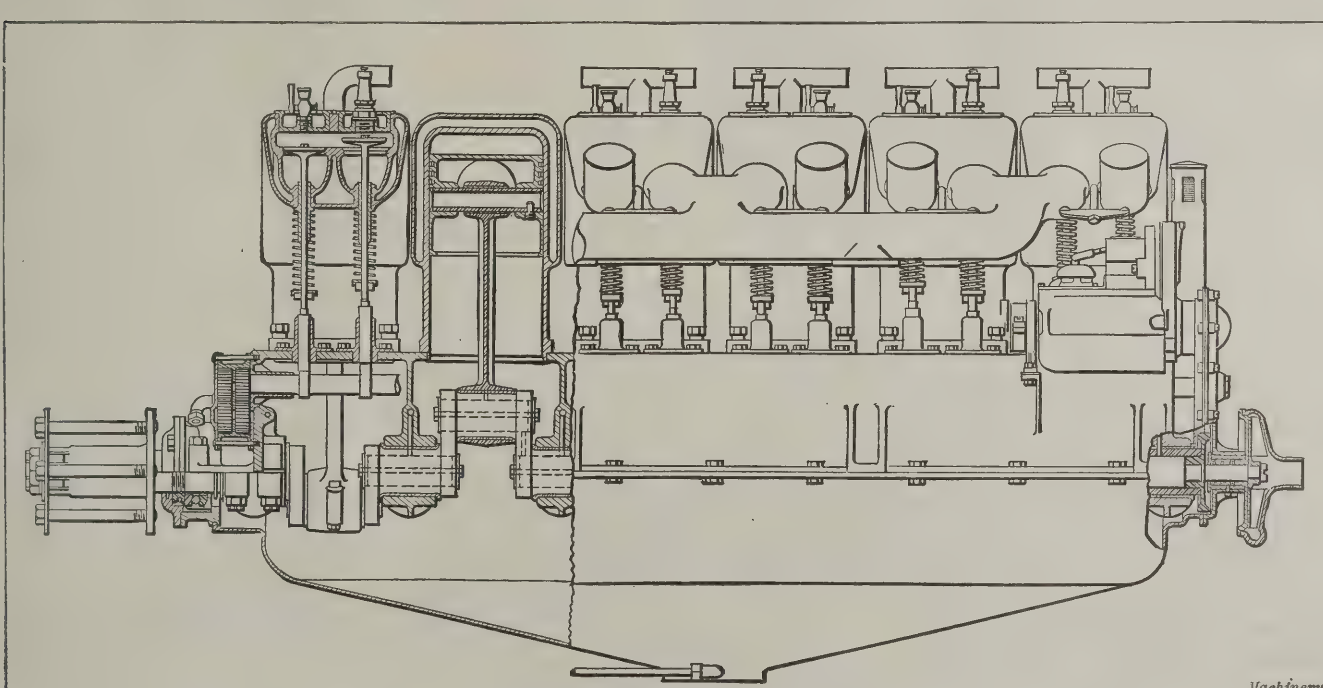

Fig. 2. Construction of Sturtevant Motor, Six-cylinder

The Rotary Type of Aeronautical Motor

Without doubt the rotary type of engine, of which the Gnome make is representative, is at present the most powerful type of motor in proportion to its weight. Its advantages, aside from being of light weight, are that up to certain powers it may be satisfactorily air-cooled; the torque

* For additional articles on this and kindred subjects, see MACHINERY, September, 1911, engineering edition, "Seventy-two Horsepower Adams-Farwell Aviation Motor; January, 1911, engineering edition, "Aeroplanes and Airship Engines" and articles there referred to.

† Associate Editor of MACHINERY.

is exceptionally uniform, due to the fact that while in operation, the group of cylinders acts as a flywheel, so of course no added weight is given to the motor. An additional advantage is present in this type of motor in that all the cylinders are in one plane, thus minimizing the effect of unbalanced forces.

On the other hand, however, the head resistance offered by a motor of this type is considerable; there is a large waste of lubricating oil due to the centrifugal force which tends to throw the oil away from the cylinders; the gyroscopic effect of the rotary motor is detrimental to the best working of the aeroplane, and moreover it requires about seven per cent of the total power developed by the motor to drive the revolving cylinders around the shaft. Of necessity, the compression of this type of motor is rather low, and an additional disadvantage manifests itself in the fact that there is as yet no satisfactory way of muffling the rotary type of motor.

Stationary Type of Motor

The advantages and disadvantages of the stationary type of motor may be summed up by considering the same points

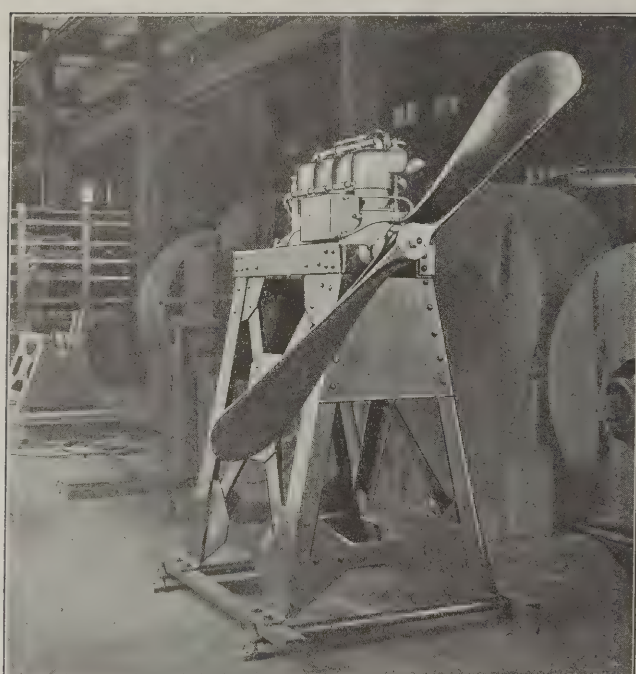

Fig. 3. Four-cylinder Motor mounted on Testing Stand

as set forth in connection with the rotary type. Of necessity, it is heavier in proportion to the power developed; it is not successfully air-cooled, nor is the torque as uniform. The reciprocating movements cause wear and loss of power and except for engines employing six or more cylinders, the balance is not nearly as good in this type of motor.

On the other hand, the head resistance of the stationary type of motor is much less than in the case of the rotary motor; it is very economical in its use of lubricating oil, and it has little gyroscopic effect upon the aeroplane. Less power is consumed in driving a revolving member about the shaft; when water-cooled, the compression may be kept high and it may be satisfactorily muffled, if desired.

While a much simpler motor may be designed by employing the two-cycle principle, its operation is not nearly as satisfactory as the four-cycle, and there are many sources from which trouble may arise. The V-type of motor is usually employed when the cylinders are above six in number, mostly on account of the compactness of this cylinder arrangement. The increased head resistance offered by this type of motor is, however, considerable. The opposed type of motor is seldom used except on two-cylinder engines.

Performances of Various Makes of Aeronautical Motors

The accompanying table has been compiled to show general characteristics and performances of several makes of aeronautical motors. The data used has been furnished by the respective makers of these motors and it is believed that this table should be of assistance to those interested in aeroplane power plants.

The Sturtevant Aeronautical Motor

The Sturtevant aeronautical motor was recently brought out by the B. F. Sturtevant Co., Hyde Park, Mass. Fig. 1 shows

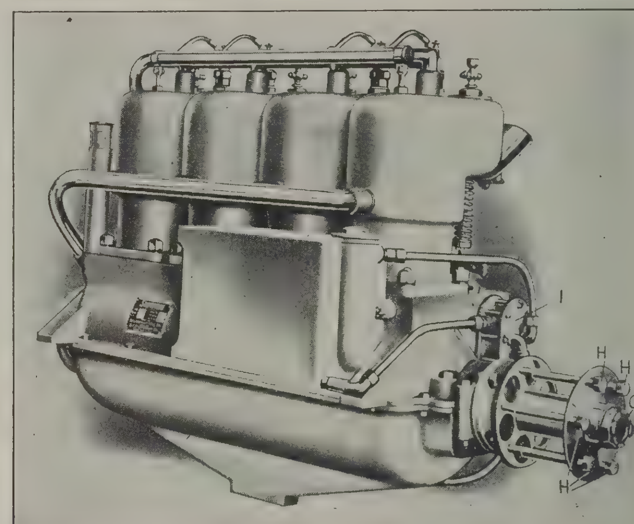

Fig. 4. Rear View of Four-cylinder Motor showing Method of Attaching Propeller

the general appearance of the six-cylinder motor, rated at 60 H. P., and Fig. 2 shows the same motor partly in section. The motor is also built as a four-cylinder type, rated at 40 H. P. This motor is shown in Figs. 3 and 4, and in Fig. 13, where it is set up ready for a propeller test. In designing this motor, the primary consideration was to build an absolutely reliable engine which could be depended upon when making long flights. While the weight has been reduced at every point possible, it has not been done at the expense of strength or reliability. The motor is of the stationary type, having either four or six cylinders. The company has endeavored to make this motor conform as nearly as practicable to the automobile type of motor, for the reason that this type of motor has been found the most practical for general use as evidenced by its employment in automobiles and, though a secondary consideration, it seems to be one which is generally appreciated by the average mechanic.

Crankshaft

The crankshaft which may be seen at *C* in Fig. 9 and in detail in Fig. 5, is machined from a bar of 3½ per cent nickel steel, containing 0.40 per cent carbon. After being machined, the crankshaft receives two heat treatments and has an ultimate tensile strength of 125,000 pounds per square inch of section. The bearings of the crankshaft are each 2⅜

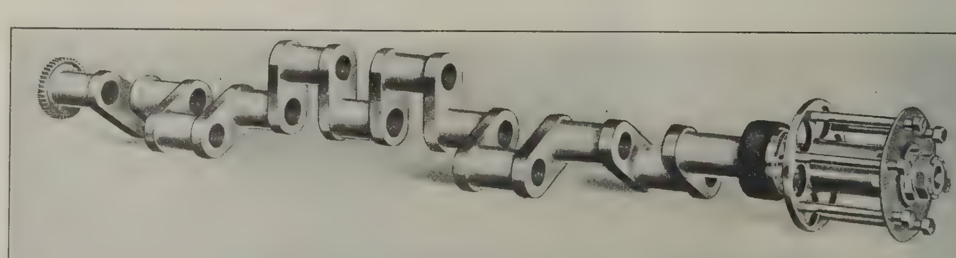

Fig. 5. Six-throw Crankshaft

inches long and are 1¾ inch diameter, the pins also being of the same dimensions. In order to lighten the crankshaft as much as possible, the pins and bearings are drilled and bored, the drilling operation being shown in Fig. 10, and the boring operation being illustrated in Fig. 11. The drilling of the pins and journals is accomplished by strapping the crankshaft to a suitable base located upon the Prentice Bros. drilling machine as shown. The boring to size is done in a

lathe by means of special boring-bars of the proper sizes. It is interesting to note that in finish-boring the crankshaft, the diameters of the holes in the successive journal bearings decrease regularly commencing with the first cylinder, which is bored to a diameter of 1⅜-inch and thence down to the sixth cylinder which is bored to a diameter of 1 inch. The reason for this is that at the driving end of the crankshaft, it is not necessary that there be as much strength as at the position of the sixth bearing where the power delivered by all six of the connecting rods is being transmitted. The pins are bored uniformly in order to preserve the balance of the crankshaft. These hollow pins and journal bearings are connected by drilled cross holes, and by closing the ends of the holes in the journals and pins by suitable caps *R*, shown in Fig. 9. The crankshaft is thus provided with a lubricating duct through which oil may be pumped. Fig. 12 shows the operation of grinding the pins and journals on a Norton grinding machine. The propeller end of the crankshaft is fitted with a ball thrust bearing shown at *T*, Fig. 9, which may be arranged to take the thrust in either direction as desired. The method of attaching the propeller is worthy of noting. The end of the crankshaft which receives the propeller is slightly tapered; a flange *G*, Fig. 1, is provided having six holes to correspond with the attaching bolts *H*, and the opening in the flange is castellated to slide over the end of the shaft which has, in turn, been castellated to receive this flange. Thus, by means of the flange the propeller is supported from both sides and the tendency of shearing the attaching bolts is distributed over both ends of the hub.

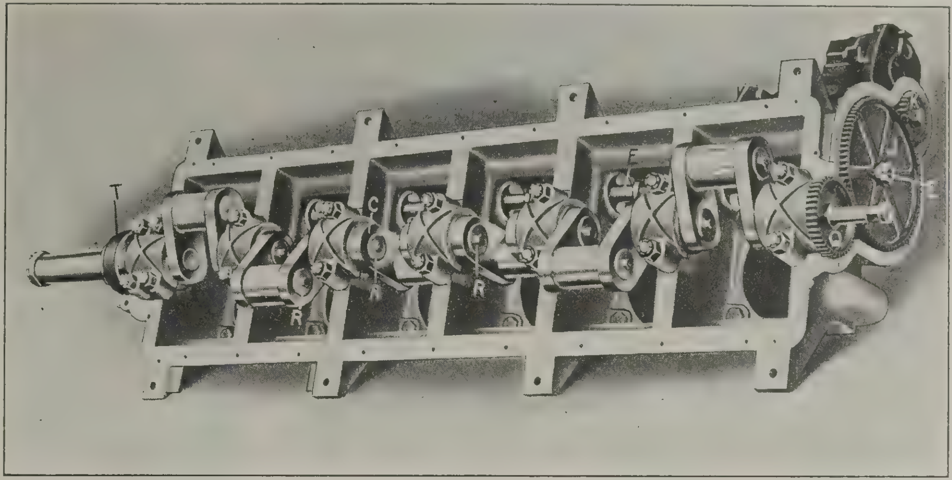

Fig. 9. Crankshaft and Base, showing Method of Mounting

Connecting-rods

The connecting-rods are made from drop-forgings of 3½ per cent nickel-steel and are of I-section. The bearings are die-cast bushings of Parsons white brass. When it is stated that some connecting-rods are made of non-ferrous metals it will be readily understood how inadequate they must be for use as aeronautical motor connecting-rods, and it is little wonder that they will not do the work required. Sturtevant connecting-rods are balanced with respect to the center of gravity, being placed on balances with opposite ends together; that is, the large end of one connecting-rod, together with the small end of another connecting-rod, is placed in the pans on one side of the balances, while the opposite ends are placed in the pans on the other side of the balances. Before being machined and balanced, the connecting-rods are heat-treated in accordance with the S. A. E. specifications. The connecting-rod caps are adjusted in position by the use of shims of laminated metal. Pieces of this metal are shown in Fig. 14 and, as will be seen, the metal is about 3/32-inch thick, and is composed of many thicknesses of thin sheet brass, each 0.002 inch thick and sweated together with soft solder. Successive layers of the metal may be easily pulled off as required in adjusting the boxes.

Pistons

The pistons, one of which is shown in Fig. 6, are cast from semi-steel having a tensile strength of 40,000 pounds. The exterior of the piston is ground and balanced to within two drams of standard weight. This balancing is done by removing metal from a boss which is left projecting within the interior of the piston, enough metal being removed to bring the pistons to standard weight. The piston rings are cast iron, of the ordinary type and are three in number. The piston pins are of 3½ per cent nickel steel and are bored hollow to reduce weight.

Cylinders

The cylinders, as shown in Fig. 7, are of the L-type, having the exhaust and intake valves located on the same side. An important reason for selecting this type of cylinder lies in the fact that with the straight cylinder which has been used to a large extent on aeronautical motors, there is always danger from broken valve parts being caught in the cylinder and causing damage to the motor. Of necessity, on cylinders of this type, the water jackets are cast integral. Experiments have been conducted in electro-depositing copper jackets, but so far, at least, the integral jacket seems to be the most satisfactory. The metal from which the cylinders are cast is the same semi-steel mixture from which the pistons are cast, and, of course, the jackets are made as thin as it is possible to cast the metal. After being machined, the cylinders are

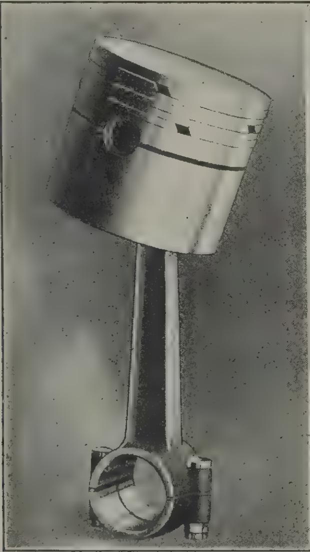

Fig. 6. Piston and Connecting-rod

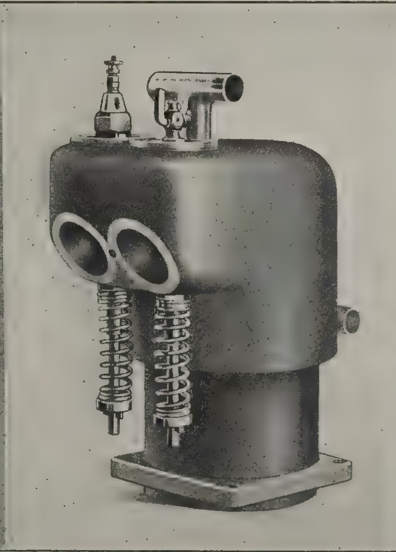

Fig. 7. Cylinder

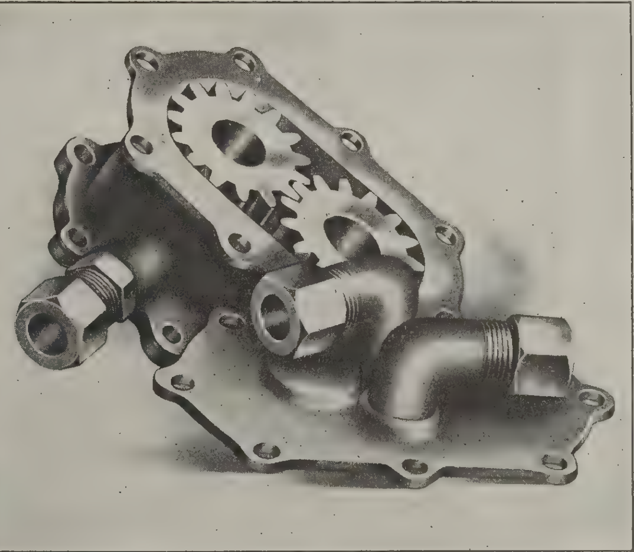

Fig. 8. Lubricating System Pump

hydraulically tested to 600 pounds per square inch. They are then heat-treated and accurately ground. The ratio between the stroke and the bore of these cylinders is 1 to 1, the stroke and bore each being 4½ inches. Upon this point of cylinder design there seems to be a difference of opinion, some designers being in favor of long stroke motors, while others consider the short stroke to be the better.

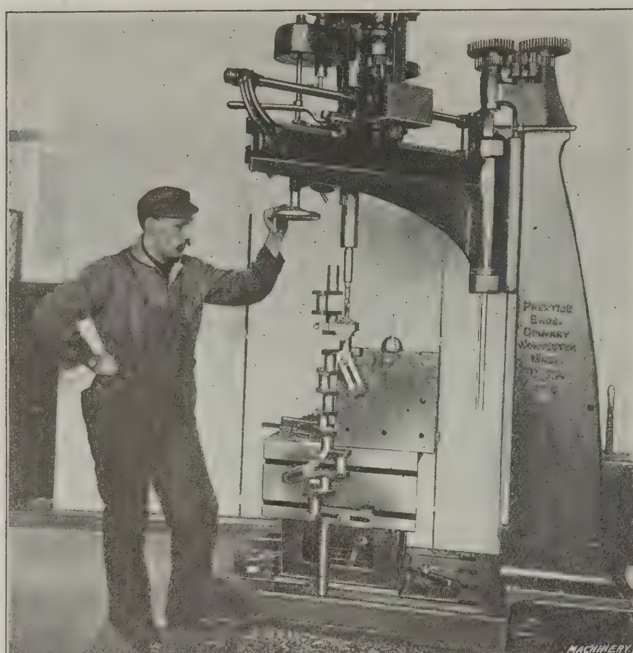

Fig. 10. Drilling out the Pins of the Hollow Crankshaft

Camshaft, Valve Mechanism and Other Parts

The camshaft, a portion of which may be seen at E, Fig. 9, is turned and ground from nickel steel, being ground with the Norton cam-grinding attachment. Previous to being finish-ground the camshaft is pack-hardened. Upon the forward end a gear J is mounted which transmits motion from the gear Q on the crankshaft to give rotation to the camshaft. This gear J also acts as an intermediate gear in the driving train which operates the magneto L, Fig. 1. These parts are also shown in Fig. 9. The camshaft is supported throughout its length in phosphor-bronze bearings. The inlet and exhaust valves for each cylinder, made of 30 per cent nickel steel, are located in the pockets cast integral with the cylinders. The exhaust pipes are shown at P in Fig. 1. The water pump, M, Fig. 1, is attached directly to the end of the crankshaft, the inlet C being coupled to it.

Means are provided for starting the motor in mid-air; this is an advantage in that it will enable an aviator to shut off his motor while "volplaning," and yet be able to start it again at will without landing. Referring to Fig. 1, at F may be seen a valve-lifting rod whose function it is to lift the exhaust valves, should the motor stop while in flight. By thus lifting the exhaust valves, the action of the air on the propeller will cause the motor to start automatically. The base of the motor, indicated at A, is a strong aluminum casting reinforced throughout and the cylinders are held to this base by means of four bolts, each of which passes through flanges on the cylinder bases. The construction of this base is illustrated in Fig. 9, and as will be seen, the bearings for the crankshaft are bolted to the under side. These bearings are die-cast bushings of Parsons white brass. The oil pan or sump B shown in Fig. 1, is of slightly different design than that ordinarily used. As the deepest point is at the center, the oil will gravitate toward the center of the sump, even though the motor be operating in an inclined position.

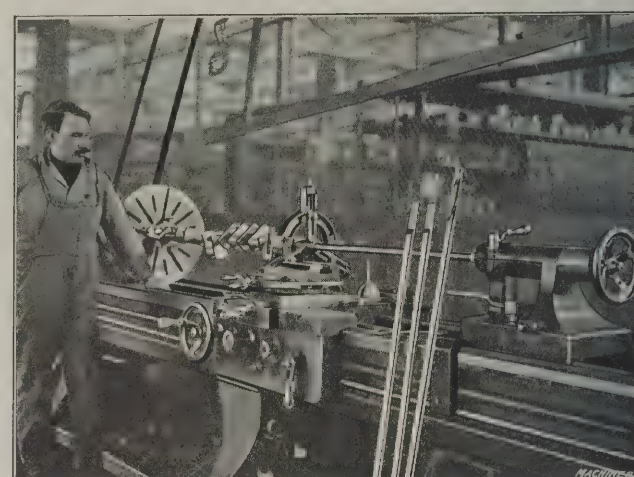

Fig. 11. Boring the Journal Bearings

Lubricating System

The lubrication system employed in the Sturtevant aeronautical motor is of more than ordinary interest. The fundamental idea in designing this system was to provide a method of lubrication that would be absolutely dependable. By means of a pressure pump shown in Fig. 8, driven directly from the end of the camshaft, the oil is forced through cored holes in the base and into the hollow crankshaft already described. It is thus distributed to the bearings in which the crankshaft runs, and also to the connecting-rod bearings. From these points the oil flies in a fine spray to all parts

* Recommended by manufacturer. † Consumption in gallons per hour at developed H.P. ‡ Cylinders revolve 800 R.P.M. in one direction and crankshaft 1000 R.P.M. in opposite direction. Both are direct-connected to two propellers. § Propeller revolves at one-half engine speed or 900 R.P.M.

of the mechanism enclosed within the crank case, finally gravitating to the sump. Mounted in tandem with the first pump is a second pump. This pump is of slightly greater capacity and its function is to remove the oil from the sump, force it through the oil filter and into the tank ready to be used again. As this second pump is of slightly greater capacity than the pressure pump, the sump is always kept drained, and, moreover, as the filter is in advance of this pump, the oil is *forced* through the filter. In the event of the filter becoming clogged, the pump would exert sufficient force to burst the filter and prevent the lubrication system from failing. These pumps are shown detached from the motor in Fig. 8.

The lubricating oil storage tank holds sufficient oil for three

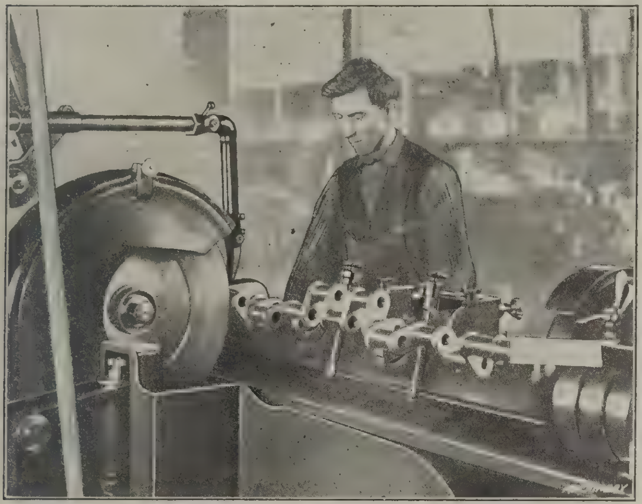

Fig. 12. Grinding the Crankshaft

hour's use and by virtue of the form of sump employed, there is no danger of overlubrication of the end cylinders when the motor is being operated continuously at an angle, since the sump is kept drained of its oil by means of the pump. The 40 H. P. motor requires 0.3 gallon of lubricating oil per hour's run.

Muffling

The subject of muffling aeronautical motors seems to have been an after-consideration with most manufacturers. The

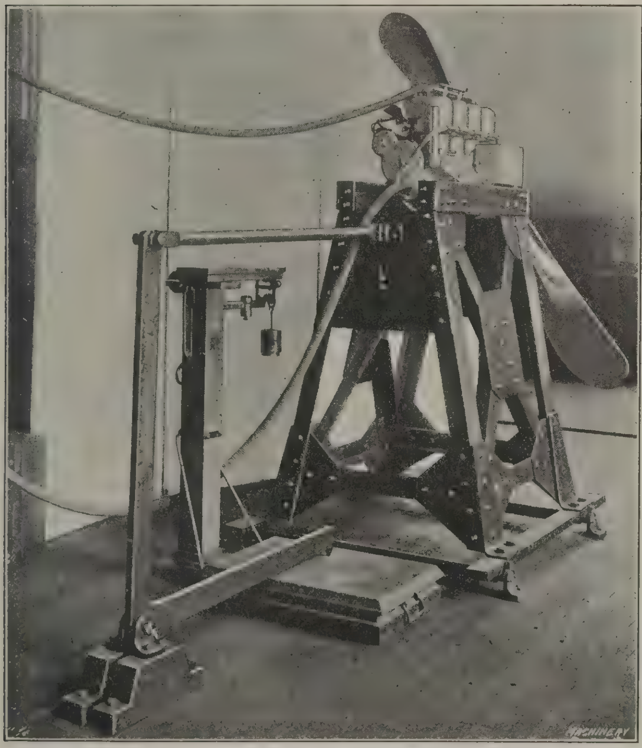

Fig. 13. Sturtevant Engine set up for a Propeller Test

Sturtevant muffler is a part of the power plant and can be shipped with the motor, or if ordered at any future time can be easily applied. It is very probable that in the near future no aeronautical motor which cannot be efficiently muffled will have commercial standing. As a forerunner of this view, the design of the Wright engine has recently been changed in order that it may be muffled. The Sturtevant muffler can be instantly detached from the motor when not required, and as its total weight is but eighteen pounds, it does not seri-

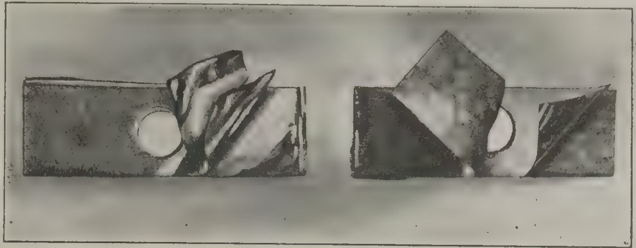

Fig. 14. Laminated Metal

ously handicap the aviation equipment. The loss of power due to the muffler is about five per cent.

Carbureter

The carbureters employed on this motor are of the Zenith make. An advantage claimed for the Zenith carbureter over other makes lies in the fact that after once being set no adjustment is required. Provision is also present for furnishing the carbureter with hot air from the exhaust, so that there will be no danger from freezing of the mixture in high altitudes. The carbureters may be seen at *N* in Fig. 1.

Tests

In addition to flying tests which have been conducted with the Sturtevant motors, interesting shop tests are being made from time to time. One of these tests was conducted over a period of 100 hours, the motor being operated for twelve consecutive days, 8 hours per day for 11 days, and 12 hours on

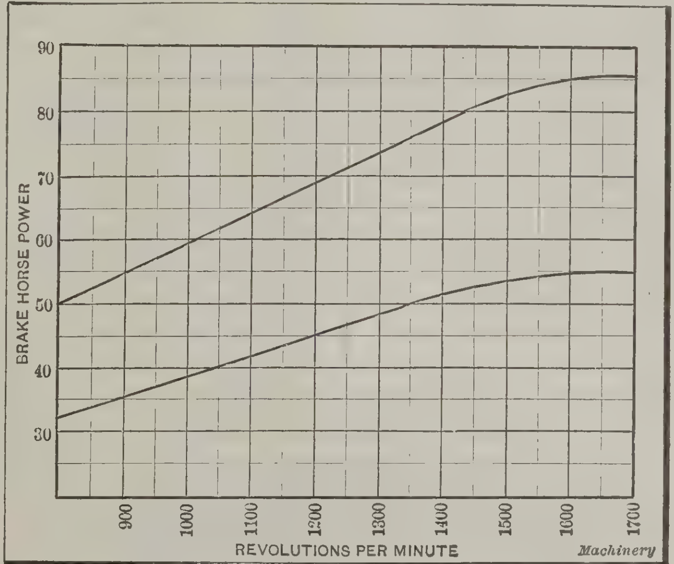

Fig. 15. Power Curves of Six-cylinder (Upper) and Four-cylinder (Lower) Motors

the last day. The motor used was four cylinder, 40 H. P., equipped with a 7½ foot diameter 4½-foot Sturtevant propeller. It developed brake horsepower as indicated upon the power curve chart shown in Fig. 15. During this test an average thrust of 360 pounds was recorded, the speed on the propeller being 1200 revolutions per minute. The only attention which the motor received was the cleaning of the spark plugs and the supplying of oil and gasoline to the tanks at the end of each day's run.

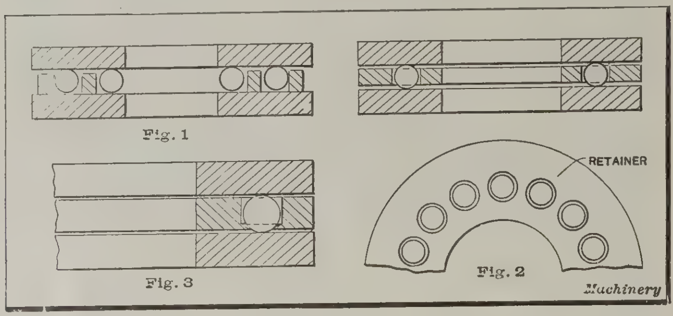
Referring to the power chart, Fig. 15, the comparison of A. L. A. M. ratings with the actual performances of these motors is very interesting and shows exceptionally high efficiency. The A. L. A. M. rating assumes a piston speed of 1000 feet per minute, with which speed the 4½-inch motor necessitates 1332 R. P. M. At this speed the four-cylinder motor is rated at 32 H. P., while its actual performance at 1332 R. P. M. is 50 H. P. The A. L. A. M. rating of a six-cylinder motor is 48 H. P., while the motor actually develops 76 H. P., at 1332 R. P. M. In both cases the peak of these power curves is reached at 1700 R. P. M., at which speed they develop 55 and 86 H. P. respectively.

BALL AND ROLLER THRUST BEARINGS*

By ROBERT H. GRANT†

In the early development of so-called "anti-friction" thrust bearings, there was no data with which the engineer could begin to work, and the great difference between the point bearing of a ball and the surface bearing of a collar or washer was not generally appreciated. In a great many cases, therefore, the early bearings were poorly designed and were made of materials which were not adapted for the purpose. Hence, they were often condemned by the user, and a general opinion was created that they were almost worthless; in fact, if the bicycle, which became so popular simply on account of the introduction of ball bearings, had not been a great factor in counteracting the hostile feeling, the adoption of ball and roller bearings in many fields would undoubtedly have been much slower. The automobile, the development of which followed immediately upon the bicycle, added to the favor with which ball bearings were received.

When ball bearings were first introduced, grinding machines were used to a very small extent, except as tool-room appliances. Hence, the bearing surfaces of the first ball bearings



Figs. 1 to 3. Evolution of the Ball Thrust Collar

were simply polished, and the balls touched only on the "high spots," producing a bearing which did not work smoothly and which soon wore out of true. This also accounts for the unfavorable results obtained with early ball bearings.

Early Development of Ball Thrust Collars

The first and simplest ball bearing made was that known as the "thrust collar." In 1888, Simonds Rolling Machine Co. made a worm-driven machine and experienced considerable trouble with the end thrust of the worm. This company manufactured balls at that time and decided to try a ball thrust bearing for the worm. The thrust collar, as it was first made, consisted of two washers, with two rows of balls

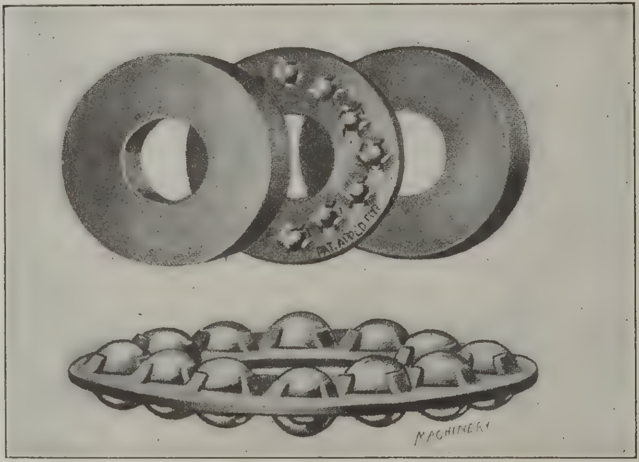


Fig. 4. Pressed Steel Ball Retainer of the Type made by the Pressed Steel Mfg. Co., Philadelphia, Pa.

and two rings, as shown in Fig. 1. In assembling this bearing, the washer was first placed upon the shaft against the bearing collar or shoulder and then the small ring was placed on the washer, after which a row of balls was placed between the shaft and the ring. The second ring and row of balls were then placed upon the washer, after which the second washer was put on the top. The washers and balls had to be held together by one man while another man put the shaft in place. However, the bearings often came to grief by the balls falling out, and it was therefore suggested that a soft steel washer of the same diameter as the hardened bearing washers be drilled with holes slightly larger than the balls. This washer would then act as a retainer and keep the balls in place. Experiments were made and it was found that this

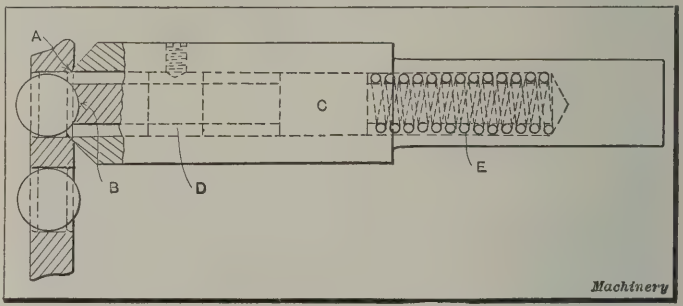

Fig. 5. Spinning Tool used in the Manufacture of Ball Cages

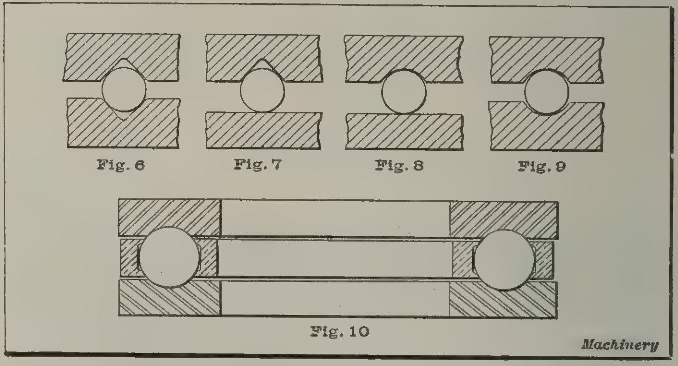
method worked satisfactorily. This type of bearing is shown in Fig. 2.

After this style of cage had been used for some time, a further improvement was made in that the holes in the cage were not drilled quite through, but as shown in Fig. 3, so that the balls could not fall through the retainer. This aided the assemblers in handling the balls in the cage without losing them. A groove would soon wear in the washers, however, and in order to cover as much of the surface of the washer as possible with the balls, the balls were later staggered in the cage so as to distribute the load and wear over a greater part of the washer surface.



Figs. 6 to 10. Different Types of Grooves for Balls

The Standard Roller Bearing Co. of Philadelphia made its first retainers by drilling holes in the periphery of the washer, and after the balls had been inserted in each hole, the edges of the holes were peened over at the outside. The drill, of course, was somewhat larger in diameter than the thickness of the washer, so that the balls could project on the sides of the retainer. The balls were thus arranged in a radial line from the center of the washer, but were not staggered, so that each row of balls took the same circular path. The generally adopted cage is now pressed out of sheet steel and the openings made of such a size that the balls can be sprung into them by a slight pressure. Such a cage is shown in Fig. 4. In special bearings the cage is made of brass and the holes are drilled the size of the balls. They are not drilled quite through, however, and after the balls have been inserted the holes are spun over with a tool of the type indicated in Fig. 5. The spinning edge *A* of this tool is hardened. The end of the plunger at *B* is concave so as to center the tool with the ball. At *C* is a shoulder on the plunger which is a sliding fit in the hole, thus keeping it straight; *D* is a collar held in place by a headless set-screw, which retains the plunger; *E* is a spring which presses the plunger forward and allows it to recede while in operation.

Thrust collar washers can be made either from bar stock in an automatic screw machine with a multiple cutting-off tool, or from punchings. The latter method is the preferable one, as the sheet steel is rolled lengthwise and the grain or fiber

* For information on ball and roller bearings, see the following articles previously published in MACHINERY: "Some Notes on Ball Bearings," May, 1909, engineering edition, and also other articles there referred to. See also MACHINERY'S Reference Book No. 56, "Ball Bearings."

† Address: 912 Oakland Ave., Ann Arbor, Mich.

is so arranged that the point bearing of the ball does not come in contact with the ends of the fibers, as it does when the washers are cut in the automatic screw machine. The punched washers, therefore, have from 35 to 40 per cent better wearing qualities than the other type. The thrust collar is not used for heavy loads except in special cases, and the washers are, therefore, seldom made of tool steel, but of casehardened machine steel. As the washers are perfectly plain, a number of them can be put at a time on a magnetic chuck and can easily be ground parallel so that all the balls will have a bearing and take their share of the load. Table I gives the loads and speeds recommended by the ball bearing manufacturers.

Grooved Ball Thrust Bearings

The grooved ball thrust bearing can be made with grooves of different shapes, but the round groove is the only one to be recommended. In Fig. 6 is shown a thrust bearing with V-grooves. It is difficult to get the grooves in the two washers directly opposite each other so that there will be a perfect four-point bearing. Of course a sample bearing in the tool-room can be easily made to meet all requirements, but when the bearings are made in quantities, difficulties are met with. This, however, is not the greatest objection to this bearing. The main objection is that when the load is applied, the ball is squeezed into the V and prevented from turning freely. While the bearing is hardened, it is not glass hard, and it will allow the ball to seat itself so as to wear the bearing out of true in a short time.

TABLE I. GENERAL DIMENSIONS AND APPROXIMATE LOAD PER BEARING FOR REGULAR BALL THRUST BEARINGS

Diameter of Bearing, Inches		Diam. of Balls, Inches	Load in Pounds at					
Inside	Outside		1500 R.P.M.	1000 R.P.M.	500 R.P.M.	300 R.P.M.	150 R.P.M.	10 R.P.M.
$1\frac{1}{4}$	$2\frac{11}{32}$	$\frac{1}{4}$	350	500	600	750	800	2750

$1\frac{5}{8}$	$2\frac{31}{32}$	$\frac{5}{16}$	600	750	850	1100	1350	4000
$1\frac{3}{4}$	$3\frac{3}{32}$	$\frac{5}{16}$	750	850	1000	1350	1750	5000
2	$3\frac{11}{32}$	$\frac{5}{16}$	850	1000	1250	1600	2000	5500
$2\frac{1}{8}$	$3\frac{19}{32}$	$\frac{5}{16}$	1000	1250	1500	1850	2500	7000
$2\frac{1}{4}$	$3\frac{23}{32}$	$\frac{5}{16}$	1100	1350	1750	2100	2750	7500
$2\frac{1}{2}$	$3\frac{31}{32}$	$\frac{5}{16}$	1250	1600	2000	2500	3000	9500
$2\frac{5}{8}$	$4\frac{11}{32}$	$\frac{3}{8}$	1500	1750	2250	2750	3500	10000
$2\frac{3}{4}$	$4\frac{15}{32}$	$\frac{3}{8}$	1750	2000	2750	3000	4200	12500
$3\frac{1}{4}$	$4\frac{31}{32}$	$\frac{3}{8}$	2100	2350	3200	3750	5000	15000
$3\frac{1}{2}$	$5\frac{7}{32}$	$\frac{3}{8}$	2500	2850	4000	4750	6000	17500

In the three-point bearing, Fig. 7, where there is one V and one flat surface, the objections to the V groove are the same as already mentioned, and the flat surface does not allow a greater load to be carried than that which can be carried by a plain thrust collar. Hence, this bearing is not superior to a regular thrust collar ball bearing, but is more difficult to make; nor is a bearing having one plain and one grooved washer as shown in Fig. 8 superior to a thrust collar. In Fig. 9 is shown the regular grooved ball thrust bearing in its simplest form. The radius of the groove is made from five to ten per cent greater than that of the ball used in the bearing. This allows some latitude for the washers so that they can line up properly. It can be readily seen that when the load increases on the ball, the surface bearing between the ball and the washer will become slightly greater on account of the fact that the radius of the groove is slightly larger than that of the ball. Theoretically, there is only a point contact when there is no load, but as the load gradually increases this point contact will become a surface contact over a gradually increasing length of the ball circumference.

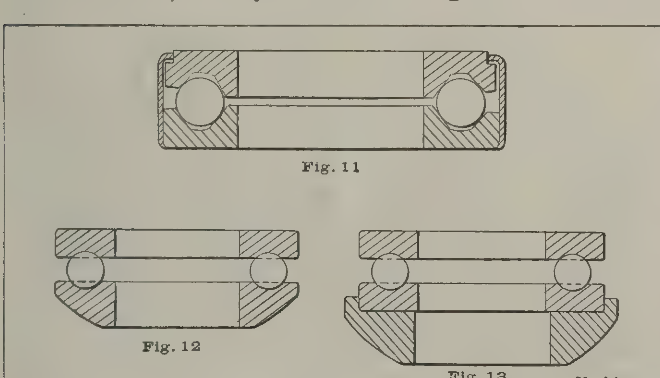

Fig 11. Ball Grooves with Different Angles on the Sides. Figs. 12 and 13. Thrust Bearings with Leveling Washers

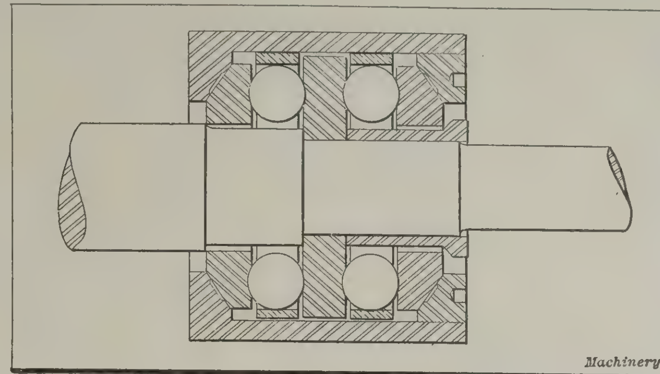

Fig. 14. A Ball Bearing taking Thrust in Both Directions

This makes it possible for the bearing to stand up under heavy loads. But it is difficult to make both grooves bear equally upon the balls unless the bearings are made in a very careful way.

Grooved thrust bearings require the use of a separator the same as the thrust collar. In Fig. 10 is shown the simplest form of retainer for this purpose. When the grooves in the washers are made very deep, the retainers must be made rather thin.

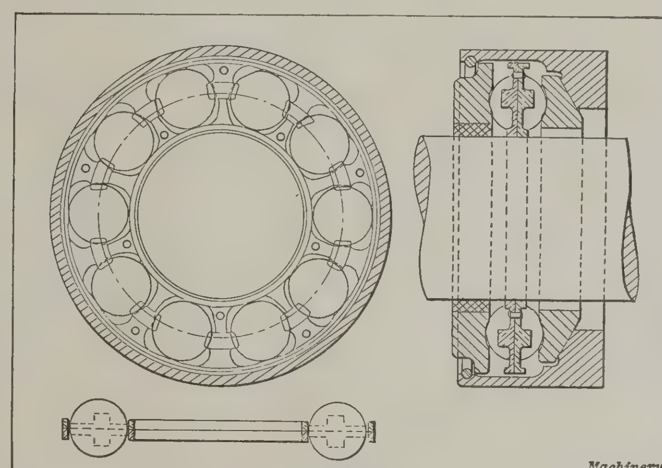

Fig. 15. Skeleton Cage for Ball Bearings

In order to overcome the slippage caused in the V-grooves on account of the inside bearing of the ball running slower than the outside, the Auburn Ball Bearing Co. makes a bearing in which the angle of the V is greater on one side than on the other, as shown in Fig. 11. This prevents slippage of the ball, but it does not overcome the squeezing effects of heavy loads. Nevertheless, this bearing has given satisfaction in light and mediumly heavy service.

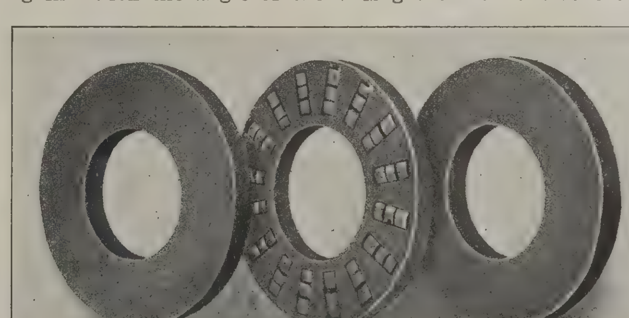

Fig. 16. Simple Form of Roller Bearing

Applications of Ball Thrust Bearings

For convenience in assembling and handling ball bearings, the self-contained thrust bearing is the most satisfactory. It

is necessary to have the surfaces against which the bearing rests perfectly parallel with each other. Many bearings do not give satisfaction on account of the poor methods employed in their application to the machinery on which they are to be used. In order to overcome the results of neglect on the part of the user, leveling washers are often provided on one side of the bearing to take care of any lack in alignment and insure that the entire surface of the thrust washers will take its proportion of the load. This method prevents breakage and should be universally adopted. It adds but little to the cost of the bearing and saves the user much trouble.

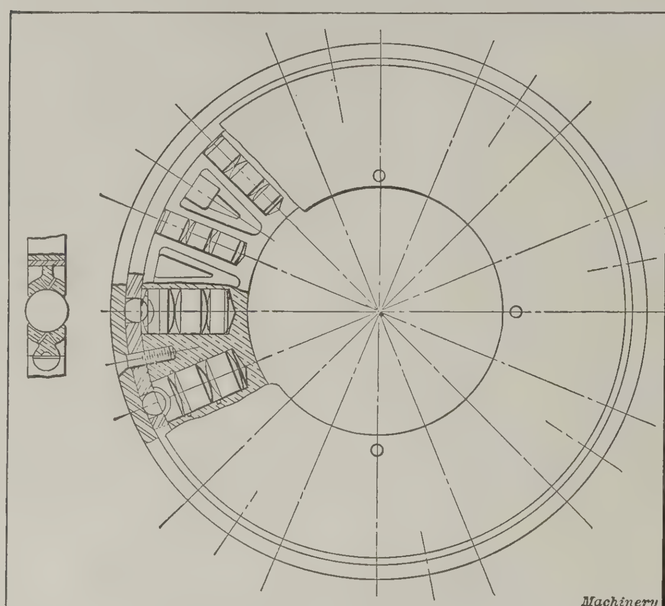

Fig. 17. Means for Taking Care of End Thrust of Rollers in Roller Thrust Bearings

The leveling washer, sometimes termed "radius washer," is made in two ways. In Fig. 12 it is made integral with the lower thrust bearing washer. This is done when the space for the bearing is limited. A corresponding concave surface must, of course, be provided in the housing or part which holds the thrust bearing. If there is plenty of space for the bearing, it is cheaper to use a standard grooved thrust bearing and a leveling washer with a slight recess beneath the lower bearing washer, as shown in Fig. 13.

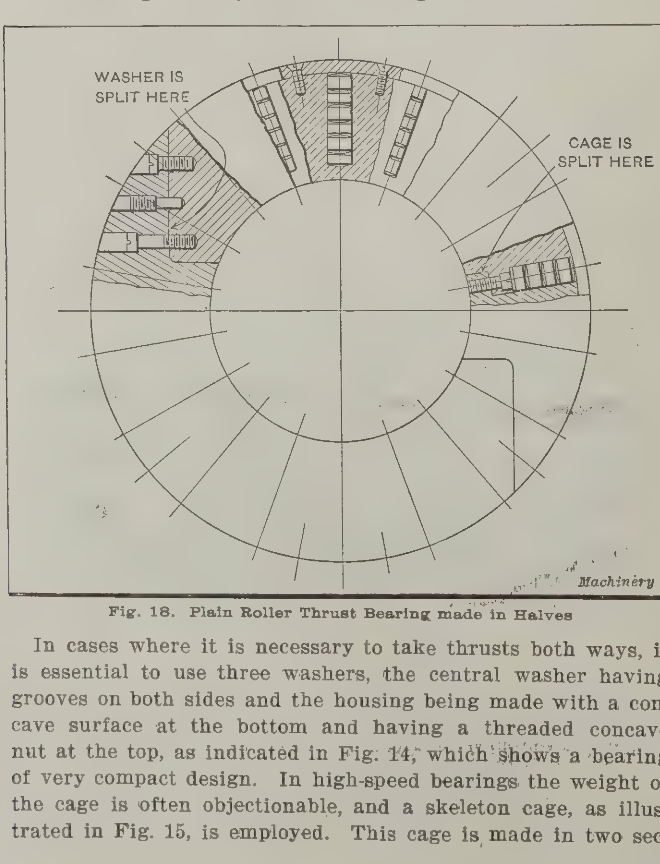

Fig. 18. Plain Roller Thrust Bearing made in Halves

In cases where it is necessary to take thrusts both ways, it is essential to use three washers, the central washer having grooves on both sides and the housing being made with a concave surface at the bottom and having a threaded concave nut at the top, as indicated in Fig. 14, which shows a bearing of very compact design. In high-speed bearings the weight of the cage is often objectionable, and a skeleton cage, as illustrated in Fig. 15, is employed. This cage is made in two sections, riveted together, and the only surfaces that are finished are those on which the balls and the shaft bear.

Roller Thrust Bearings

The principle of the roller thrust bearing, as shown in Fig. 16, is not theoretically correct, as apparently the rollers must slip to a certain extent. The outer and inner ends of the cylindrical roller roll along paths of different circumferences, and, hence, there cannot be a perfect rolling action. In fact, the rollers follow the path of a polygon with a great number of sides and a slight slippage takes place each time the roller changes its course. From a practical point of view, however, this bearing has proved a great success. Fig. 16 shows the simplest form of plain roller thrust bearing. The rollers are straight and cut into short sections so that they will turn readily. A bearing of this type will sustain loads from four to eight times greater than that carried by a ball thrust bearing of the same dimensions. The slippage that takes place as the rollers change their course in short, jerky movements around the circular path, has proved an advantage in that it partly takes care of the outward thrust caused by the centrifugal force. In large thrust bearings this outward thrust is very great and must be taken care of in other ways besides this.

One of the greatest advantages of this bearing is its simplicity, and the ease with which it can be manufactured. The washers and rollers can be readily ground. A high degree of

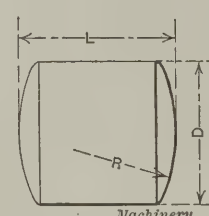

TABLE II. DIMENSIONS OF ROLLERS FOR ROLLER THRUST BEARINGS

Long Type			Short Type		
Diam. D	Length L	Radius R	Diam. D	Length L	Radius R
1/8	3/32	3/16	1/8	1/16	1/2
5/32	7/64	3/16	5/32	5/64	1/2

1 1/2	1	2	1 1/2	3/4	4
1 3/4	1 1/8	3	1 3/4	7/8	5
2	1 1/4	3	2	1	5

accuracy is also possible as all parts can be easily measured. The type of bearing shown in Fig. 16 is made by drilling holes into the periphery of the washer at equal distances around the circumference. The rollers are then inserted, allowing them to project a trifle beyond the sides of the washer; an annular ring or band is then forced onto the washer and is drilled and riveted in place.

The cages, of course, can be made in a great number of different ways. One company makes the slots the full size of the roller and then peens over the sides to retain the rollers. Another company used to make their cages by broaching rectangular holes through the washers and then staking them over to prevent the falling out of the rollers. In all the early types of ball bearings the rollers were all the same length, thereby allowing the roller to cut a path into the washer. To overcome this difficulty two widths of rollers were made, as shown in Table II. It will be noticed that the rollers are rounded on the ends so as to reduce the friction between them. The corners are also slightly rounded so as to prevent crumbling or chipping, which is apt to occur on account of

the slippage of the rollers. With these two different lengths of rollers put into the cage alternately, the whole surface of the washer can be covered.

In fast running roller thrust bearings, it is necessary to take care of the outward thrust of the rollers by placing a ball at the end of the rollers to take the thrust, as shown in Fig. 17. Two bands are placed on the outside of the cage instead of only one; the first band is a soft steel ring and the second is hardened to take the thrusts. The outside roller in each pocket is countersunk to receive the ball. In Fig. 17 is also shown a small section of the cage indicating its skeleton form in order to provide for a light construction. In high-speed horizontal bearings of this class a small thrust bearing

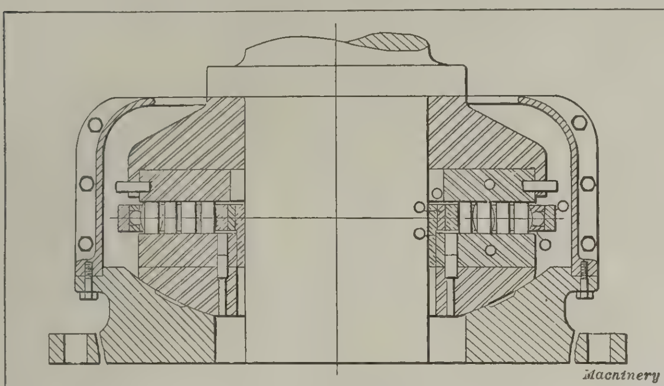

Fig. 19. A Complete Design of Roller Thrust Bearing

is often used to carry the cage. In slower running bearings there is usually a small shoulder on the cage upon which it revolves. Large roller thrust bearings of this class can seldom be used without leveling washers, as already described in connection with ball thrust bearings.

The ordinary form of bearing is made solid, but some are made in halves with all the joints accurately ground, and if properly designed will give as good service as those made from solid plates. The splitting, as shown in Fig. 18, is done in such a way that the rollers pass over the joint at an angle. Bearings made in this way are somewhat more expensive than solid bearings, but are especially desirable in cases where it may become necessary to remove them from the shaft without removing other parts.

Fig. 19 shows a roller thrust bearing with a leveling washer. The bearing washers are made reversible in case of wear. A

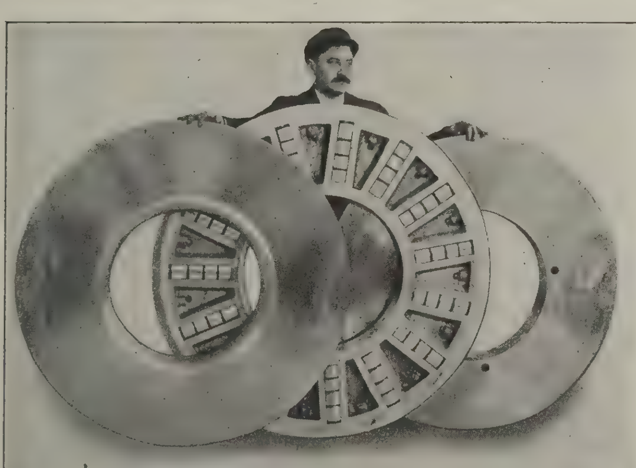

Fig. 20. Example of Unusually Large Roller Thrust Bearing

complete housing is used so that the whole bearing can be run in oil; at the same time the bearing can be easily taken apart, if necessary. The upper washer is held from the outside so as to prevent wear on the shaft. The housing, which is concaved to receive the bottom or leveling washer, is recessed at this joint so as to reduce the bearing surface. This is an example of a compact roller thrust bearing.

As an example of what has been done in large roller thrust bearings, that in Fig. 20 is shown. This is probably the largest bearing of this type ever made and it is installed at the Carnegie Steel Works. This bearing is capable of carrying a load of 1,500,000 pounds running at a speed of 100 R. P. M. The machine upon which this thrust bearing is used is designed for making steel car wheels by hydraulic pressure. The diameter of the washer of this bearing is 46 inches and the cage diameter, 50 inches. The washers, made from chrome-nickel steel, are $3\frac{1}{2}$ inches thick and weigh nearly 1700 pounds. The cage is made in skeleton form from manganese bronze and is provided with 4-inch chrome-nickel steel rollers. At the end of each set of rollers a large ball is placed to take the outward thrusts, as shown in Fig. 17. These rollers were made from a bar, four at a time, and were not cut entirely apart but simply "necked" so that they would hold together during the hardening process. They were then ground to the same diameter and broken apart and oil grooves ground in the face so as to prevent their cutting the washers. Oil holes were also drilled at the bottom of the recess in the cage from the bore to the pockets which hold the rollers. The pockets in the cage were carefully bored so that the rollers would have a running fit.

For hardening these thrust washers, a track was provided in the furnace, the door of which was made level with the floor, and a truck was made with a table on ball bearings; then a hole was cut in the side of the furnace so that the table could be revolved from the outside. The washers were allowed to heat for ten hours and the table was revolved at certain intervals to insure that they would be uniformly heated. In order to avoid confusion, the men in the hardening room had been previously drilled in removing the washer from the furnace to the hardening tank which was twenty-five feet long, four feet wide and ten feet deep. There was a

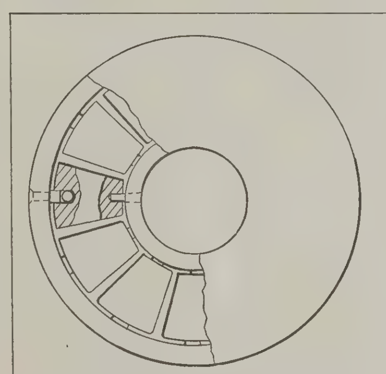

Fig. 21. Tapered Roller Thrust Bearing

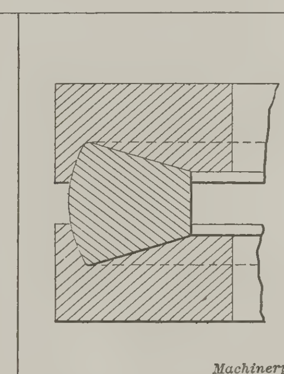

Fig. 22. Method of taking the End Thrust in a Tapered Roller Thrust Bearing

track overhead with a pneumatic hoist and two ropes were attached to the hook so that the washer could be pulled back and forth in the water. Seventeen seconds was required for the first washer hardened, from the time it left the furnace until the time it was submerged in the water. It was then raised and lowered by one man while two other men pulled it back and forth in the tank. After the washer was perfectly cold, it was placed in an oil tank over night and upon inspection was found to be perfectly hard. It had warped only about 0.020 inch.

Tapered Rollers in Thrust Bearings

It would seem upon first consideration as if it would be better to use a tapered roller rather than a cylindrical one in a thrust bearing of the type described, in order that a perfect rolling action might be insured. Bearings provided with tapered rollers, however, have not, as far as the writer knows, proved successful, except in very rare cases where the load has been light, or, if the load has been heavy, where the speed has been very slow. The difficulty to be overcome with the tapered roller is the great outward thrust. Several methods have been used to overcome this difficulty. In Fig. 21 is shown a tapered roller thrust bearing with a hardened pin driven into the cage ring and a hole drilled into the end of the roller in which a ball is inserted. This would prove quite successful if every roller were of exactly the same diameter and could be drilled to the same depth, and if all the balls and pins were exactly alike, but, if they are not, the rollers nearest to the center will bear all of the load until some of the parts wear so as to bring the other rollers into action. The rollers must also all be of exactly the same angle, and,

hence, a bearing of this type presents many practical difficulties in its manufacture.

Fig. 22 shows another method by means of which the end thrust of the rollers can be taken care of—that is, by having the washers extend over the ends of the rollers. This, however, is not a practical method for high-speed bearings, as it does not give the roller freedom of action. In cheap bearings, however, this method has proved quite successful. A great many different schemes have been evolved for this class of bearing, such as placing set-screws in the cage ring so that each roller could be adjusted to take its share of the load, etc. Methods of this kind may have worked well for a short time, but as the readjustment has to be done by an expert, the bearings have been considered impracticable for regular use.

* * *

BRITISH ENGINEERING STANDARDS COMMITTEE

In a report by Consul General John L. Griffiths of London, England, a brief history of the British Engineering-Standards committee is given.

The committee was originally appointed in January, 1901, by the council of the Institution of Civil Engineers, to consider the advisability of standardizing various kinds of iron and steel sections. It was then composed of seven members, and the first meeting was held in February, 1901, when it was decided to approach the councils of the Institutions of Mechanical Engineers, Naval Architects, and of the Iron and Steel Institute in order to secure, if possible, their cooperation. These invitations were accepted, and the reorganized committee began work in April, 1901. In November of the same year it was suggested that the standardization of electrical plants should be undertaken, with the result that the Institution of Electrical Engineers was also invited to nominate members of the committee, and in June, 1902, the committee was enlarged.

The work as originally undertaken has thus from time to time been expanded, and numerous subjects have been considered. Some idea of their diversity may be suggested by an enumeration of the several sectional committees. They are: Main; finance; publication and calculations; sections and tests for materials used in the construction of ships and their machinery; steel castings and forgings for marine work; iron for shipbuilding and ships' cables; bridges and building construction; railway rolling-stock under frames and locomotives, with subcommittees on component parts and types, tires, axles, and springs, steel plates, copper and its alloys, iron for railway rolling stock, railway rails, tramway rails, tire profiles, screw threads and limit gages, automobile threads, and also on small screws and screw heads, rolled and drawn sections, keys and keyways, pipe flanges, cement, vitrified-ware pipe, cast-iron pipes for hydraulic power, water, gas, and sewage, heating, ventilating, and house drainage, and for electrical purposes; electrical plant with subcommittees on generators, motors, and transformers, prime movers, physical standards, telegraphs and telephones, cables, electric tramways, and electrical plant accessories. The main committee, with the sectional and subcommittees, now has a membership of 321.

The various original standard specifications are carefully revised from time to time in order to keep abreast with new inventions and improvements. It is pointed out, on behalf of the committee, that perhaps its most salient feature is the advantage which accrues to Great Britain in that it possesses a central organization from which information may readily be obtained, both as to standards and as to the causes that led to their adoption.

Some fifty-seven reports on various subjects have been published and may be secured at prices ranging from 60 cents to \$5.10 each. A minimum subscription of \$51.10 entitles the subscriber to a copy of each report as published and of each revised report and to information two or three times a year concerning the various subjects dealt with by the committee and early information of any revisions in hand.

Steps have been taken for holding at an early date—probably in London—a conference on international electrical standardization.

NATURAL ALLOY STEEL*

By E. F. LAKE†

Natural alloy steel is rapidly becoming prominent in the manufacturing field. It derives its name from the fact that the steel is manufactured from an ore in which nickel and chromium are alloyed by nature. While such ores have been known to exist for some time, it is only within the last decade that ores were discovered that had a uniform composition and existed in quantities sufficiently large to warrant their manufacture into steel.

Shortly after the Spanish-American War, such ore was discovered at Mayari and Moa in the Province of Oriente, in the eastern part of Cuba. These ores showed a remarkable uniformity of composition and covered some 25,000 acres on a plateau on the northern slope of a mountain range. In this place there is something like 1,000,000,000 tons of ore in sight, low in phosphorus and sulphur. The Pennsylvania Steel Co., Steelton, Pa., obtained the control of these ore beds and is, besides the Maryland Steel Co. of Sparrows Point, Md., the only company manufacturing steel billets, blooms, bars, and miscellaneous forgings from the ore. The steel made by the Pennsylvania Steel Co. is known by the trade name "Mayari steel." Other companies purchase the billets, bars, etc., and roll and forge them into commercial shapes. The Philadelphia Steel & Forge Co., Philadelphia, Pa., is one of these firms and it has given the product the trade name "natural alloy steel," while the Carpenter Steel Co., Reading, Pa., calls it "Samson steel." Both of these latter firms make a specialty of rolling and forging shapes suitable for automobile parts, but they also manufacture the steel into bars and shapes that can be used for die-blocks, spindles, tools, and numerous other purposes.

Composition

The various grades of steel into which this ore is manufactured contain from 1.00 to 1.50 per cent of nickel; from 0.20 to 0.70 per cent of chromium; and from 0.30 to 1.50 per cent of carbon; the manganese runs from 0.50 to 0.80 per cent; while the silicon is kept below 0.20 per cent and the phosphorus and sulphur below 0.04 per cent. These two latter elements, however, seldom reach 0.035 per cent, and a phosphorus content that is below 0.02 per cent is often obtained. The commercial stock is manufactured into two types, one of which contains between 0.20 and 0.40 per cent of chromium, and the other between 0.40 and 0.70 per cent. Both of these can be obtained in any of the following carbon percentages: 0.15, 0.20, 0.25, 0.30, 0.35, 0.40, 0.45 and 0.50 per cent. Another brand that is used to a large extent for leaf springs, and also for other purposes, contains from 0.90 to 1.50 per cent of carbon and between 0.20 and 0.40 per cent of manganese, which is in accordance with the spring steel specifications of the Pennsylvania Railroad Co. Titanium, vanadium and other purifying materials can be added to the steel if it is so desired, and thus further enhance the physical properties.

These natural alloy steels are carefully made by the open-hearth process and are, in the heat-treated condition, in every way the equal to 3½ per cent nickel steel. In some ways they are superior to this steel and especially is this so of the type that contains the higher percentages of chromium, or when they are manufactured into parts that have a comparatively large sectional area. They are also cheaper than the nickel steels made by the same process, and in the billet form they are but little higher than the ordinary carbon steels. The high-grade and high-priced nickel-chrome steels are the only ones that are superior to the natural alloy steels in static strength, and this is largely due to the fact that they are usually made by the crucible process and contain a higher percentage of chromium, this being approximately 1.00 and 1.50 per cent in the two best brands.

* The following articles on alloy steels and kindred subjects have previously been published in MACHINERY: September, 1911, engineering edition, "Titanium Steel," and "Composition and Heat Treatment of Carbon and Alloy Steels"; May, 1911, engineering edition, "The Properties of Vanadium Steel;" April, 1911, engineering edition, "Manganese Steel"; October, 1909, "Heat Treatment of Alloy Steel"; June, 1909, "Remarkable Physical Characteristics of Rolled Manganese Steel Rails"; May, 1909, "The Machining of Manganese Steel"; October, 1907, engineering edition, "Vanadium Steel"; September, 1907, "Nickel Steel." See also the note referring to other articles, published in connection with that last mentioned.

† Consulting Metallurgist, 184 Ave. B., Cor. 47th St., Bayonne, N. J.

Properties of Natural Alloy Steels

For comparing the static strength, a large number of tests were made with natural alloy, nickel and carbon steels that contained 0.40 per cent of carbon and were hardened at the critical point and then drawn at various temperatures between 500 and 1500 degrees F. The average results obtained from these three kinds of steels are shown in Fig. 1. The steels compared all contain 0.40 per cent carbon. The natural alloy steel was quenched at 1520 degrees F.; the 3½ per cent nickel steel at 1500 degrees F.; and the carbon steel at 1530 degrees F. The average strength of each steel at a given drawing temperature can be obtained by following the line indicated by the desired number of degrees downward, until it meets the curve of the tensile strength, elastic limit, elongation or contraction, according to which is to be found, and from this point following the horizontal line to the left, where the number of pounds per square inch, or the percentage, is recorded. In Table I are shown the average elastic limit and ultimate strength of the fiber stress as ascertained in some torsional tests made at the Pennsylvania State College. All heat-treated specimens were hardened and drawn to develop the best properties for driving shafts, axles, etc.

Much care has to be used in manufacturing the ordinary nickel or nickel-chrome steels to prevent either of these elements from segregating in the bath or when teeming it into ingots. This is largely due to the fact that the nickel and

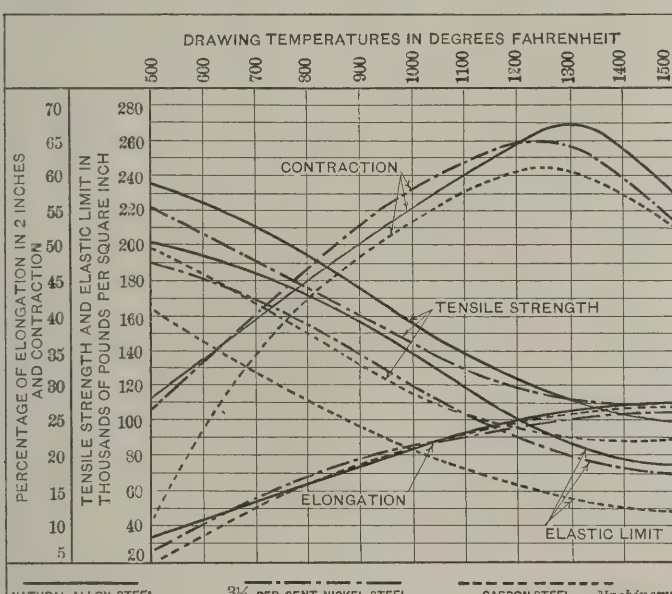

Fig. 1. Comparison of Characteristics of Natural Alloy, Nickel and Carbon Steels

chromium are additions and the bath must be heated to a comparatively high temperature just before teeming. In the natural alloy steel, however, the nickel and chromium are alloyed in the ore and are present in the bath from the time the melting operation starts until the finished steel is poured into ingots. Hence the bath does not have to be heated to any higher temperature at the time of tapping than do ordinary steels, and any tendency towards segregation is largely overcome. Thus, the elements are more uniformly distributed throughout the mass, and a homogeneous metal is obtained. When such elements segregate and the steel is rolled, they produce laminations in the metal which have a very injurious effect upon its strength, especially at right angles to the direction in which they are rolled.

The chromium gives the steel a mineral hardness and refines the grain remarkably, owing to its tendency to prevent the development of a crystalline structure. In the annealed state, every increase of chromium up to a content of 6.50 per cent raises the tensile strength, while the elastic limit is gradually raised until a chromium content of 3.00 per cent is reached. This latter remains constant until the chromium content has passed 9 per cent, but after this a rapid reduction takes place. In the hardened steels, both the tensile strength and the elastic limit increase until a chromium percentage of 5.00 per cent has been reached, and beyond this point both gradually decline.

When 2.00 per cent of chromium has been added to a steel that has a carbon content between 0.75 and 1.50 per cent, it combines great hardness with ability to resist shock. It is one of the best materials for piercing armor plate, and is also used in making projectiles. A chromium content of 3.50 per cent in a tool steel that contains 8.25 per cent of tungsten, gives the steel the well-known property of red hardness; that is, the hardness is not drawn and the cutting edge is maintained when using the tool at a red heat. A high percentage of chromium is also added to a steel that is forged between layers of wrought iron or soft steel and hardened in water. This is used in safes, vaults, etc., to make them burglar proof, and is also used for ploughshares and similar work.

TABLE I. AVERAGE FIBER STRESS IN POUNDS PER SQUARE INCH OF TORSIONAL TESTS MADE AT PENNSYLVANIA STATE COLLEGE

Kind of Steel		Natural Alloy Steel	3½ % Nickel Steel	Carbon Steel
Annealed	Elastic Limit	41,500	40,800	32,500
	Ultimate	93,400	78,200	75,100
Heat-treated	Elastic Limit	93,600	76,400	60,500
	Ultimate	130,200	108,000	102,400

Extreme hardness may be obtained in chromium steels, as the chromium intensifies the sensitiveness of the metal to quenching and greatly reduces the liability to fracture that is found in carbon steels. This is due to the fact that in chromium steels the critical changes that take place when heating all steels to the hardening temperature take place more slowly. Chromium is also one of the best elements in a steel that is to be carbonized or casehardened, as it greatly increases the susceptibility of steel to heat-treatment and acts as a carrier of the carbon. Thus, in steels containing chromium, the carbon will penetrate to a much greater depth, and a higher percentage will be absorbed by the outer layer in a given time, than with any other kind of steel, especially carbon steel. The increase in depth of penetration of carbon is about 30 per cent of the penetration in ordinary carbon steels.

The extreme hardness produced by chromium makes it necessary to use comparatively small percentages in steels that are to be machined. When the chromium content reaches 2.00 per

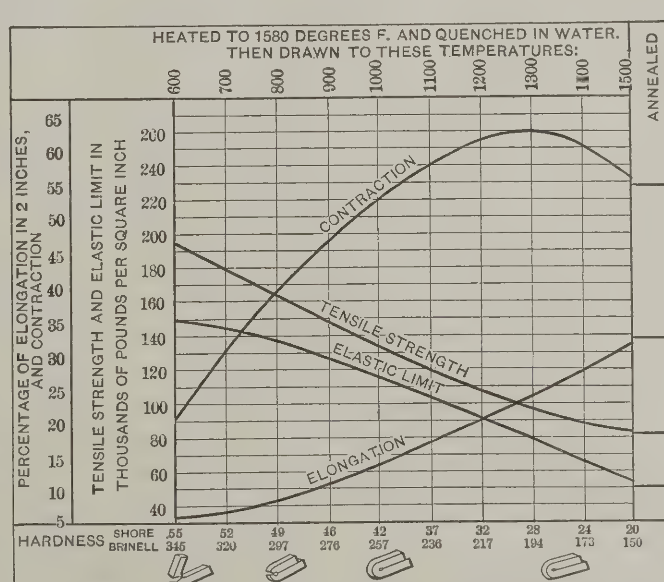

Fig. 2. Physical Properties of 0.20 Per Cent Carbon Natural Alloy Steel

cent, the steel is very difficult to cut when cold, and when higher percentages are used, the steel cannot be cut with any kind of cutting tools and must be ground to shape, this latter being an expensive method to pursue. Thus, in the high-grade nickel-chrome steels that are to be manufactured into parts of machines or instruments, the chromium is usually at or below 1.50 per cent. Owing to the difficulty of working even this steel, however, many grades of steel have been made with a chromium content of 0.25, 0.50 and 0.75 per cent, and it is for these grades that the natural alloy steel can be used.

In steel, the chromium gives the metal a hardness simi-

lar to that given by carbon, but to a lesser degree for the same percentage. It is a hardness, however, that makes the cohesion of the molecules much greater and thus greatly increases the static and dynamic properties. Chromium also greatly retards the formation of any grain or fiber, and thus makes the steel practically grainless. All of these effects of chromium upon steel cause it to increase its tensile strength, elastic limit, hardness, resistance to torsion, shocks, vibrations, or other stresses, and also increase its wearing qualities and prolong its life.

Influence of Nickel

Nickel increases the ductility, toughness and resiliency of steel, and also increases its susceptibility to heat-treatment. It reduces the size of the crystalline structure and microscopic cracks that are liable to develop into large cracks and produce ruptures. It was first added to steel to overcome the property of "sudden rupture" which is inherent in all carbon steels. It reduces the tendency of steels to become damaged by overheating in hardening, and shows its effect in the hardening operations by making the tensile strength and elastic limit two and three times that of the un-treated, or annealed steel. Nickel raises the elastic ratio in steels, *i. e.*, the elastic limit is raised to a higher percentage of the tensile strength. This condition is always sought for in the better grades of steel.

The tensile strength is rapidly increased with each increase in the percentage of nickel until a content of about 8 per cent has been reached. From that point to 15 per cent it makes the steel so brittle that it can be powdered under a hand-hammer, but after 15 per cent has been passed, the tensile strength returns, but not to quite as high a figure as is reached with an 8 per cent content. The elastic limit also continues to rise until 8 per cent has been reached and after the zone of brittleness has been passed, it again returns, but in a much smaller ratio than the tensile strength. From 20 per cent of nickel, upwards, the elastic limit cannot be made much greater than that of steels that do not contain nickel.

The elongation shows a slight rise until about 3 per cent of nickel is added to the steel, and after that it shows a rapid decrease, until the zone of brittleness is reached, when it becomes nil. With from 20 to 25 per cent nickel, the elongation again rapidly rises and from that point to 100 per cent it shows a slight increase. The best results, therefore, in steels that are used for machine parts, are obtained with a nickel content of 3½ per cent, although for some purposes 5 per cent nickel steel is used at a sacrifice of the elongation.

The two above elements in natural alloy steel, therefore, greatly enhances the value of this material for the various parts of machinery that are submitted to severe stresses. These steels also resist corrosion much better than other steels, the sulphuric acid test showing that they corrode from 10 to 20 per cent less than the low carbon and manganese, basic and open-hearth metals with nearly all of the impurities removed, and which have been given such names as "pure ingot iron," "old-fashioned iron," "toncan metal," etc. While there are some that doubt whether this test agrees with the actual weather conditions, it is generally conceded that steels containing nickel, corrode less rapidly than carbon steels and wrought iron.

Working Alloy Steels

Natural alloy steel can be hammered, rolled, drop-forged, pressed, stamped, or machined with the same ease and at the same temperatures as carbon steel; no special precautions are necessary. The high-grade nickel-chrome steel, however, must be heated to a white heat before being hammered, rolled, or drop-forged. The high temperature must also be maintained during this mechanical working, and if it falls very much, the steel must be reheated. Nickel steels must also be carefully handled when thus working them, and hence it will be seen that natural alloy steel is more cheaply worked into shape than other alloy steels. Natural alloy steel is similar to other alloy steels, however, in that it is very difficult to weld by ordinary methods; parts that are to be submitted to great strains should not be welded together. Like other alloy steels it can be welded with more or less success by the various electric welding processes and machines that are on the market. The electric machines that squeeze the parts together are preferable, as these prevent the grain from becoming coarse, as it does when other methods are used. If the steel is hammered after welding, this will aid in refining the grain that has become coarse at the weld. By careful workmanship with the electric process it is often possible to obtain from 70 to 80 per cent efficiency at the weld, whereas an efficiency of between 30 and 40 per cent is all that can be obtained by ordinary welding methods.

Natural alloy steels, like all other steels, will attain the highest strength only when properly heat-treated. In the untreated or annealed state, they show a tensile strength and elastic limit that is from 8000 to 10,000 pounds per square inch higher than carbon steels of the same carbon content, but when properly heat-treated they compare favorably with other alloy steels. Some figures that were obtained from annealed and heat-treated forgings are given in Table II.

TABLE II. EFFECT OF HEAT-TREATMENT ON FORGINGS OF NATURAL ALLOY STEELS

Per Cent of Carbon	Annealed				Heated to 1550° F. and Quenched in Water

Heat-treatment

The heat-treatment is practically the same as that given other steels. The hardening temperature may vary somewhat, but not to any great extent. The brands containing from 0.15 to 0.20 per cent carbon should be heated to 1500 degrees F. and quenched in brine to obtain the best results. Those with a carbon content between 0.30 and 0.50 per cent should be heated to 1550 degrees F. They can then be quenched in water as readily as carbon steels, although oil and special liquid compositions can be used for the quenching bath with equally good results. The temperature at which they are afterwards drawn, of course, varies with the kind of work that the finished piece would be called upon to perform.

When hardening steel, a cold piece should never be put in a highly heated furnace, as it is liable to crack. It should either be preheated to above 600 degrees F., or it should be put in a cold furnace and heated up slowly. It should soak in the heat at the hardening temperature long enough for the piece to heat clear to its center. The work should never lie directly on the hearth of the furnace, but should be raised sufficiently to allow the heat to attack it from all sides, and it should be supported in a way that will not allow it to sag, as hot steel is soft and pliable and likely to bend. The axis of the piece should be vertical when plunging it into the quenching bath to prevent unequal contraction in cooling. The work should never have sharp grooves, corners, or other features, that easily develop cracks when the steel is heated and quenched.

In drawing steel, a furnace should never be used that is hotter than the drawing temperature. It is difficult to judge the temperature that the work has attained in such a furnace

and get within 50 degrees of the desired results. If the piece attains too high a temperature, it will be softer than that required, and if the drawing is too low, it will not be soft enough. With a tempering furnace held at the correct temperature, the work can be allowed to remain in it until it has absorbed the heat of the furnace and then accurate results can be obtained. A difference of 50 degrees in the drawing temperature is of much more importance than 50 degrees in the hardening temperature, and it is more difficult to estimate.

Casehardening

Carbonizing or casehardening can be performed in any of the various ways that are now used for other steels. Pieces can be heated to a red heat and quenched in cyanide to give them a depth of casehardened surface of a few hundredths of

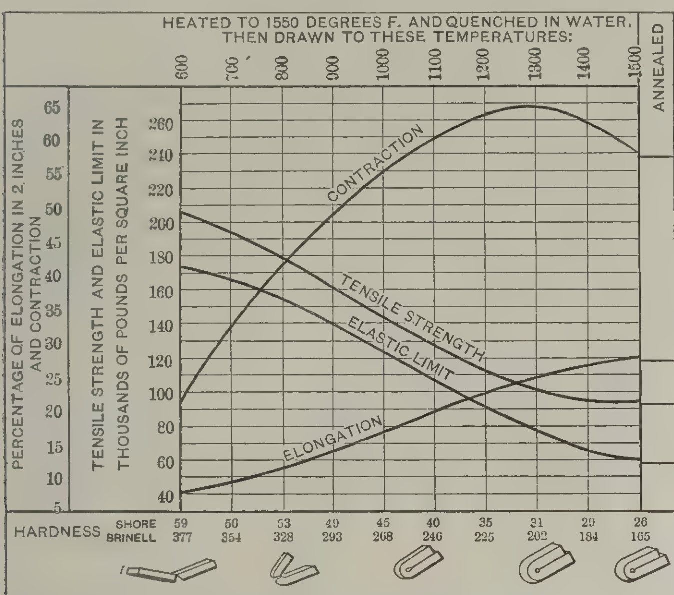

Fig. 3. Physical Properties of 0.30 Per Cent Carbon Natural Alloy Steel

an inch; or they can be packed in iron boxes with bone and charcoal, or other carbonizing materials, and then heated in furnaces for a time that is sufficient to give them a greater depth of penetration. Where the output would warrant it, however, the special furnaces that have been designed for carbonizing with gas would probably give the most uniform results, if the work is properly done. This is also the cheaper method when large quantities are worked or handled.

In any case, however, the carbonizing mixtures should not contain over 15 per cent of moisture or 0.50 per cent sulphur. Moisture might cause a pitting of the steel which is liable to cause it to chip on the surface, while the sulphur soaks into the casehardened shell to a considerable extent. A carbonizing temperature of from 1750 to 1800 degrees F. can be used, and this will probably give the most rapid absorption and most uniform composition of the case. The time the steel is submitted to this temperature depends upon the depth of carbonized case desired.

After carbonizing, the work should be allowed to cool slowly until it becomes black in daylight. It should then be reheated to 1500 degrees F. and quenched in either oil or water. After this it should again be reheated to 1350 degrees F. and again quenched in either oil or water. This double quenching gives much better results on all steels than does the ordinary practice of quenching directly from the carbonizing furnace and reheating but once to about 1375 degrees F. and quenching in oil.

In casehardened work, the core of the piece has a carbon content of about 0.20 per cent while the carbonized shell contains about 1.00 per cent. Thus, there are two steels of a different nature and these should be given different heat-treatments. In the double quenching, the first heating and quenching hardens the core but overheats the case and makes it brittle. The second re-heating restores the case to its finest grain structure and also toughens the core, and the final quenching hardens the case.

Uses of Natural Alloy Steels

Natural alloy steels are largely used in the manufacture of automobile parts. A grade containing 0.15 per cent of carbon is often used for carbonized parts where the toughness of the core is of more importance than the strength or ability to resist shocks. When parts are required to withstand severe shocks or strains and have a good wearing surface, steel containing 0.20 per cent of carbon is used. This grade responds more readily to heat-treatment. Thus the change-speed gears, differential gears, drive gears, etc., are made from this steel. It is used without carbonizing where considerable toughness is required rather than strength, as in various structural parts. It is also used for cold rolling or cold pressing, and for such work as seamless tubes, small drop forgings, etc.

Tensile Strength, Elastic Limit, etc.

The tensile strength, elastic limit, elongation and contraction of this steel, as affected by various heat-treatment temperatures are shown in Fig. 2. The vertical lines show the drawing temperatures which are marked in degrees at the top, while the horizontal lines represent the tensile strength and elastic limit and the percentage of elongation and contraction. Below the chart are given the hardness scales of the steels, at these temperatures, taken from both the Shore and Brinell instruments. The cold-bend testing properties at the various temperatures are illustrated by the sketches below the chart.

From this diagram the heat-treatment that should be given this steel to obtain any of the properties that are within its range, can readily be ascertained. Thus if an elastic limit of 144,000 pounds per square inch, with a contraction of 31 per cent, is desired, the vertical line will show that the drawing temperature should be 700 degrees F. This would also give a tensile strength of about 177,000 pounds per square inch, and an elongation of about 6.5 per cent. The diagrams are based on 7/8-inch round stock; if larger pieces are used, the drawing temperature should be lowered.

The grade containing 0.25 per cent carbon is usually used for such parts as can be cold pressed, for instance, such parts as brake drums, frame members, axle housings, etc. These parts require all the strength that can be obtained in combination with enough toughness to withstand the operation of bending

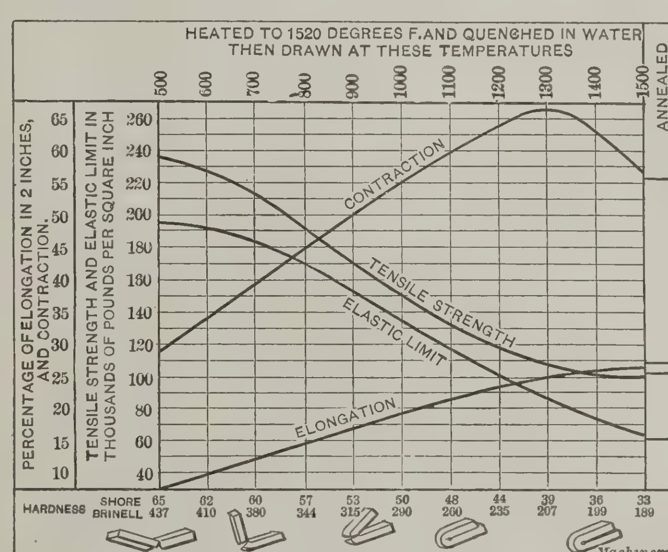

Fig. 4. Physical Properties of 0.40 Per Cent Carbon Natural Alloy Steel

into shape without developing cracks or checks. Steel 1¼ inch round, of this grade, when made into bolts, has a tensile strength of 106,000 pounds per square inch, an elastic limit of 87,500 pounds, an elongation of 26 per cent, and a contraction of 69.5 per cent.

The grade containing 0.30 per cent carbon is still harder and more applicable to heat-treated parts. Hence it is made into axles, connecting-rods, jack-shafts, drive shafts, and other parts that require considerable strength and at the same time a high degree of toughness. It is also used for drop-forgings, heavy forgings and numerous other things. The strength, hardness and cold bending properties of the 0.30 per cent natural alloy steels are shown in Fig. 3. That still greater strength can be obtained than shown in this chart was proved by a test made by one of the automobile manufacturers. The test bar was

properly hardened and drawn at 600 degrees F.; the tensile strength was found to be 236,000 pounds per square inch, the elastic limit, 215,000 pounds, the elongation in two inches, 10.8 per cent, and the contraction, 36 per cent.

The grades containing 0.35 and 0.40 per cent carbon are usually used for spindles, rear axles, crankshafts, etc. From the 0.40 per cent grade are also made locomotive driving axles and heavy automobile truck axles, connecting-rods, piston-rods, steering knuckles, etc. The properties of the 0.40 per cent carbon grades are shown in Fig. 4. Some finished cranksnafts, 2½ inches in diameter of the 0.35 per cent grade, had a tensile strength of 148,400 pounds per square inch, an elastic limit of 127,300 pounds, an elongation in two inches of 15.3 per cent, and a contraction of 53.8 per cent.

The 0.45 and 0.50 per cent carbon grades are used where extreme strength is needed in combination with considerable ductility. Thus, transmission gears that are to be heat-treated without carbonizing are usually made from this brand. The strength when heat-treated will, of course, be greater than shown in Fig. 4, but the ductility will be reduced.

At the present time there seems to be a tendency to "load" steels with alloying materials, and thus make them difficult to forge, weld, machine, or heat-treat; the results obtained do not always warrant the high prices of the finished parts. This natural alloy steel, however, is not overloaded with such alloying materials, but at the same time has properties that are well within the specifications for which many manufacturers are using much more expensive steels.

* * *

LIMITS FOR VARIOUS KINDS OF FITS*

The accompanying table gives the limits of accuracy used by the firm of Ludwig Loewe & Co., Berlin, Germany. The tabulated values are directly "translated" from the metric system, which accounts for the use of four decimal places in practically all instances. The table on which the one here published is based was published by *Verkstäderna* (Stockholm, Sweden). Only a few words are necessary to explain the use of the table.

It will be noted that three kinds of loose fits are specified. Loose fit *A* is for shafts resting in a single bearing; loose fit *B* for shafts resting in two or more bearings; and loose fit *C* for shafts with large clearance, lubricated with heavy lubricants, such as grease, etc. The sliding fit indicates a fit where the parts can be moved by hand, but without shake or play. The drive fit indicates a fit where it is necessary to assemble the parts with simple means, such as light blows or easy pressure. The press and shrinkage fits have their ordinary significance. By using this table, it is not necessary to put the limits on every dimension on the drawing, but simply to specify the kind of fit required.

* See MACHINERY, engineering edition, April, 1912: "Table of Allowances and Limits." See also MACHINERY'S Data Sheet Book No. 7, pages 26 to 31, inclusive: "Allowances and Tolerances for Various Kinds of Fits."

FOUNDRY AND MACHINE SHOP STATISTICS

The thirteenth census statistics of factories engaged in the manufacture of foundry and machine shop products are summarized in an advance bulletin issued by the director of the Bureau of the Census, Department of Commerce and Labor. These statistics show the number of establishments, the number of persons engaged, capitalization and value of the manufactured products. In the statistics are included all industries in the machinery field except those which manufacture distinctive products individually classified in the statistics, such as cash registers, calculating machines, sewing machines, and electrical machinery. The statistics are for the year 1909.

In this year there were 13,253 establishments, employing 615,485 persons, of which number 9851 were proprietors and firm members, 21,754 were salaried officers, superintendents, and managers, 42,242 were male, and 10,627 female, clerks; the average number of wage-earners was 521,011; the number of wage earners in the maximum month, December, being 597,234, and in the minimum month, January, 482,080. The total number of wage earners on December 15, 1909, or the nearest representative day, was 604,167, of which 587,636 were males and 11,895 were females, all 16 years of age and over; while 4093 were males and 543 females, under 16 years of age. The capital invested was $1,514,332,273. The total expenses were $1,077,736,456, of which $47,817,236 were paid officials, $45,977,781 clerks, $321,520,917 wage-earners, $23,750,838 fuel and rent of power, $516,260,301 other materials, $5,970,800 rent of factory or works, $6,269,172 taxes, including internal revenue, $6,653,816 contract work, and $103,515,297 other miscellaneous expenses. The value of products was $1,228,475,148. The value added by manufacture, which is the difference between value of products and cost of materials, was $688,464,009.

The states which lead in this industry are, in the order of their importance: Pennsylvania, New York, Ohio, Illinois, Massachusetts, Connecticut, New Jersey, Wisconsin, Michigan, Indiana, Rhode Island, California, and Missouri. The average number of wage-earners employed in 1909, the total number of products, and the value added by manufacture (value of products less cost of materials) for these states, is tabulated in the accompanying table.

State	Average No. of Wage Earners	Value of Products	Value added by Manufacture
California	8,377	$26,730,891	$13,830,000
Connecticut	37,736	65,535,155	40,715,099
Illinois	52,266	138,578,993	74,768,805
Indiana	15,809	39,883,774	21,265,086
Massachusetts	44,179	86,925,671	55,743,781
Michigan	21,649	45,399,023	26,688,471
Missouri	7,443	19,975,149	10,819,432
New Jersey	27,815	65,398,437	35,458,387
New York	64,066	154,570,346	92,749,146
Ohio	64,817	145,836,648	81,276,753
Pennsylvania	86,821	210,746,257	109,735,517
Rhode Island	10,937	20,611,693	12,598,192
Wisconsin	24,219	54,124,000	31,590,264

ANALYSIS AND HEAT TREATMENT OF LOW-CARBON AND ALLOY STEELS*

PRACTICE FOLLOWED BY THE FROST GEAR AND MACHINE CO., JACKSON, MICH.

By DOUGLAS T. HAMILTON†

The heat treatment of low-carbon steel differs considerably from that used for hardening ordinary tool or high-carbon steel. To begin with, low-carbon steel must be carburized, so that its outer surface will harden when the steel is again heated and dipped in oil. With tool steel it is only necessary to heat the steel to the desired temperature and plunge it in oil or water, after which the temper is usually drawn.

To obtain the best results when heat treating the modern alloy steels, the percentage of the constituent elements must

Fig. 1. Samples of Bar Steel and Milling Chips used in obtaining Chemical Analyses

be definitely known, and, therefore, a sample of each bar of steel should be analyzed before any parts are made from it. The greatest difficulty encountered in heat treating alloy steel is that if the carbon content varies but a few points, unsatisfactory results will be obtained unless this variation is taken into account. This is particularly true in heat treating drop forgings for automobile gears, which are subjected to heavy duty. The very best steel obtainable is of little value unless properly heat treated. The annealing, harden-

Fig. 2. Electric Furnace and Combustion Train used in determining Carbon Content of Milling Chips from Sample of Bar Steel

ing and tempering must be attended to with great care and thoroughness. Drop forgings are more difficult to heat treat properly than parts made from bar stock.

In no branch of the metal working industry is greater care given to the heat treatment of steel than in automobile manufacture. This industry has practically revolutionized former methods of making and heat treating alloy steel. In the following article a description is given of the heat treating methods employed by the Frost Gear & Machine Co., Jackson, Mich., which firm makes a large number of gears for the automobile trade. After having had considerable difficulty in heat treating automobile parts, owing to the variations in the carbon contents, and often to variations in the entire chemical composition, this firm installed a chemical laboratory in connection with its hardening department. Now, before any material is made up into gears or other parts, it is analyzed and its chemical composition ascertained.

In order that a manufacturer may be able to guarantee that all parts turned out by him are up to a certain standard, it is absolutely necessary that he follow some definite plan of analyzing and heat treating the different grades of steel. It is not wise to rely solely upon the steel mills for the correct analysis, for the simple reason that it is difficult to keep defective material from getting mixed up with the good stock. This is not always due to negligence on the part of the steel mill, but sometimes happens during transportation, unloading, etc.

Grading and Analyzing Steel

In ordering steel, the Frost Gear & Machine Co. gives the steel mill a complete analysis of the steel required. When the steel is received the bars are painted according to a certain standard. For gear stock the following colors are used to designate the different grades of steel:

Grade of Steel	Color
3.5 per cent nickel..................	Lemon yellow
0.15-0.20 per cent carbon, open-hearth machine steel	Pale green
0.30-0.40 per cent carbon, open-hearth	Medium green
0.40-0.50 per cent carbon, open-hearth	Dark green
Chrome-nickel steel	Deep red
Vanadium steel	Black

Report from Actual Service

Fig. 3. Record of Analysis of a 3 1-2 per cent Nickel Halcomb Electric Annealed Alloy Steel—Actual Size of Record Sheet, 9 by 7 3-4 inches

A wide stripe denoting the character of the steel is painted longitudinally on the bar, and a narrow diagonal stripe, of a different color, is used to designate the steel maker's name.

There are at the present time three common methods for determining the carbon contents of steel. The first and possibly the most common method is the use of the electric furnace and combustion train; the second is microscopic analysis; and the third, color comparison.

To obtain the carbon contents by means of the electric furnace and combustion train, a sample must be cut from each bar and chips obtained from these samples by milling or drilling. Milling chips are to be preferred, as these can be obtained quickly and can be taken from the entire cross-section. In milling off the chips, no oil should be used on the cutter, because a drop of oil in the chips would raise the carbon content far above its true percentage, due to the fact that oil is composed largely of carbon.

These chips are placed in small bottles labeled as shown in Fig. 1, the labels carrying the serial invoice number and the number of the bar. For example, suppose twenty-two bars of a certain brand of steel have been ordered, and that the serial invoice number is 130; then the first bottle, containing the chips from bar No. 1, would be labeled $\frac{130}{1}$, and the following bars and bottles would be marked consecutively

*See MACHINERY, June 1912, engineering edition: "Society of Automobile Engineers Specifications for Steel," and the articles there referred to.

† Associate Editor of MACHINERY.

$\frac{130}{2}$, up to and including $\frac{130}{22}$. The sample from which the chips are taken is also marked, and kept on the shelf with the bottles, as shown in Fig. 1. A sheet, as shown in Fig. 3, is made out for each bar of which an analysis is made, and this is filed away for future reference.

Obtaining the Carbon Contents by Means of the Electric Furnace and Combustion Train

The distinctive features of the different grades of steel are due more to variations in the carbon contents than to variations of any of the other elements, so that the carbon analysis is really the most important point to consider. A very small percentage of carbon makes a considerable difference in the quality of the steel after hardening.

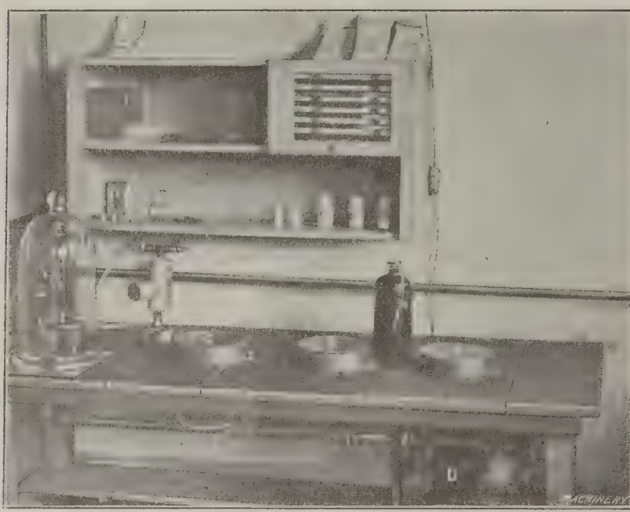

Fig. 4. Polishing Disks for Polishing the Specimen of Steel and Microscope used for Determining Structure of Steel

To obtain the carbon analysis by the electric furnace and combustion train, the milling chips are put in a small alundum boat *A*, containing aluminum oxide, as shown in Fig. 2. The latter is placed in the electric furnace *B*, where the chips are heated to about 1800 degrees F. A stream of oxygen from tank *C* is passed over the chips until the carbon has been burned out, the resulting gas—carbon dioxide (CO_2)—being collected in a liquid, potassium hydrate, in the potash bulb *D*. Now, after all of the carbon has been burned out of the milling chips, the weight of bulb *D* is compared with that of counterpoise bulb *E*, and its gain in weight noted; before burning out the carbon of the chips the difference in weight between bulbs *E* and *D* was ascertained. By a simple calculation, taking into account the weight of the milling chips, which have also been weighed before being put into the furnace, the percentage of carbon in the steel is obtained.

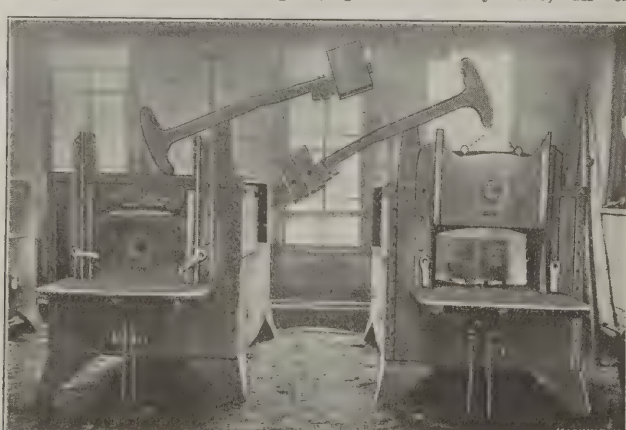

Fig. 5. Two of the Casehardening Furnaces

The names of the various tubes and devices used in connection with the electric furnace and combustion train shown in Fig. 2, starting at the left, are as follows: *F*, extra oxygen tank; *C*, oxygen tank; *G*, concentrated potassium hydrate bulb; *H*, concentrated sulphuric acid bulb (these two bulbs are called gas washers and act as the purifying train for the oxygen); *I*, granulated calcium chloride tower; *J*, cooling wick for the terminal of the quartz combustion tube; *N*, quartz combustion tube; *B*, electric furnace; *K*, another cooling wick; *L*, a U-tube containing granulated zinc; and *M* a U-tube containing calcium chloride. U-tubes *L* and *M* comprise the purifying train for the carbon dioxide collected from the milling chips being heated in the electric furnace. Finally, *D* is the weighed potash bulb and *E* the counterpoise bulb.

Analyzing Steel by Microscopic Inspection and Chemical Analysis

The microscopic examination of steel is of the utmost importance, as it reveals the nature of the metal to such an extent that the knowledge obtained thereby can be used to good advantage for practical purposes. Some of the problems which previously were beyond the scope of chemical analysis have been elucidated by means of the microscope. Of course, to use a microscope to the best advantage, it is necessary that the characteristics of steel and their relation to the appearance of a section when greatly enlarged, be understood.

To prepare the steel for microscopic examination, a small piece of the required size is cut from the bar and then ground as smooth as possible. After this, it is polished by means of different abrasive materials on the small polishing stands shown in Fig. 4. The first stand *A* consists of a disk covered with canvas and charged with fine alundum. The disk on stand *B* is covered with ordinary pocket lining, and is charged with lenigated alumina, while the disk on stand *C* is covered with broadcloth and charged with rouge. These polishing stands are driven from a shaft located beneath the bench, which, in turn, is operated by a small electric motor *D*. The disks are used in the order in which they are placed, starting at *A*. Covers are placed over these disks to prevent dust and dirt from collecting on the abrading surface.

Fig. 6. The Lead Baths used for Heat-treating the Parts

After the piece to be examined under the microscope *E* has been polished to a high degree, it is etched with a five per cent solution of picric acid, in alcohol for annealed steels. This brings the structure of the steel into prominence, the less readily attacked constituents being left standing in slight relief, and the structure thus rendered visible. One of the most striking objects which appears under the microscopic treatment, sometimes causing a beautiful play of colors, is pearlite, which has a pearly lustre, from which it derives its name. Pearlite is an intimate mixture of ferrite and cementite and consists of 87 per cent of ferrite and 13 per cent of cementite. Lamellar pearlite, which was clearly defined in the analysis recorded in Fig. 3, is a formation which consists of alternate plates of ferrite (pure iron) and cementite (carbon of iron Fe_3C). The ferrite is readily attacked by the etching acid, leaving the cementite standing out in relief.

The other constituents in the steel, such as nickel, manganese, sulphur, etc., are generally obtained by chemical analysis. This method can only be carried on successfully by an experienced metallurgist, as the determination of the percentage of any one constituent usually is obtained by volumetric titration with standard solutions of reagents.

Carburizing

When the material has passed analysis and is found to be "O. K.," the blueprint number of the piece for which this grade of steel is to be used is painted on the end of each bar.

This gives the foreman authority to use it. Any bars found to be of wrong chemical composition or difficult to machine, or that do not show up properly under microscopic inspection—showing slag and defects—are picked out and returned to the mill. After the part is made that is to be carburized, it is painted with fire clay where a hardened surface is not required, and then put in a carburizing compound, composed

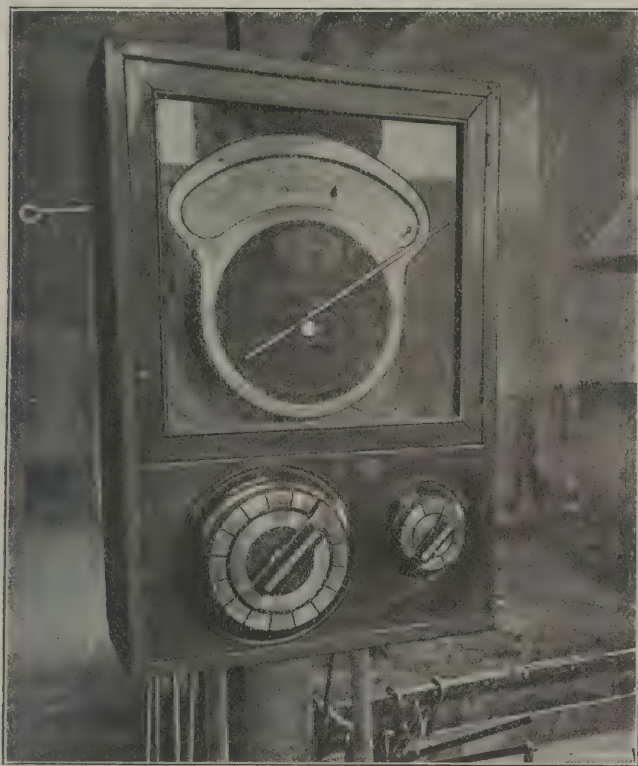

Fig. 7. Hoskins Electric Pyrometer used for Regulating the Temperature of Casehardening, Heat-treating and Tempering Furnaces

of charred leather, crushed charcoal and ammonium carbonate.

The work is packed in pots in this mixture, the lids put on and sealed with fire clay, and then the pots are put in the carburizing furnaces, two of which are shown in Fig. 5. The temperature in these furnaces is raised to the desired point and maintained for a sufficient length of time to let the carbon penetrate into the steel about 0.02-0.04 inch. This generally requires from three to five hours after the correct temperature has been reached. Of course, the length of time depends entirely upon the depth of casehardening desired and the size of the piece to be treated. The temperature in the pot is slightly greater than that near the walls of the furnace, and is consequently greater than that registered on the pyrometer.

The carburizing furnaces are heated by high-pressure fuel oil burners having a pressure of 18 pounds on the oil and 40 pounds on the air for atomizing, and about 12 ounces for supplying air for combustion through a two-inch pipe. The temperature is recorded on a Hoskins electric pyrometer, Fig. 7, which is provided with "reading contact points" for all the furnaces in the room. After the parts have been left in the furnace for a sufficient length of time, the pots are taken out of the furnaces and allowed to cool down gradually, the covers not being removed until the pots are perfectly cold; then the covers are taken off and the parts unpacked and heated to treat the core, and plunged in oil; they are then again heated to from about 1350 to 1425 degrees F., to harden the case, dipped in oil, and tempered.

Heat-treating Automobile Drive Gears

Automobile drive gears which contain 3½ per cent nickel, are put in a lead bath after carburizing (see Fig. 6), and are heated from 1550 to 1600 degrees F. After the gear is brought to this temperature it is taken out and quenched in the bath of running oil shown at *A*, Fig. 6. Charcoal is put on top of the lead to prevent it from oxidizing. This also helps to keep the temperature even and prevents the lead from sticking to the gear. After quenching, the gear is again heated to a temperature of from 1325 to 1350 degrees F., so as to harden the case. After the gear is brought to the proper temperature, it is quenched in the running oil bath.

Tempering

Most automobile gears and other parts require to be tempered after being heat treated. The tempering is accomplished in an oil bath shown in Fig. 8. The work is placed in the basket shown and the latter lowered into the oil, which is a grade of fish oil, called "No. 14 tempering oil." This is heated to from 325 to 400 degrees F. for nickel steel, and from 550 to 600 degrees F. for oil-hardening chrome-nickel steel. After the work has been brought to the same temperature as the bath, it is allowed to remain for a certain specified time, and is then removed and allowed to cool off gradually. It is then washed in a lye solution and sand blasted.

All of the oil tempering, casehardening and heat treating furnaces are supplied with the same type of oil pressure burners. The cold ends of the thermo couples are surrounded by water jackets in which cool water is circulated as indicated at *B* in Fig. 6. This water jacket keeps the couples at an exact temperature and thus makes possible correct reading on the pyrometer. The pyrometer is tested from time to time and is automatically regulated according to the temperature of the room.

Examining the Fracture of a Broken Gear

After a sample is carried through in the manner previously described, it is broken with a sledge hammer to determine if the core has been heat treated properly, or whether crystallization has taken place. This process of breaking and examining is carried on until a piece is obtained which shows that it has been properly heat treated. The operations are slightly varied until a satisfactory final result is obtained.

Fig. 9 shows a drive pinion for an automobile, which has been broken to show the fracture. This pinion was made from a drop forging as is clearly indicated in the illustration, where the grain of the steel is seen to follow closely

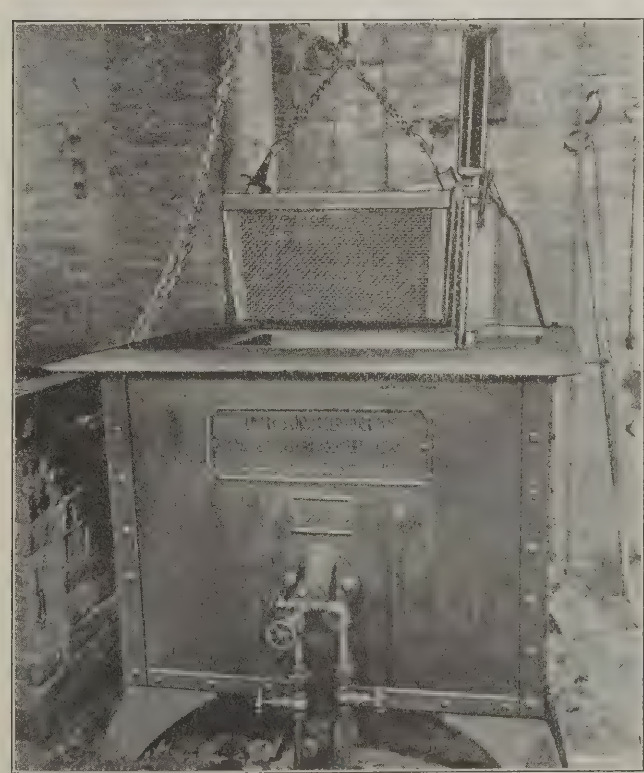

Fig. 8. Oil Bath for Drawing the Temper after Hardening

the shape of the gear. The depth of the case also stands out very prominently. At *B* are shown cracks which illustrate that the case, which is extremely hard, cracked when breaking the gear, but the core still remained intact. A tooth broken off by the sledge is shown at *C*.

The scleroscope is used to determine the hardness of a gear after being heat treated, but it is not relied upon altogether. Sometimes a gear can be "touched" with a file after a high reading has been obtained by the scleroscope. The

main point in heat treating steel is to get a close-grained and "velvety" structure. If the structure is coarse, the part will not be strong and will be easily broken. After a piece has been carried through the process previously outlined, broken and found to be all that is desired, all parts made from the bars containing the same percentages of the various ingredients are given the same treatment. The data thus collected, are tabulated, and filed away for future reference, as shown on the chart in Fig. 3.

Heat-treating a Main Drive or Ring Gear for an Automobile

The main drive or ring gear used on an automobile is considered by most automobile manufacturers as one of the

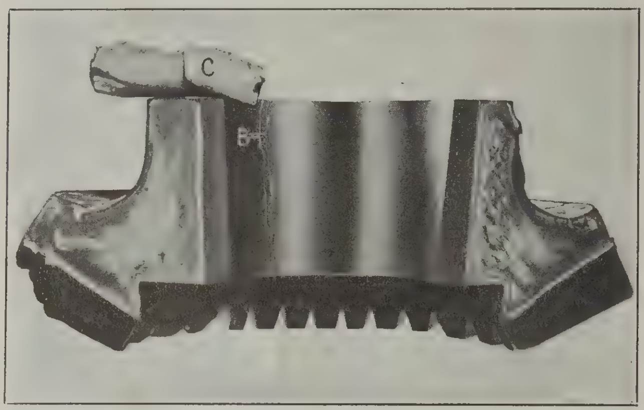

Fig. 9. An Automobile Drive Pinion broken to show Structure of Steel after Heat-treating

most difficult parts to make, and more money is being spent on perfecting this one gear than on any other part. It is very difficult to turn out a gear which has not been slightly distorted during the heat treating operations; such gears will produce considerable noise when running at a high speed. This is a very objectionable feature, and every possible means is devised and employed to obviate it.

The gear shown in Fig. 10 is made from 3½ per cent nickel steel, containing 0.18 per cent carbon. The blank is cut from flat stock of oblong section, split in the center and then expanded to form a ring. This ring is then heated and finished to the desired shape by drop forging. It is evident

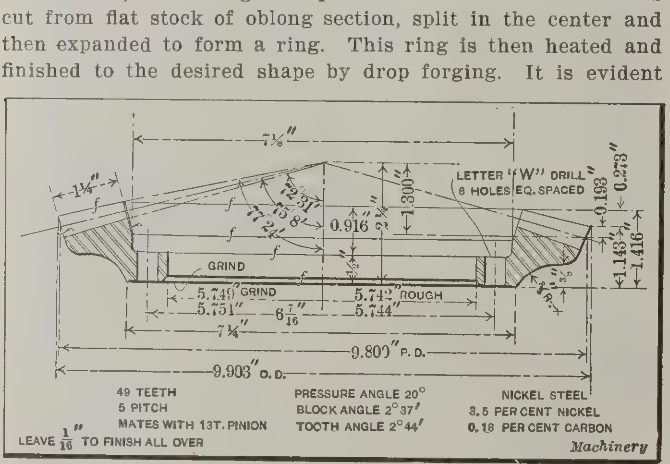

Fig. 10. Automobile Main Drive or Ring Gear to be heat-treated

that the grain of the steel will practically form a complete circle when worked in this way, and this tends to prevent the finished piece from distorting much during the heat treatment. After being drop-forged, the gear is annealed and allowed to cool off gradually; then it is sent to the machining department where it is machined to the correct shape, the teeth cut and all the operations, except grinding, performed. It is then painted on the back with fire clay, put in the carburizing furnaces, and passed through the operations previously outlined.

The heat treatment for this particular gear was as follows: Heated in carburizing compound for four hours at a temperature of 1650 degrees F. and allowed to cool off in the pots; then heated in lead pot to a temperature of 1580 degrees F. and quenched in oil; heated in lead to 1325 degrees F. and quenched in oil; after this, allowed to remain in the oil tempering furnace for one hour at a temperature of 375 degrees F., taken out, allowed to cool off gradually, washed and sand blasted.

It has been found from actual experience that the best way to determine the proper heat treatment for any particular grade of steel or parts made from it is to put a sample through the regular heat treating process, break it and examine the structure. By following this method and using the tabulated data obtained when making the analysis as a guide, very satisfactory results are secured without recourse to any "rule of thumb" methods.

In closing, the writer wishes to express his appreciation of the assistance given him in the preparation of this article by Mr. E. J. Frost, president of the Frost Gear & Machine Co.

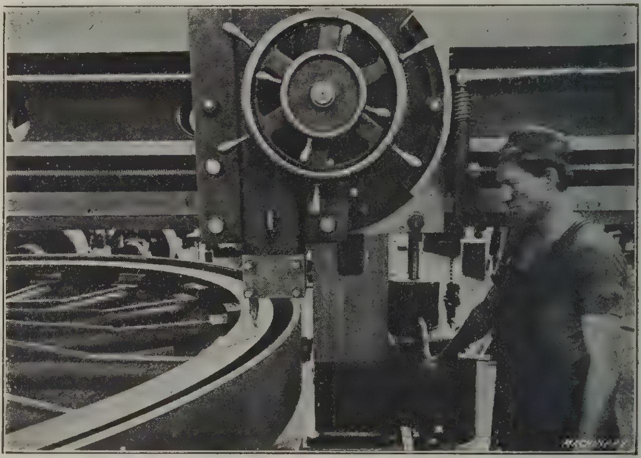
CUTTING AN OIL GROOVE IN A BORING MILL

A simple but rapid method of producing a zig-zag oil groove in a circular piece of work is shown in the accompanying illustration. The work is a 10-foot table for a Cincinnati boring mill, and the machine in which this unusual feat is being accomplished is a Cincinnati 10–16-foot boring mill. The oil groove is 1/4 inch wide and about 3/32 inch deep, and is completed in one minute—the time required for the table to make one revolution. The zig-zag path of the groove is the result of the combined movements of the work and tool-head.

In action, the operator after setting the tool and feeding it down to the proper depth, grasps the shifting lever for operat-



Set-up and Method of Cutting an Oil Groove 1-4 inch wide by 3-32 inch deep, and over 32 feet long in One Minute on a Cincinnati 10-16-foot Boring Mill

ing the rapid power traverse of the tool-head (as shown in the illustration), and then starts up the machine. He watches the cutting tool closely, and as it approaches the edge of the circular bearing, shifts the lever to traverse the tool-head in the opposite direction. This procedure is followed until the table has made one complete revolution, when the oil groove is completed. Formerly this oil groove was laid out, and then chipped with a chisel and hammer, the time required being about six hours.

The cutting of this oil groove in the manner described, illustrates the ease of control of the boring mills manufactured by the Cincinnati Planer Co., Cincinnati, Ohio. D. T. H.

THE BEGINNINGS OF MONEL METAL

About seven years ago one of the large smelting companies began investigating the chemical and physical properties of an alloy that had been reduced directly from a nickel-copper matte without the previous separation of the two metals. This alloy was found to possess not only the valuable properties of nickel, but also other desirable properties in addition, that would insure a wide usefulness, and owing to the simple method of production, was obtainable at about one-third the cost of nickel. In 1905-6 the International Nickel Co. considering, no doubt, that for many purposes there was no need to separate the amicable metals nickel and copper, took up the problem of reducing them together and obtaining an alloy of the two metals in the proportions in which they occur in the ore. The alloy thus obtained was named Monel metal, after Mr. Ambrose Monel, the president of the International Nickel Co.

BOSTON GEAR WORKS NEW FACTORY

LAY-OUT AND MACHINE EQUIPMENT

Of the few large plants in the United States devoted exclusively to the manufacture of gears the Boston Gear Works probably is the largest manufacturing such a great variety of gears. This firm started business in Boston in May, 1891, with twelve men, under the management of Mr. Frank Burgess. The business gradually grew so that during the spring of 1906 an enlargement became necessary, and a modern one-story factory of saw-tooth construction, with the exception of the office department, was built at Norfolk Downs, about six miles from Boston. This plant was completely destroyed by fire November 27, 1909.* In less than one week after this fire, gears were cut in a nearby building on machinery taken from the ruins.

By February 10, 1910, a new and better factory was completed on the site of the old structure, and running on full time. This record was due to the great energy of Mr. Burgess, and the cooperation of his 125 employes.

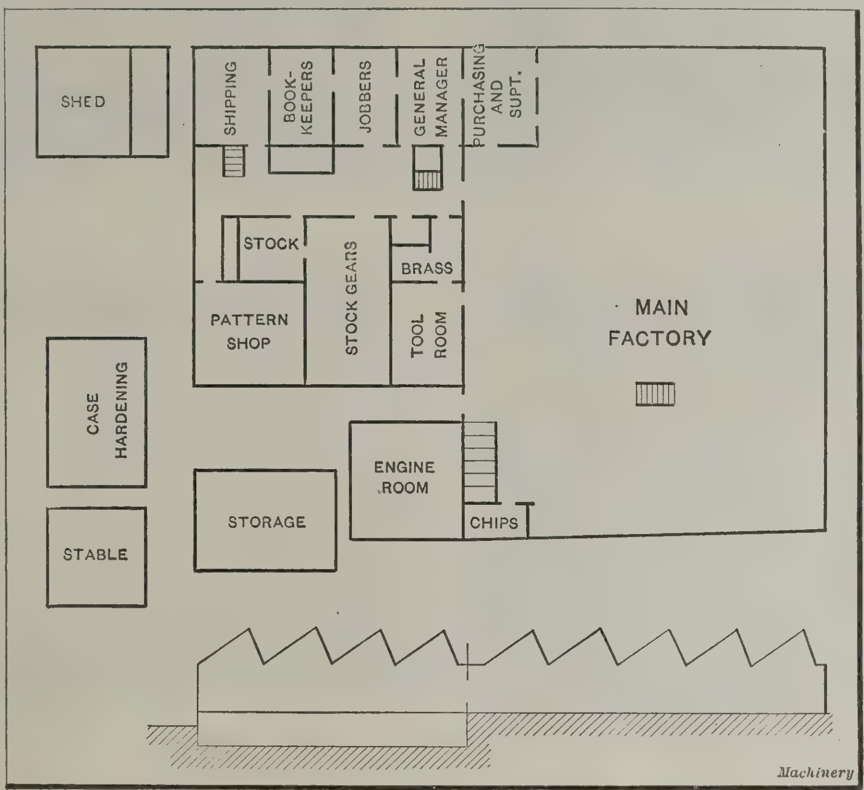

Fig. 1. Plan of Boston Gear Works

The new factory, like the old, is of saw-tooth roof construction, which had proved very satisfactory. The office is placed on the first floor in order to give more uniform light and direct communication with the factory. There is 29,000 square feet of floor space in the main building, and a total floor space, including other buildings, of 37,000 square feet.

The main building is divided into two parts by a fire wall, the factory section being 90 feet by 131 feet, and the office section 90 feet by 71 feet. In the office section are located the pattern shop, two gear stockrooms, toolroom, shipping room, and three offices, on the ground floor. The three offices, being those of the general manager, bookkeepers and jobbers, are so arranged that quick communication can be had with each other, as well as with the main factory section.

In the basement under the office section are storage, millwright and experimental rooms, a steam heating plant, and one 50 H. P. De LaVergne oil engine, and in the basement under part of the main factory building are located a 50 H. P. De LaVergne oil engine generator, pumps, etc., several cutting-off machines, and steel racks. In 1910 a power plant was erected in a new building 31 feet by 32 feet, adjacent to the fire wall of the main factory building, and an 85 H. P. Hornsby-Akroyd-De LaVergne oil engine installed.

The main factory is divided into about fourteen separate departments, each under a working foreman, scientifically arranged so that the work may progress in the most systematic manner. The entire equipment consists of about 225 machines, seventy-five of which are automatics, most of them being of the latest design. The equipment by departments is as follows:

The model, or small gear department, consists of over forty turning and gear cutting machines, ten of which are automatics. Most of these machines were designed and built by the Boston Gear Works. The Cleveland automatic section consists of seven Cleveland automatic turning machines, handling bar stock up to six inches diameter. This department also includes four Acme and two Hartford automatic screw machines. The Potter & Johnston section contains three Potter & Johnston automatic chucking machines, one plain chucking machine, one Jones & Lamson, one Prentice, one Bullard and two Fay lathes. The Gleason gear planing section consists of six bevel gear generators and three single tool planers, taking in work up to forty-eight inches diameter. The Whiton section comprises nine automatic milling machines for cutting sprockets, spur and bevel gears of small diameters. The spiral section contains ten machines for cutting spiral and worm gears up to thirty-six inches diameter. The hobbing department includes seven machines for cutting spur, helical and worm gears, up to ten feet in diameter. The Fellows and Gould & Eberhardt department consists of six Fellows gear shapers, including one rack cutter; seven Gould & Eberhardt automatic spur and sprocket gear cutters, and

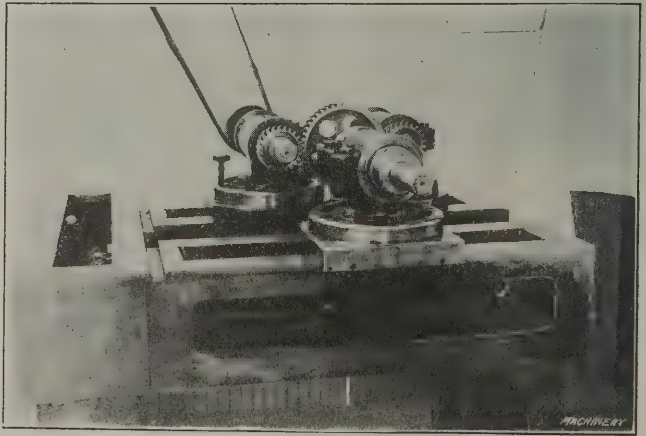

Fig. 11. Universal Gear Testing Machine

one Brainard machine. Gears up to seventy-four inches diameter can be cut in this section. The lathe, drill and miscellaneous department contains twenty-two machines. The tool section consists of twelve machines, among which are milling and special hobbing machines. The grinding department comprises nine universal, plain and internal grinding machines.

In 1911 a new casehardening plant, 26 by 45 feet, of fire-proof construction was built, consisting of a steel frame covered with asbestos protected metal. This plant is equipped with two modern brick coal carbonizing furnaces, two of the American Gas Co.'s furnaces equipped for burning fuel oil,

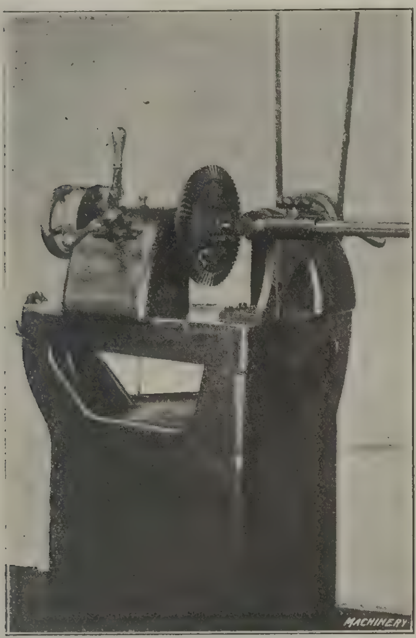

Fig. 12. Bevel Gear Testing Machine

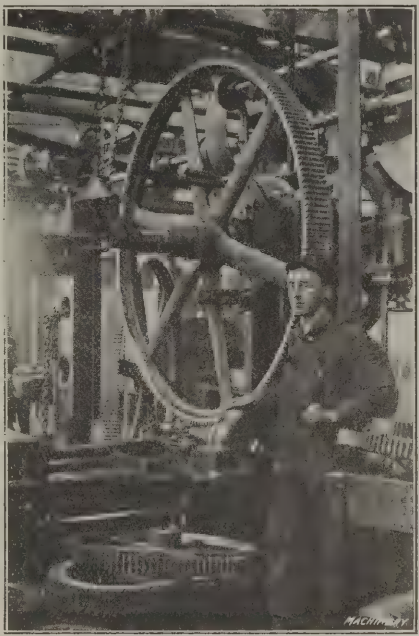

Fig. 13. Gould & Eberhardt Department

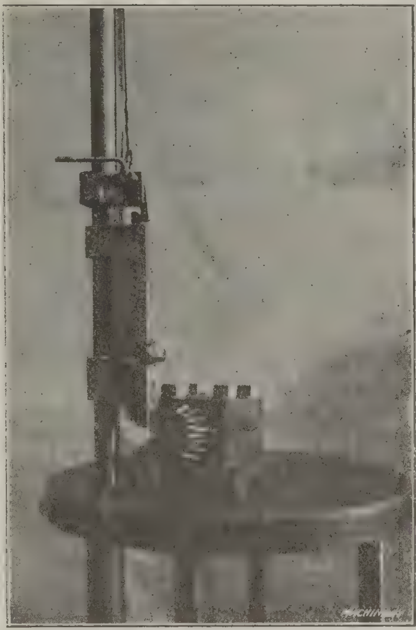

Fig. 14. Drop Hammer Testing Machine

and lead reheating and oil tempering furnaces, also using fuel oil. The temperatures are recorded by a Bristol pyrometer, and the very latest and best methods are used for treating all kinds of steel.

The inspection department is equipped with the latest and best machines for testing gears under actual running conditions; there are also all kinds of measuring tools, such as plugs, micrometers and tooth vernier calipers, drop hammer machine and scleroscope for testing heat-treated gears. Back of all this

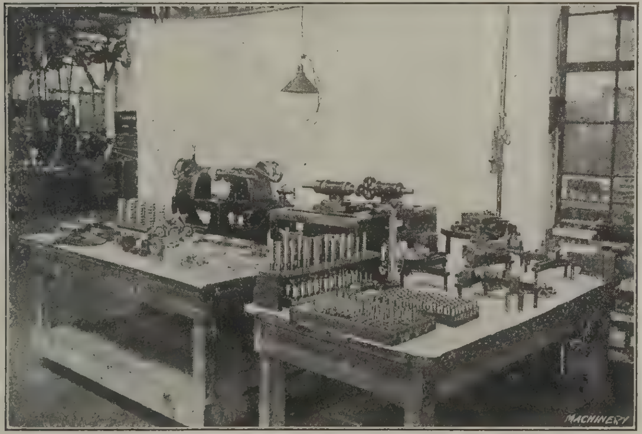

Fig. 15. Inspection Department

equipment is thirty-two years experience in the manufacture of all kinds of gears.

The works are prepared to handle large or small quantities of special gears from one-eighth inch to ten feet diameter. They make a specialty of all kinds of steel gears, including automatic differential and transmission gears, as well as fan, cam, timer, and pump gears for engines. Recently a number of worm and helical gear cutting machines were developed to manufacture special worm gear combinations both small and large to transmit light and heavy power. They will also soon be prepared to manufacture in large quantities worm gears for automobile rear axle drives, both of the straight and Hindley types.

IRON AND STEEL INDUSTRIES IN U. S.

The director of the Bureau of the Census, Department of Commerce and Labor, has issued an advance bulletin giving a summary of the thirteenth census statistics with relation to the number of establishments, persons engaged and capital invested in the steel works and rolling mill industry in the United States. This industry, considering the value of the products, ranked fourth among the industries of the country in 1909.

In that year there were 446 establishments with a total number of 260,762 persons engaged, of which 47 were proprietors and firm members, 4239 salaried officers, superintendents and managers, 14,613 male, and 1767 female, clerks. The average number of wage-earners was 240,076; the number in the maximum month, December, was 283,629, and in the minimum month, March, 215,076. The primary horsepower was 2,100,978. The capital invested was $1,004,735,111. The total expenses were $889,501,220. The value of products was $985,722,534. The value added by manufacture, which is the difference between cost of materials and value of products, was $328,221,678.

With regard to the number of wage-earners employed, the

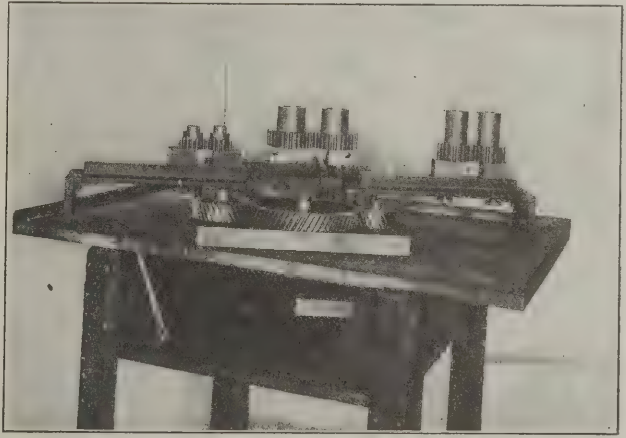

Fig. 16. Spur and Spiral Gear Testing Apparatus

leading states in the order of their importance were as follows: Pennsylvania, Ohio, Illinois, Indiana, New York, West Virginia, New Jersey, and Massachusetts. The accompanying table gives the average number of wage-earners, the value of the products, and the value added by manufacture in these states.

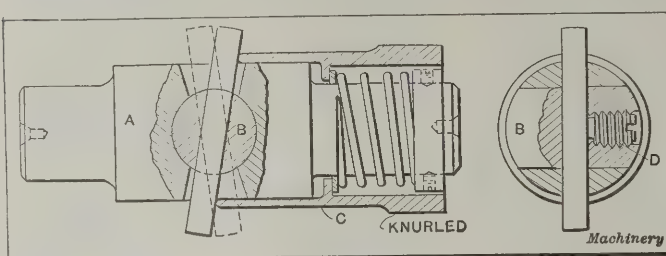
States	Average No. of Wage Earners	Value of Products	Value added by Manufacture
Illinois	17,584	$86,608,137	$30,363,674
Indiana	12,255	38,651,848	12,553,089
Massachusetts	3,115	13,567,628	3,535,355
New Jersey	4,671	12,013,719	5,378,679
New York	10,091	39,532,414	13,643,244
Ohio	38,586	197,780,043	58,536,888
Pennsylvania	126,911	500,343,995	171,330,574
West Virginia	5,060	22,435,411	6,539,111

LETTERS ON PRACTICAL SUBJECTS

We pay only for articles published exclusively in MACHINERY.

GRINDING GAGES WITH SPHERICAL ENDS

A number of spherical end gages, from 2½ to 6 inches long, were to be made, and the device shown in the accompanying engraving was designed for grinding them so that they would be of the correct length when measured anywhere over the ends. This device can be used on any grinding machine having ordinary centers. The illustration practically explains itself. One end of bar *A* is turned down to suit the ordinary driving dog. The other end is turned down for a spring and provided with a stop-collar. The central portion is bored and ground to fit the swiveling plug *B*, and



Device for Grinding Gages with Spherical Ends

has a slot cut through it at right angles to the plug. This slot should be of the same width as the diameter of the gage to be ground. The swiveling plug is drilled and reamed to fit the gage and provided with a clamping screw *D*.

A piece of round steel of the same diameter as the gage to be ground and with a length equal to the diameter of the bar *A*, is inserted through the slot and clamped in the swiveling plug. The outside of the bar and the ends of the plug are now ground up together to suit the bore of sleeve *C*. This sleeve keeps the plug in position when the gage is removed, and, being provided with a cam surface on its end, gives the required motion to the gage being ground. The right-hand end of this sleeve is knurled so that the operator can grip it and hold it stationary while the remainder of the device rotates.

The gages to be made are rough-turned, cut off to the required length with proper allowances, and the diameter ground to suit the slot and the bore of the swivel. Then the centers are removed and the gage inserted in the fixture and clamped central by screw *D*, and finish-ground on the ends. Only a slight grip on the sleeve is required to hold it stationary, so that the gage to be ground will swivel to and fro against the cam surface on the end of the sleeve.

G. R.

SEASONING CAST IRON

In the June number of MACHINERY, R. L. S. asks for some method for quickly seasoning castings. The writer would advise him that the quickest way of removing the internal strains is to anneal the castings, provided facilities for this process are at hand. Mr. George M. Bond of Hartford, Conn., whose work in connection with accurate measuring machines is well known, first has the beds of the machines rough-planed and then anneals them in the Jones process furnace. In this furnace, which is the invention of Mr. H. K. Jones of Hartford, Conn., the work to be annealed is kept in a closed receptacle. This prevents oxidation and the work will come out as bright as it goes in.

The measuring machine beds mentioned are of box section about three feet long; 1/16 inch is allowed for the finishing cut after annealing. The planing is practically all on one side and none of the castings have warped in the annealing process to such an extent that they would not finish up properly in the subsequent replaning; *i. e.*, they have sprung much less than 1/16 inch.

The special skill in connection with annealing lies in choosing proper points for supporting the casting and heating it to a low red heat only. It has not been found necessary to run the heat higher in order to eliminate all the internal strains. At the higher heat the casting would undoubtedly sag out of shape by its own weight.

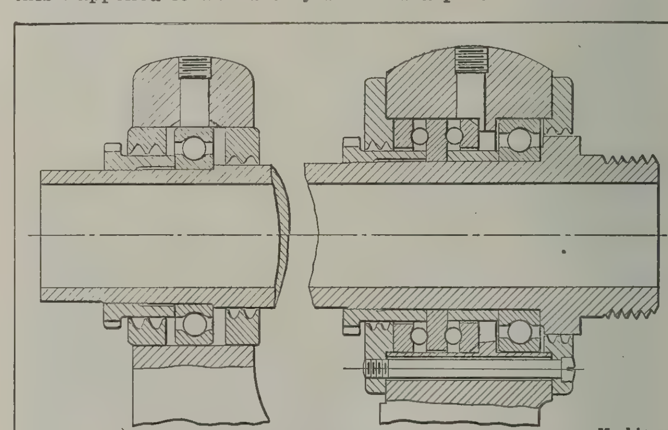
New Britain, Conn. R. S. BROWN

BALL-BEARING LATHE SPINDLE

Frequent references have been made of late in MACHINERY to the use of ball-bearings for the spindles of heavy machine tools. The accompanying drawing shows an example from actual practice of a spindle of a lathe of 16-inch center (32-inch swing) which has been in constant use for about two years. During the preliminary tests it was found that about 25 horsepower was needed for some of the cuts taken, although probably a 10-horsepower motor would have been ample for the ordinary duties of the machine.

The spindle runs at a speed varying from 22 to 505 revolutions per minute and has so far given no trouble whatever and has never required adjustment. The outside diameter of the front end of the spindle is 4¼ inches, and in addition to chucking work it can take bars up to 2½-inch diameter through the spindle. No vibration is felt under the heaviest cuts or during forming operations.

It will be seen that the thrust is taken at the front end by a double thrust bearing, the middle unit of which, together with the journal bearing, is clamped solidly to the front shoulder of the spindle by a notched nut, the bearings being retained at correct distances by sleeves or bushings. The retaining plates are clamped to the headstock by four fillister-head screws, as indicated. The one at the left-hand end of the bearing is adjusted once for all, it being considered advisable to make it impossible for the workmen to tamper with the adjustment. The argument for absence of facilities for adjustment is as follows: If adjustment should prove to be necessary after running, it would indicate that wear had taken place and if this happened it would only serve as a proof that the scheme



Mounting of Ball Bearings for Lathe Spindles

was a failure—at any rate, as regards the thrust bearings; and if the thrust bearings were subject to wear, the journal bearings would, in all probability, be subject to wear also. In fact, it may be said generally of ball bearings that wear proves that either they are unsuitable or the bearing is too small. In the particular arrangement shown it was thought that since the thrust bearings were very closely adjusted this had some influence in restraining vibration. S. PINDLE

LOCALLY CASEHARDENING GEAR AND CUTTER TEETH

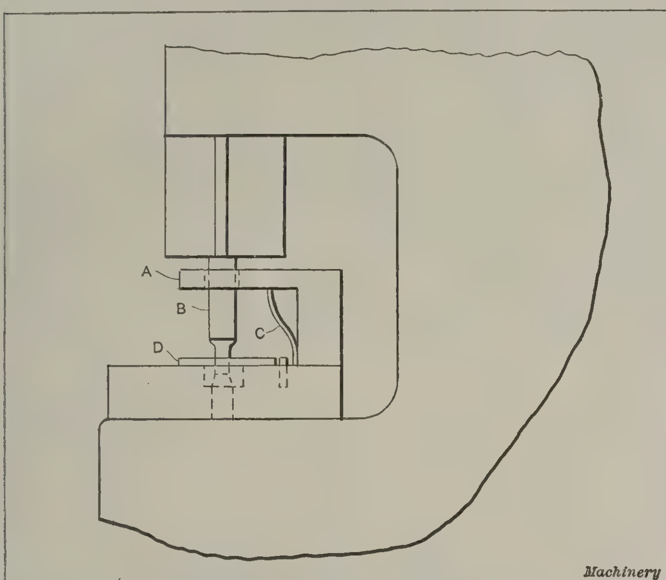
In the May number of MACHINERY I noticed an item on casehardening gears without distortion, stating that the Cadillac Motor Car Co., of Detroit, Mich., has solved the problem by copper plating the teeth after the roughing cut, and then taking a finishing cut which removes the copper plating from the faces of the teeth; then when the teeth are casehardened only the faces of the teeth harden, the remainder staying soft.

This process may be new to the Cadillac Motor Car Co., but not to me and many other skilled mechanics. As long ago as ten years I made long reamers that way and later I made broaches 4 feet long for broaching keyways in automobile gears, hardening them by this process. The only parts of the broach that were hardened were the teeth, and it worked very successfully in the shop of which I was then foreman.

J. A. L.

SPRING EJECTOR FOR PIERCING DIE

The accompanying illustration shows a device which in certain instances is useful in connection with piercing dies. With this device in use, flat blanks being pierced will be thrown out in front of the machine. The construction is simply as follows:



A Spring Ejector Arrangement for a Piercing Die

The piece *D* when punched sticks to the punch *B* on the upward stroke, until it strikes stripper *A*, when it is stripped off. On its upward way, however, it compresses spring *C*, and is, therefore, suddenly pushed outward by the spring as soon as it is released from the punch. This device, while not new, may be of interest to many who have not seen it employed.

W. ALTON

SUPERSTITION VS. COMMON SENSE

It is true that we no longer burn witches at the stake as did our Puritan forebears in Salem but superstitious beliefs are still too common to let us be very proud of our superiority. Common sense is a trait so uncommon that people endowed with it are regarded as uncommonly smart if not actual geniuses. In the past, MACHINERY has expressed a few ideas on the prevalence of superstition among engineers and others in charge of machinery. An engine or pump may have run satisfactorily for several years and then without apparent reason it goes wrong. After perfunctory tinkering and a half-hearted attempt to find the cause and correct it, the job is given up in despair by those immediately responsible for its operation. If it be a small, comparatively cheap apparatus it may be unceremoniously dragged out and replaced with a new one on the assumption that the old one is beyond hope, and a lurking belief is betrayed that no amount of repairs could have made the thing go. The men in charge may be able to learnedly discuss steam engine diagrams, heat units in steam, condenser capacity, etc., and would be righteously indignant if called superstitious.

To illustrate the attitude of workmen toward apparatus I will mention a case of an ordinary kitchen range in a rented house which gave trouble to the good housewife who essayed to use it. It would not bake or boil. The fire burned red and lifeless. Plumbers, experts and non-experts examined and agreed on a common verdict, "That range is no good; it must be replaced." Replaced it was, but the owner who is not a believer in witchcraft and who holds that the laws of nature operate without regard to location, set the stove up in his own house and quickly discovered the cause of the trouble—a wide gap between the water back and the casing that let the air pass which should have gone through the fire and supported combustion. A few handfuls of furnace cement stopped the air leak and converted a worthless range into a thing of joy and a household delight.

No, superstitious beliefs in the mechanical world are not dead. They will live as long as ignorance exists and men are not taught to seek diligently and intelligently for causes and effects.

F. E. R.

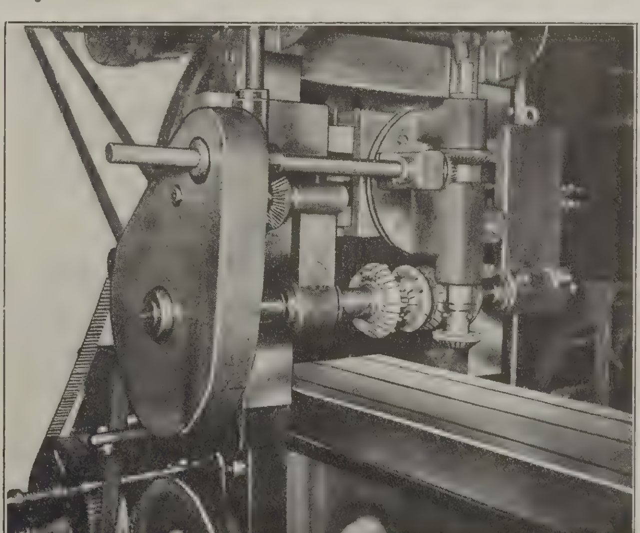
PREVENTION OF RUST ON TOOLS

No doubt a great many of the readers of MACHINERY have noticed the rust formation that takes place on tools within a few hours after they have been hardened in brine or in any of the numerous hardening solutions containing different salts used for this purpose. To counteract this rusting of tools, they should be boiled in a strong solution of soda water for fifteen or twenty minutes after having been hardened. Sal-soda (common washing soda) is the kind to use for the solution. A kettle holding about six or eight gallons of water may be used. About five pounds of soda are put in at the start, and after that about one to one and one-half pound is added every day. In this way the strength of the solution is kept about right. The addition of soda is necessary on account of the overflow which is required because of the method used for heating, the solution being brought to the boiling point by introducing steam. The work should always be boiled before being put into the tempering furnace and the latter should be at a temperature of about 212 degrees F. when the tools are changed from the soda kettle to the furnace. A basket arrangement with windlass may be used for raising and lowering the work to prevent scalding the hands. The directions given, if followed, will prove of advantage in hardening and tempering tools, in that the formation of rust will be prevented.

Decatur, Ill. GEORGE COLES

A MILLING ATTACHMENT FOR THE PLANER

The accompanying halftone illustrates a milling attachment designed for, and mounted on, a Putnam planer. This attachment is used for milling a great variety of work. It consists mainly of a horizontal head, a vertical head, a tailstock, and driving mechanism. The cutter heads are driven from the regular planer countershaft by means of a cone pulley mounted on the countershaft and belted to a cone



A Milling Attachment for the Planer

pulley on the main driving shaft of the attachment. A planetary gearing mechanism is provided to reduce the table travel to a rate suitable for milling. This mechanism is also driven from the regular countershaft on which is placed a small two-step cone pulley belted to a large two-step cone pulley on the planer, which carries the planetary pinion. The motion is then transmitted to the planer table by a Morse silent chain and sprockets, in addition to the regular gearing. The planetary gearing is of such a ratio that the

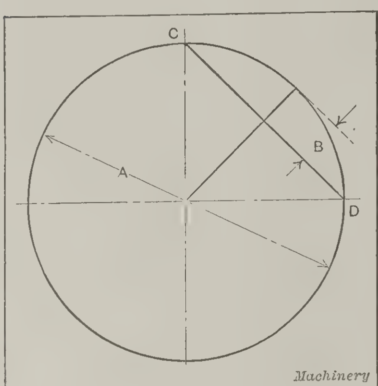
driven gear makes one revolution for every fifty revolutions of the cone pulley.

The attachment is very convenient and durable and has been in operation for eight years without any repairs. It is used on a planer with a 16-foot table. It is easily attached and detached. The planer is run back with the regular planer reverse belt, and, in general, is operated with the regular equipment for table travel, such as stops, etc.

Seneca Falls, N. Y. W. H. RUNGE

LAYING OUT THE CIRCUMFERENCE OF A CIRCLE ALONG A STRAIGHT LINE

The accompanying illustration indicates a simple method for laying out the circumference of a circle along a straight line. This is frequently required in laying out cylindrical grooved cams, and in finding, graphically, the angles of thread helixes or spirals. The method is, briefly, as follows: Divide the circle by two diameters into four equal parts; then draw a line *CD*, bisect this line, and measure the distance *B*. This distance, added to three times the diameter, is a close approximation of the total circumference.



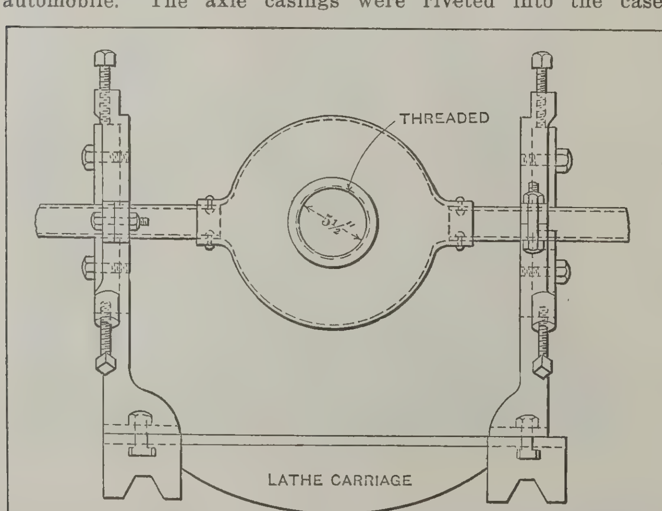
Laying Out Circumference of Circle

The accuracy of the method may be easily investigated. The distance *B* is the versed sine of 45 degrees, which equals 0.29289. This multiplied by the radius of the circle, plus three times the diameter, gives the approximate circumference obtained by this method. Assume, for example, that the circle is 4 inches in diameter; the actual circumference then equals $4 \times 3.1416 = 12.5664$. By the approximate method we obtain $3 \times 4 + 2 \times 0.29289 = 12.5858$. The difference between these two dimensions is negligible in ordinary drafting-room lay-out work. I believe this will be found helpful to readers who are looking for a simple graphical method which saves calculation or reference to tables.

Christchurch, New Zealand. PERCY W. FRAMPTON

THREADING A DIFFERENTIAL GEAR CASE IN THE LATHE

The writer was recently confronted with the task of cutting an internal thread in a differential gear case for an automobile. The axle casings were riveted into the case



Threading a Differential Gear Case in the Lathe

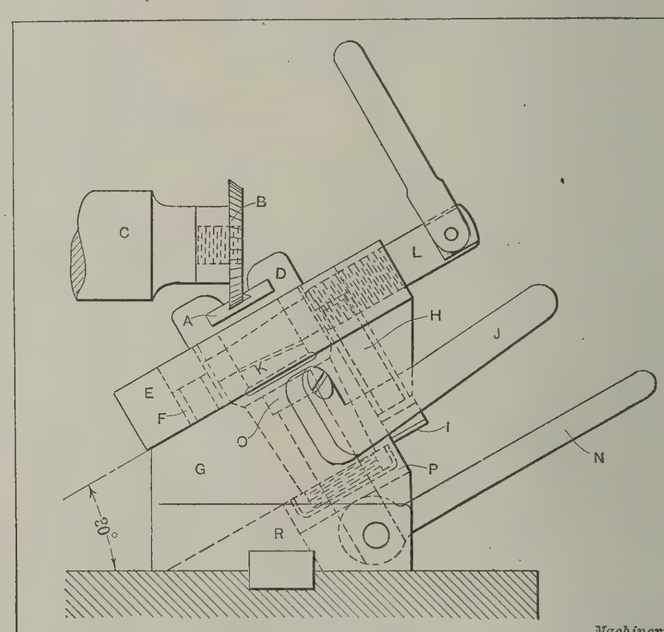
as shown in the accompanying engraving, which prevented swinging the case in the lathe; hence, it was necessary to clamp the work to the carriage and use a rotating tool fastened to one of the chuck jaws. The clamping of the case was done as shown, the work being performed in a 28-inch lathe. Steadyrests, which supported the work, were taken from two smaller lathes in the shop. These rests were bolted to the 28-inch lathe carriage. The jaws of the steadyrests clamped the work very securely, and furnished a simple method for setting the work central.

Denver, Colo. STANLEY EDWARDS

FIXTURE FOR MILLING DOVETAIL SLOTS

Previous to the design of the fixture, the principle of which is shown in the accompanying engraving, the dovetail slot in the steel block *A* was cut with a 60-degree angular cutter, 7/32 inch in diameter, having a neck about 5/32 inch in diameter, and a No. 4 Brown & Sharpe taper shank; or in other words, a cutter was used of the same size and shape as the slot. A roughing cut was first taken with an ordinary slitting saw. The finishing mill in that case, of course, had to be exactly to size, and to run true. High-speed steel was used for the mill, and a fine feed was required; the operator also had to exercise considerable care in starting the cut, as otherwise the cutter was likely to break.

By milling these pieces as indicated in the illustration, the cutter *B* can be made large in diameter; it is easily ground to the required angle and can be re-ground without materially affecting its efficiency; a coarse feed can also be taken. Another favorable feature of the fixture is that the slot is finished at one handling, although, of course, two cuts are taken. As will be seen, the cutter is mounted on a threaded arbor *C*.



A Fixture for Milling Dovetail Slots at a Rapid Rate

The work is held in block *D*, which is the end of the spindle of the fixture. The square indexing plate *E* is keyed to this spindle. In this plate there are two bushed indexing holes *F*, 180 degrees apart. Chips are prevented from getting into these holes by plugs at the top of the plate. The base casting *G* is provided with the usual tongue to locate it in alignment with the milling machine table. The upper surface of this casting is machined at an angle of 30 degrees as indicated. As the axis of the spindle is inclined at right angles to the 30-degree surface of the base, one edge of the dovetail slot is brought at right angles to the center line of the cutter arbor. A 60-degree cutter is used, and as its width is a little more than one-half the distance across the bottom of the dovetail, the two cuts, the second of which is taken after indexing the work around, finish the piece. The index pin *H* is held in bushing *F* by a flat spring *I*. Lever *J* is used for pulling the pin *H* out before indexing.

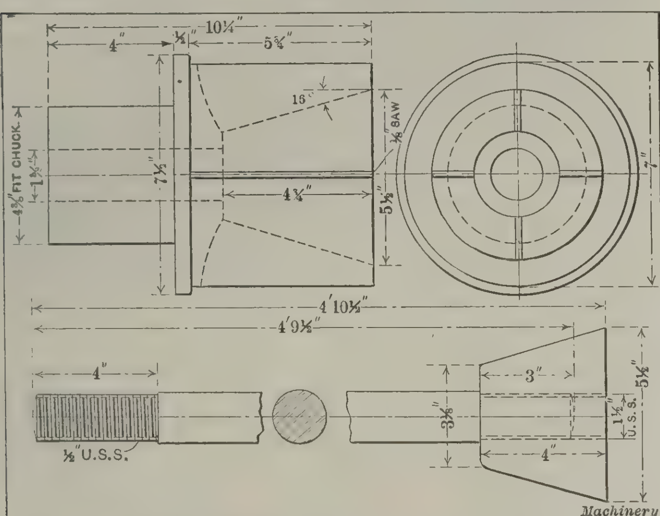
The work *A* is clamped against the upper side of the slot in *D* by means of the plunger *K*, which is actuated through screw *L*, the handle of which acts as a wrench. The clamping is done by means of the wedge action due to the taper of screw *L* on that part of it which is inside of *K*. The spindle and plate *E* are clamped in position before taking a cut by means of cam lever *N* acting through cam-shaft *O*,

which has on its upper end a head for pulling the spindle down. Some of the details are rather obscure in this view, but it is all that is necessary to explain the principle involved.

East Orange, N. J., J. W. WEED and
Tottenville, N. Y. S. J. PUTNAM

EXPANDING ARBOR FOR HEAVY TURRET LATHE WORK

The accompanying engraving shows an expanding arbor of heavy design which has proved satisfactory for rapid and accurate work on a heavy turret lathe. As will be seen, the arbor is intended to fit the chuck on the machine, and is provided with an expander having a bolt which extends through the entire spindle, this arrangement allowing for quick ex-

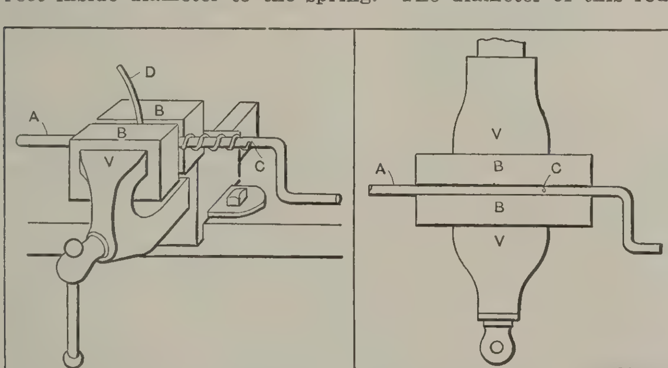


Expanding Arbor for Heavy Turret Lathe Work

pansion by means of a handwheel and washer on the end of the bolt. By means of this arbor the work is secured and held central for facing, turning or counterboring, independently of the chuck jaws, and the jaws are needed only to act as drivers. Whether the chuck is of the independent or universal type, it is possible to hold the casting true to the bore by means of this arbor, and a great deal of time is saved that is ordinarily spent in truing up work held by the chuck jaws only. At the same time, variations in the bore are taken care of by the expansion feature. M. W. W.

METHOD OF WINDING SPRINGS IN A VISE

The accompanying illustrations show a method of winding springs in a vise. The writer has used this method for a number of years, but has never seen it described in MACHINERY. In the device, *A* is a rod so selected that it will give the correct inside diameter to the spring. The diameter of this rod



Winding Springs in a Vise

must be determined experimentally, as there must be some compensation for the enlarging of the spring when released. This rod is bent at one end to form a crank. A hole *C* is drilled near the crank end. This hole should be large enough to allow the end of the spring wire to enter. At *B* are shown hard-wood blocks, *V* being the vise jaws.

The rod *A* is clamped between the wooden blocks with the crank as close to the blocks as possible, and with the hole *C* in a vertical position. The end of the spring wire is inserted into the hole. At the start the wire *D* must be guided so as to give the correct pitch. If held in a vertical position, the spring will be close-coiled. If inclined to the left, the coils will be open; the more the inclination, the wider the spacing. The first turn determines the pitch. After the first turn, a groove is formed in the wooden blocks and the wire will follow this groove. When the rod has passed through the blocks, or the wire has come to an end, release the blocks and cut the wire at hole *C*, thus allowing the spring to slide off the rod.

When springs are wound in this manner it seems that they do not enlarge as much in diameter when released as they do when wound in the lathe. The reason for using hard-wood blocks is that the wire "beds" into soft wood too easily.

Ft. Atkinson, Wis. E. L. WHITE

HANDY TOOL-HOLDERS

The three tool-holders shown in the accompanying engravings have proved a valuable part of a toolmaker's equipment. In Fig. 1 is shown a splining-tool holder used for work where an ordinary holder cannot be used to advantage. The tools

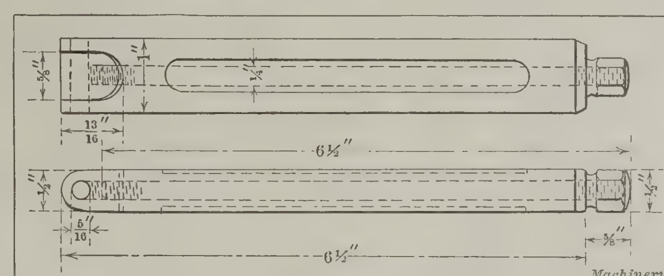


Fig. 1. Splining Tool Holder

are made of 5/16-inch drill rod, forged to the desired shape, and are firmly held in place by the clamping arrangement shown in the engraving. In Fig. 2 is shown a tool-holder for forming tools, when the cutters are made in quantities. This tool-holder is of considerable value; the forming tools may be

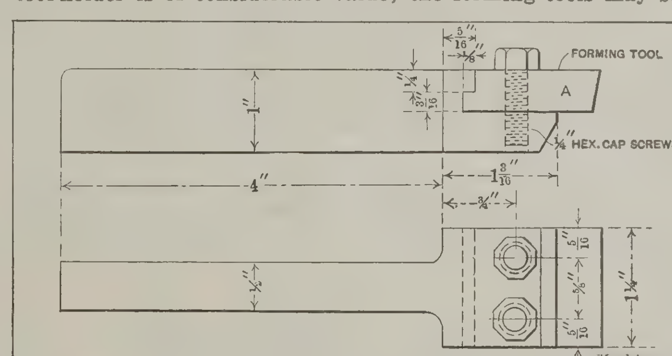

Fig. 2. Forming Tool Holder

made at low cost, and in case of breakage can be easily replaced.

In Fig. 3 is shown a tool intended primarily for threading operations, but it can also be used for light forming work. All parts of this tool are made of steel and casehardened.

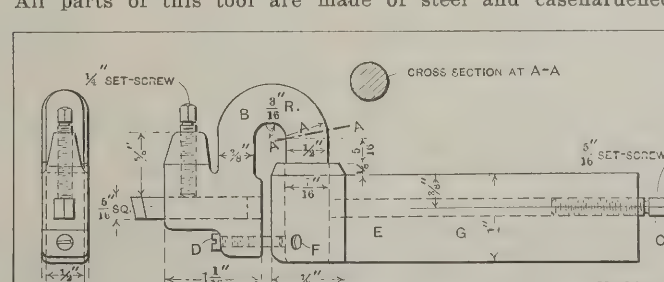

Fig. 3. Spring Threading and Forming Tool Holder

This tool is adjustable to three positions, right-hand, left-hand, and central. The head *B* is made a snug fit in body *E*, and is held in place by rod *G*, which is forced against it by set-screw *C*. Three flats are ground on head *B* so that it may be held rigidly in any of the three positions. Three holes *F* are drilled in the body *E*, one central, and the others at an angle of 30

degrees, on each side of the center, for the adjusting screw *D*. When the tool is used for threading, screw *D* does not reach fully down to part *B*, but a clearance of 1/32 inch is left. In this way the required elasticity of the threading-tool is provided for. When a rigid tool is wanted, it is only necessary to screw *D* tightly into place.

New Britain, Conn. J. M. HENRY

A DRILL JIG FOR A NUMBER OF LEVERS

Fig. 1 shows four levers, *M*, *N*, *O* and *P*. The length *l*, the width of the hub *h*, the hole *a*, and the position of the lever arm in relation to the hub, are different in all cases, while the hole *b* is the same for all. The levers are machined in sets of four (one of each kind), which go through all operations together until they are ready for the machine for which they are designated.

The hole *a* is simply bored in the center of its hub, while *b* must be drilled by means of a jig, since the distance *l* from center to center must be absolutely correct. It would mean

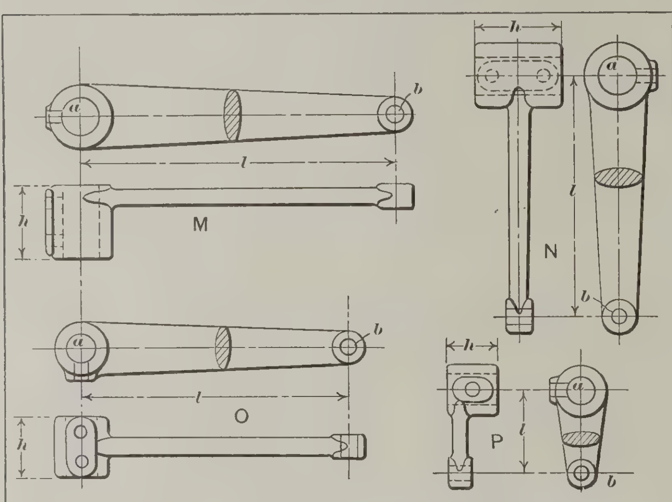

Fig. 1. The Four Levers to be drilled

a considerable loss of time, however, to change the jig for every lever, and the necessity arose, therefore, to design a jig which would allow the drilling of all the levers without taking the jig from the drill press table.

Figs. 2 and 3 show a jig constructed for that purpose. Fig. 2 shows a top view, a longitudinal section and a cross section, while Fig. 3 shows a general view of the jig with lever *M* in

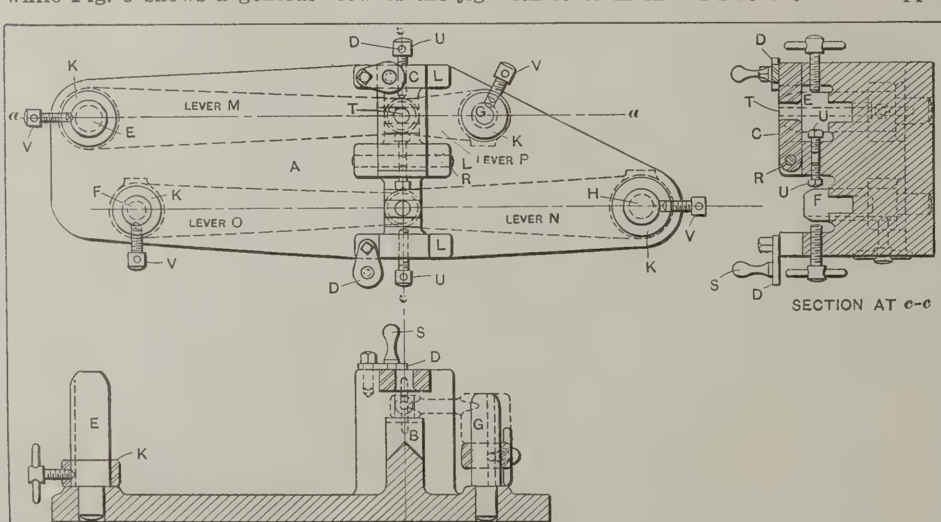

Fig. 2. Plan and Section of Drill Jig for Levers in Fig. 1

place. The jig consists of a cast-iron base-plate *A* which is cast with a projection *B*. This projection has three ribs *L*. The center rib is worked out to receive a hardened steel hinge *C* which swings about a pin *R*; *C* may be laid over to both sides, which are also worked out to suit the hinge. Each side is provided with a small steel lever *D*, with handle *S*, which serves to hold the hinge in its position while the jig is in operation. The guide hole *T* for the drill is used in both positions. The V-shaped part of *B*, directly underneath the guide hole (see section along *a-a*) aids the chips in falling off. Screws *U* are provided to adjust the levers sideways. The correct distances for the lengths of the various levers are laid off, as shown. At the points thus found, studs *E*, *F*, *G* and *H* are provided to suit the respective levers. A collar *K* is fitted to each of these studs. Every collar suits the hub of the lever

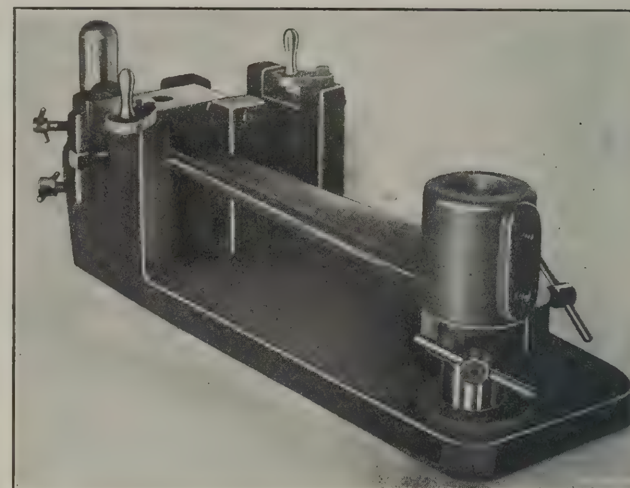

Fig. 3. General View of Drill Jig

which it is supposed to support, and may be fastened at any height by means of a screw *V*. The hardened center-point of the latter slides in a V-shaped groove provided for that purpose, thus preventing the collars from turning, and the handles of the screws from interfering with the body of the jig. Collars *K* hold the levers in the correct horizontal position.

Wyomissing, Pa. CHRISTIAN F. MEYER

SUB-PRESS DIE FOR MAKING A CLEAT

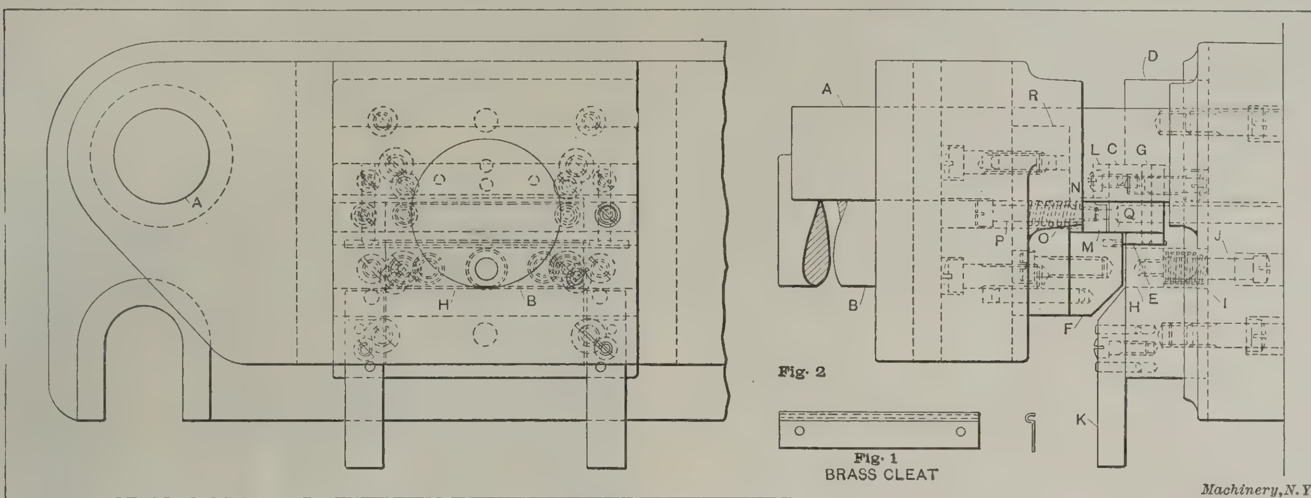
The sub-press die shown in Fig. 2 was designed for producing the brass cleat shown in Fig. 1, this die superseding a set of simple dies previously used for the purpose. With the dies previously made, it required three operations to produce a cleat, the rehandling necessary causing considerable loss of time.

The base and upper portions of the sub-press die are made of cast iron, in the usual form, and are equipped with hardened and ground pins *A* to preserve the alignment of the upper and lower members. A cast-iron shank *B*, fitted in a T-slot cut in the upper member, serves to connect the latter with the ram of the press. Attached to the lower member or base is a hardened tool-steel block *C* mounted by means of screws and dowels on a soft-steel shoe *D*, and entering into a slot cut in the latter as shown. To the block *C* is held a "ribbon bar" *E*, which, in conjunction with the slot in the block *F*, serves to fold the edge of the cleat. The ribbon bar is held to block *C* by two horizontal dowel pins *G*, so that in case of breakage a new strip may be quickly inserted.

The lower member of the die is cut out to receive a spring pad *H*, which acts as a stripper for removing the cleat from the ribbon bar *E*. This pad is actuated by three helical springs *I*, and is limited in its upward movement by the shouldered screws *J*. The two guide strips *K* make provision for the entrance of the strip into the dies. A feed stop-bar *L*, mounted on the block *C*, controls the width of the finished cleat, and a stripper-plate *M*, sliding on the piercing punches *N*, holds the stock while the holes are being pierced. On the ascent of the press, stripper-plate *M* strips the cleat from the piercing punches. The stripper *M* is pressed downward by coil springs *O*, and is retained from further movement by the

shouldered screws P. The block F which acts as a bending punch is mounted on a soft-steel block R which, in turn, is attached to the upper member of the sub-press die.

The operation of this sub-press die is as follows: Stock of the correct width is fed in until the front edge of the strip is slightly beyond the shearing edge Q of blocks F and C. The first stroke of the press shears off the front edge of the strip, thus straightening it, and at the same time forming the bend in the blank. When the ram of the press ascends, pad H forces the bent strip from the ribbon bar E, so that the strip can be fed forward against the stop L. When the ram again descends, the holes in the blank are pierced, the first blank cut off, and the part for the next blank bent to the required shape. The finished cleat is ejected by means of a wooden pencil or rod, and the stock is fed in continuously in the manner described.



Figs. 1 and 2. Cleat and Sub-press Die for Producing it

It will be noticed that the only scrap made is the small disks punched out of the strip by the piercing punches N. In practice, about 100,000 cleats may be punched without sharpening the die, for which, it will be noticed, due provision has been made.

ARON LAWRENCE

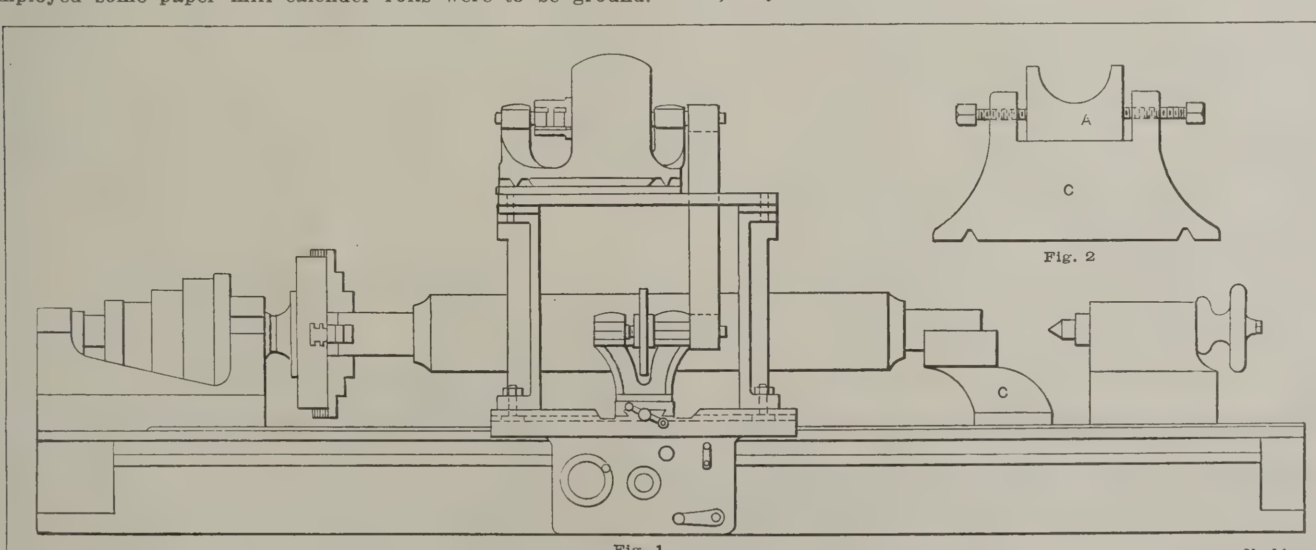
Detroit, Mich.

GRINDING CALENDER ROLLS

In a small job shop in which the writer was recently employed some paper mill calender rolls were to be ground. The machine in which the work was done was an 18-inch lathe with double back-gears. The length of the lathe over all was about 14 feet, and both ends and the middle support were set on masonry. The length of the face of the rolls to be ground was 74 inches, and as the width of the paper was 72 inches, there was left a margin of about one inch at each end of the roll which had not been subjected to wear, but from which it was possible to approximately obtain the alignment in setting up. After removing the compound rest on the cross-slide, an emery-wheel stand made for the purpose was securely mounted in its place, and so adjusted that the axis of the emery-wheel shaft was in the same horizontal plane as the axis of the spindle. A stand was also set up on the carriage and secured to it by means of bolts in the T-slots of the saddle. This formed a support for a 3 H. P. motor for driving the emery-wheel.

As calender rolls cannot be ground on their centers, but must be ground to their bearings, a bracket C was made, the face of which had grooves fitted to the ways of the lathe and which was clamped in the same manner as a steadyrest. On the top of this was a skeleton pillow-block A (see Fig. 2) that could be moved and secured by means of set-screws. The first roll to be ground was the top roll, which was about 12 inches in diameter and weighed about 3700 pounds. One end was chucked as indicated in the illustration, and the other end was temporarily held by the tail-center, while the chuck end was trued up accurately. The pillow-block was then put under the bearing at the tail-stock end and babbitt was poured into it, after which the tail-center was withdrawn.

As the roll did not need to be ground to any specified dimension, but the one consideration was absolute parallelism, any instrument by which this latter could be ascertained could be used. In this case we used a homemade measuring device which looked like an overgrown micrometer, for it had a range up to 16 inches. The measuring screw had 40 threads per inch and could be clamped in its nut. Both ends of the roll were trued up, that is, ground to equal size within a limit of less than 0.001 inch, this limit being obtained when the micrometer readings on the cross-feed



Figs. 1 and 2. Method of Grinding Calender Rolls in a Lathe

screw coincided at both ends. Then the entire length was ground, but, for some reason, the first roll was badly out of round and some time was consumed before the wheel would take an even cut over the entire length. On testing, we found the difference in diameter to be equal to six thicknesses of cigarette paper (the thickness of each paper was less than 0.001 inch). It took more than thirty hours to grind this roll. It was run at about 40 R. P. M., and the emery wheel was run at 1800 R. P. M. The diameter of the wheel was 10 inches, the face 1/2 inch, and the feed 3/16 inch. No water was used at any time.

Two wheels were used, the first a hard one but not very coarse, for the rough-grinding, and the second, a softer one, but somewhat coarser, for the finishing. The rough-grinding showed even "checks" about ½ inch wide all over the roll, and neither variation in the speed of the roll nor in the feed would eliminate them. In the writer's opinion, the comparatively slow speed of the wheel was the cause of this. The wheel should be run from 500 to 800 more revolutions per minute. After finish grinding with the softer wheel, the rolls were polished with fine emery dust and oil on a pine board. The other rolls, two of which were 6 inches, and two, 9 inches in diameter, were finished in the same way but at a comparatively higher speed. During the operation the oil holes were carefully plugged and the ways covered with canvas strips to protect them from the emery dust.

This was the third job of the same kind done in this shop. The owner said that he had been told, over and over again, that calender rolls could not be ground on engine lathes. He had, however, been able to accomplish this work satisfactorily. The only difficulty he met with was that on the first roll he found that the machine continued to grind several thousandths of an inch smaller in the middle, although sparks indicated an even cut the entire length. This difficulty he succeeded in eliminating by blocking up with paper between the frame and the middle leg on the back side of the machine. It took him, however, nearly two weeks to find this error and correct it.

It may be considered a good method to have one end of the roll gripped in a chuck as indicated. Personally the writer thinks that it would have been better if the roll had been placed in a bearing at the front end similar to that at the back. In one case, when a very heavy roll was ground, a dog engaged in the faceplate and gripping the neck of the roll—the latter being supported in bearings at each end—was used in order to relieve the spindle of the weight. This method, however, did not prove entirely satisfactory, as there seemed to be a certain spring in the tail of the dog that caused the drive to be uneven and produced something like corrugations in the roll, which were difficult to eliminate; hence, it was considered better to grip one end of the roll in a chuck.

As already mentioned, in truing up the chuck end of the roll, the other end was supported by a tail center. After truing the end as close as possible with chalk, the chuck and bearing were cleaned and covered with a thin film of lamp black, evenly smoothed out and neatly wiped off. A finely pointed scriber was clamped to the end of the emery-wheel stand and run up by the cross-feed screw. The roll was then revolved and adjusted by the chuck jaws until the scriber point traced a line evenly in the film all along the bearing.

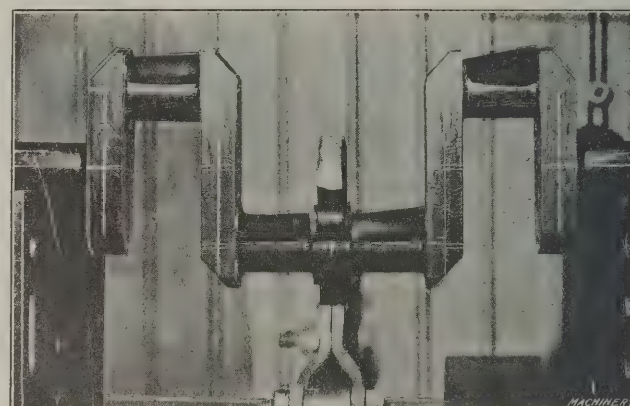
Clinton, Iowa. Olof N. Nord

OBSERVING THE DEFORMATION OF MACHINE PARTS BY PHOTOGRAPHY

It was required to study the deformation caused by deflection in a motor car crankshaft, in order to determine which of the parts should be strengthened. A photographic method was tried and found to be very successful. The crankshaft was covered all over with white enamel, followed by a light coat of a black, opaque varnish; then, by the sharp point of a surface gage, lines were traced on the crankshaft showing the various axes, these lines removing the black varnish wherever drawn, and showing white on a black background.

The crankshaft to be experimented with was of the two-throw type for a four-cylinder motor. The shaft was placed on a cast-iron bed in such a way that it had only two bearing points at the center of its outside bearings, and so that the throws were in a vertical plane. Weights could be applied by means of a hook and a lever, the load being applied to the shaft at a central point. The weights could be attached without moving the shaft in its bearings.

A camera was then placed in front of the crankshaft in such a way that the plate was parallel to the plane of the shaft, and then one photograph was taken without any load on the crankshaft; then without shifting the camera and after having suspended the load from the center of the crankshaft, a second photograph was taken on the same plate, the result



Deformation of a Motor Car Crankshaft as observed by Means of the Camera

being a composite photograph, as shown in the illustration. It will be seen that the white lines traced on the shaft are double, and the distances between two corresponding lines represent the deformation caused by the load at each point of the shaft. It will be seen that it is easy to determine which parts are the weakest, and, therefore, need strengthening. The lines on the central throws remain parallel to each other, which means that this part has not undergone any appreciable deformation. On the two vertical uprights, again, the lines are at an angle with each other which indicates that they have yielded and require greater strength. The distance between the two parallel lines at the place where the weight was attached was ⅛ inch under a load of 6600 pounds.

Turin, Italy. C. Boella

AN ADJUSTABLE PIERCING PUNCH

To pierce a number of strips, as shown at A and B in Fig. 1, the adjustable piercing punch shown in Fig. 2 was designed, which obviated the necessity of making two separate piercing punch holders. This adjustable piercing punch was made so that the punch C could be forced back out of the way when it was necessary to pierce only one hole in the strip, as shown

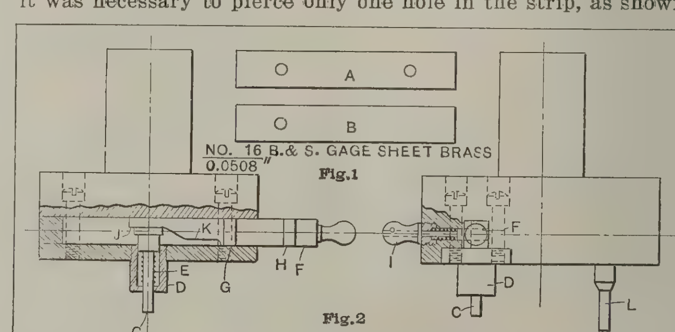


Fig. 1. Blank to be pierced. Fig. 2. Adjustable Punch used in piercing the Blanks

at B in Fig. 1. This was accomplished by holding the punch C in a bushing D which is counterbored to receive the spiral spring E, the bushing D being screwed into the punch holder.

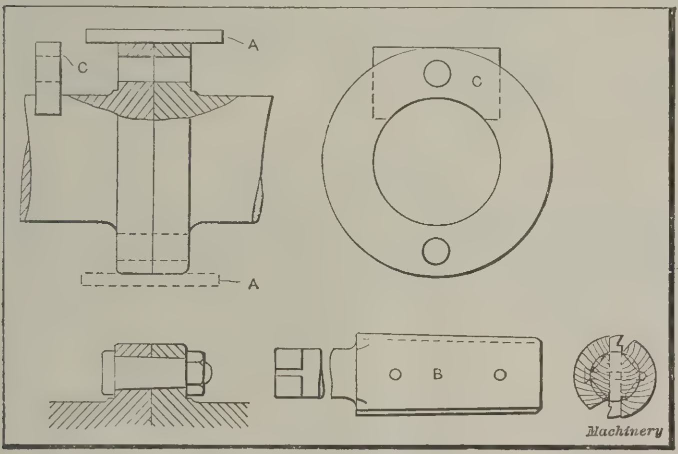
The punch C is provided with a head and is brought into or out of action by means of the cam plunger F, the latter being provided with two slots G and H in which the spring-actuated plunger I fits. When the punch is out of action it rests on the cam face J, the spring-actuated plunger I fitting in the slot G, and when it is in action the cam plunger F is pushed in so that the head of the punch C bears against the

cam face K, the spring-actuated plunger I fitting in the slot H. The other piercing punch L is fastened in the punch holder in the usual manner. The die, of course, is provided with two holes. As can be seen, it is a simple matter to make this punch either into a one- or two-hole piercing punch.

Rochester, N. Y. W. R. HUMELBAUGH

REAMING MARINE ENGINE SHAFT COUPLINGS

As shown in the accompanying engraving, solid flange couplings are used for connecting marine engine shafts. Tapered bolts fasten the flanges together and keep the shafts in alignment. If there is a sufficient amount of work of the same size, a jig may be used for drilling the coupling holes; if not, the holes are marked off and drilled as accurately as possible without a jig. After removing the burrs from the coupling faces, temporary bolts are used to fasten the couplings together, and the edges of the couplings and the holes are brought into alignment. An ordinary steel straightedge A when tried at top and bottom and on both sides of the edges of the couplings will show when they are in line. This part of the work must be carefully done; otherwise the journal portions of the shaft will not run true. The bolt-holes are then reamed, a reamer often used for this work being shown at B in the engraving. It is tapered and consists of a two-edged cutter with pieces of hard wood packing, the whole arrangement being held together by screws.



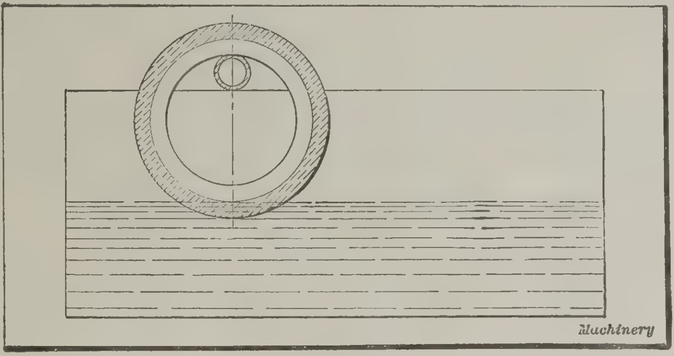
Method of Connecting Marine Engine Shafts, and Reamer used for Reaming the Taper Bolt Holes

The hard wood pieces steady the cutting edges, and the shank is supported, during the reaming operation, in a plain bearing block C of hard wood or cast iron. A slight clearance should be allowed under this bearing block, as the holes may vary slightly in their distance from the shaft center, and the bearing block can be adjusted to the correct distance from the center by packing pieces of tin or sheet iron. If greater accuracy is required, a roughing and finishing reamer may be used, although one reamer is often sufficient. For small holes the reamer is frequently turned by a hand ratchet, no support being required, while, in the larger sizes, some portable means for driving that is available may be used. While reaming the holes, the alignment of the reamer should be tested two or three times to see that it is square with the flange. If the holes are not drilled exactly in line, the reamer may have a tendency to draw to one side. After fitting a tapered bolt in the first hole, the hole opposite should be reamed next and also fitted with a bolt; afterwards there will be no danger of the couplings shifting while reaming the remainder of the holes. The bolts are driven in tight with a heavy hammer. This type of coupling is used when a three-throw crank is built up of separate parts.

Govan, Scotland W. BURNS

REDUCING THE DIAMETER OF A RING

The writer recently met with an interesting job in the form of one thousand cast-steel rings that were to be shrunk on to the hubs of motor truck wheels. The rings were of rectangular section, 10⅜ inches inside, and 16½ inches outside diameter. The thickness was 1¾ inch. These rings were faced on one side and bored to within a limit of 0.002 inch. The work was done in small lots, covering a period of more than six months, and different men and machines were employed on the work; hence, quite a number of the rings were bored too large. The specifications in connection with this work did not permit any forging to be done on these castings, and the appearance of any hammer marks would not have been permissible. A satisfactory method for shrinking the diameter of the rings, however, was developed. The rings were heated to a bright cherry red in a furnace, and then hung on a piece of pipe laid across a tank of water as indicated in the accompanying illustration. The level of the water in the



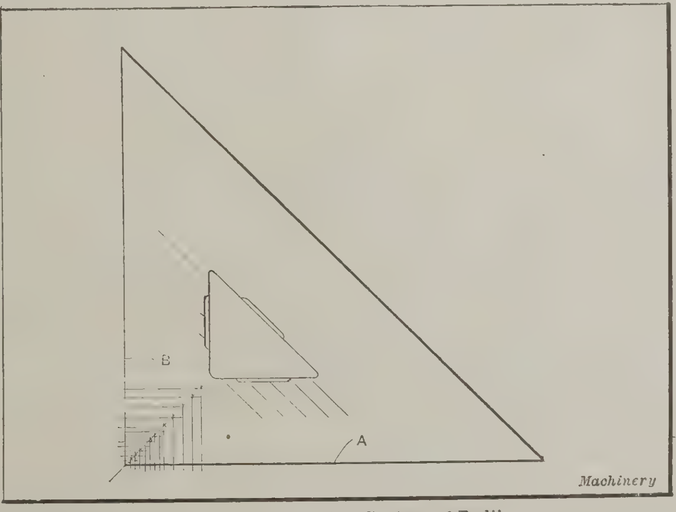
Method of Reducing the Bore in a Ring

tank was so gaged that the outer edge of the ring only was immersed. As the pipe was rolled along the tank, the outside of the ring was rapidly cooled, and in shrinking forced the inside stock inward so as to allow enough stock for reboring.

Rochelle, Ill. J. H. MAYSILLES

USING A TRIANGLE TO FIND CENTERS OF RADII

Anyone who has parts to draw requiring a number of radii no doubt will appreciate this method of locating the centers. An ordinary draftsman's triangle is laid out as shown in the accompanying illustration, for radii varying from 1/16 to 1/2 inch, advancing by sixteenths of an inch, and from ½ to 1 inch, advancing by eighths of an inch. An easy way to lay out the holes in the triangle is to use a surface gage to scribe the



Triangle for Locating Centers of Radii

lines, placing the triangle on a surface plate. The holes drilled in the triangle should be of the same diameter as the needle point on the compass.

To use the triangle, place the sides A and B tangent to the lines to be connected with the radius, usually a quadrant, and prick the center with a needle point. If the holes in the triangle are accurately spaced, any radius within the range of the triangle can be easily and quickly laid out.

New Britain, Conn. J. M. HENRY

A writer in the *Iron Age* states that by the extrusion process zinc may be transformed into a fine, crystalline structure, the tensile strength of which is 23,000 pounds per square inch.

SHOP KINKS

PRACTICAL IDEAS FOR THE SHOP AND DRAFTING-ROOM

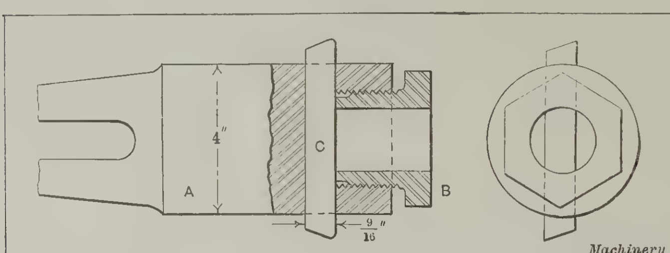
Contributions of kinks, devices and methods of doing work are solicited for this department. Write on one side of the paper only and draw sketches on separate sheets.

TO PREVENT THE FILE FROM CLOGGING

The following kink is probably known by most machinists but it may be helpful to some of the young fellows. When filing a poor quality of wrought iron in the lathe I had much trouble with the file clogging up, until I found that by bearing down slightly on the return stroke the offending chips would be removed. W. K.

EFFECTIVE MEANS OF HOLDING A CUTTER IN A BORING-BAR

The accompanying illustration shows a simple and effective means of holding a cutter in a boring-bar, which has been used successfully for boring car-wheels. The end of the boring-bar *A* is tapped out to receive the hexagon clamping

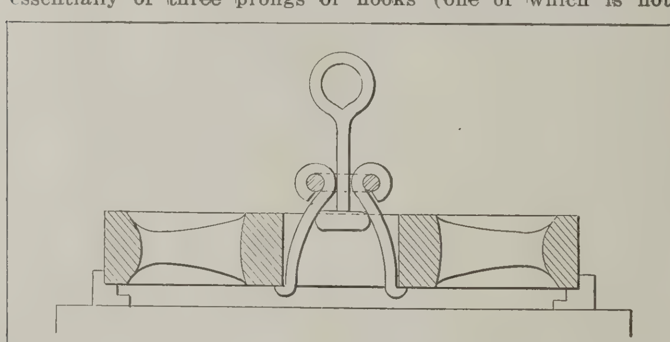


screw *B*, which holds the cutter *C* firmly in the bar, preventing it from chattering or moving. The clamping screw *B* is case-hardened on the end, and is made hollow so that the cutter will be held more firmly.

Vancouver, B. C. J. C. MATTISON

DEVICE FOR LIFTING LOCOMOTIVE DRIVING WHEELS

The accompanying illustration shows a simple device which the writer recently saw employed in a Western shop for lifting locomotive driving wheels. This device could also be used to advantage for lifting large pulleys, etc. It consists essentially of three prongs or hooks (one of which is not



shown) made from ¾-inch round iron, a welded ring and an eye having an enlarged end for opening the hooks which grip the wheel by the hub. M.

BABBITTING BOXES

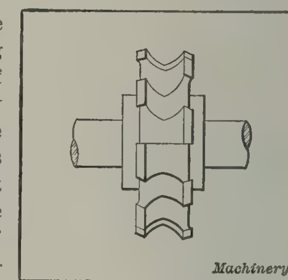
In using a shaft as a mandrel to babbitt boxes with, I have found from experience that wrapping a piece of paper around the shaft before placing it in position will make a good clean piece of work—smooth and glassy. The paper may be pasted on the shaft with shellac or glue where the edges meet. Let the paper extend the full length of the box and the edges just meet on the shaft. The paper, besides making the babbitt run smooth, also provides a little clearance, and the bearing does not require so much scraping. Those who do not care to use paper will get a smooth bearing by rubbing chalk on the shaft before babbitting.

I have seen a good many mechanics pour babbitt in boxes without venting them and then wonder why it is that they have to patch so much. I have always worked under these rules in running babbitt and have had good success: First, always have plenty of vents; second, make the babbitt good and hot; third, pour the babbitt as fast as it will flow through the pouring hole, and always use a few drops of oil on the risers.

Montpelier, Ind. J. T. CROMACK

PREVENTING A ROUND BELT FROM SLIPPING ON A GROOVED PULLEY

It is sometimes found necessary to use a round belt and a V-pulley in order to avoid a complicated mechanism. One of the difficulties which arises from using a small V-pulley is the slipping of the belt. This can be avoided by making the pulley as shown in the accompanying illustration. It is made in the ordinary manner but is provided with spaces which are cut out at intervals in the sides of the face. This type of pulley completely overcomes any slipping of the belt. F. D.



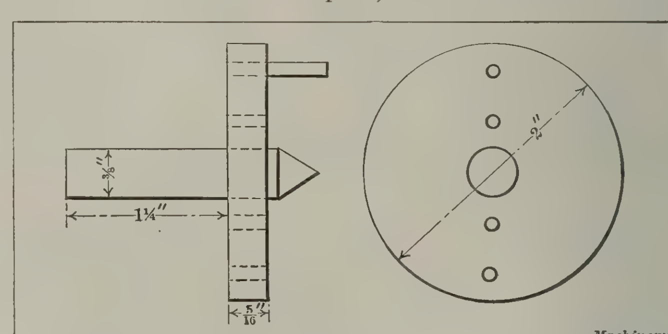
TO PREVENT SCALE ON DIES WHEN HARDENING

A good way to prevent scale on dies when hardening is to dip them in water before they are heated and then put them into dry salt, letting all the salt that will cling to them. After this the pieces are heated and immersed in brine as usual. The scale or crust of salt will fall off in the water. The piece so treated will have the appearance of a piece which has been heated in cyanide. DONALD BAKER

Syracuse, N. Y.

HANDY CENTER FOR SMALL WORK

The writer recently had occasion to turn some small work in a regular 16-inch lathe. It was difficult to drive this work when mounted on the regular centers. Therefore, a small center with a miniature faceplate, as indicated in the accompanying engraving, was made, this center being held in a collet chuck in the lathe. The holes in the faceplate were drilled to fit a standard size wire, the wires being used to drive the work. This device was found to be very handy in turning and threading small thumb-screws and similar work. S. C.



TURNING SOLID DISKS

I had to make six disks about 2¼ inches in diameter from sheet brass; they had to be turned true to size, and as there was no hole through them they could not be placed on an arbor. I cut them out with the shears, about 1/16 inch large, and then put them between two disks of wood a little smaller than the finished size of the brass disks. After knocking out the live center of the lathe, the disks were pressed firmly against the faceplate with the "dead" center. Of course, a steel disk was placed between the "dead" center and the wood, so that the center would not cut into it. After truing the disks central, I found that they could be turned very nicely by taking a light chip, as the pressure of the center against them was sufficient to prevent them from slipping. The object of using the wooden disks was to increase the friction, so the brass disks would not slip.

Mansfield, Mass. LESTER P. BROWN

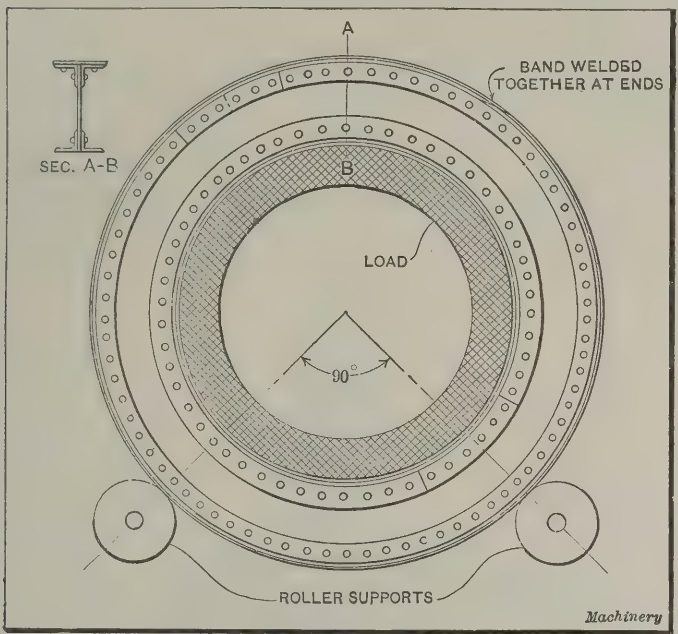
HOW AND WHY

DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST

Give details in full and name and address. The name and address will not be published with the answer.

TO DESIGN A CIRCULAR BEAM

G. A. W.—I have a circular beam made of steel angles and plates in I-beam section to design, and would like to know how to calculate the bending moment for a uniformly distributed load around the inside of the ring; also the pitch of rivets in the angles. The illustration shows the method of loading and supporting the ring. The ring revolves once in ten minutes and then stands stationary for twenty-four hours.



Circular Beam to be designed to support Load in Rotation

The question is an interesting problem in machine design which would form the subject of a good article. An answer is desired in this form.

CHANGE GEARS FOR SPIRAL GEAR-HOBBING MACHINE

R. E. N.—Two spiral gears are to be cut on a gear-hobbing machine. Gear No. 1 has 30 teeth, 24.549-inch lead, and a feed of 1/24 inch. The change gears used on the machine for cutting a spur gear with 30 teeth have 48 (driving gear) and 60 (driven gear) teeth, respectively. The hob and gear are of the same "hand."

Gear No. 2 has 60 teeth, 49.098-inch lead and is cut with a feed of 1/16 inch. The change gears used to cut a spur gear with 60 teeth, on this machine, have 48 and 40 teeth, for the driving gears, and 60 and 80 teeth, for the driven gears. The hob and gear are of the same "hand."

A.—The method to follow for calculating these gears was explained in the December, 1911, number of MACHINERY, engineering edition, and the formula there given for calculating gears to use for hobbing spiral gears, was as follows:

$$\frac{L \div F}{(L \div F) \pm 1} \times \frac{P}{p} = \frac{S}{s}$$

in which

L = lead of spiral,
F = feed per revolution,
P = product of driving gears for cutting spur gears with same number of teeth,
p = product of driven gears for cutting spur gears with same number of teeth,
S = product of driving gears for cutting spiral gears,
s = product of driven gears for cutting spiral gears.

Use + sign when gear and hob are of opposite "hand," and — sign when they are of the same "hand."

In the problems given the data are as follows:

	30-tooth Gear		60-tooth Gear
L	24.549	L	49.098
F	1/24	F	1/16
P	48	P	40 × 48
p	60	p	60 × 80

Calculations for Thirty-tooth Gear

By inserting the values given, we find that:

$$\frac{L \div F}{(L \div F) - 1} = \frac{589.176}{588.176}$$

For our purpose, the ratio written above can be simplified to the form $\frac{589}{588}$. Factoring, we have:

$$\frac{589}{588} = \frac{19 \times 31}{12 \times 49}$$

Now, multiply this value with the ratio of the gears for a 30-tooth spur gear:

$$\frac{19 \times 31}{12 \times 49} \times \frac{48}{60} = \frac{76 \times 31}{60 \times 49}$$

Having obtained the gears that should be used, we may now investigate what lead these gears will give. Apparently they will not give the exact lead desired, as we have used an approximate ratio instead of the exact one.

To prove, assume $F = 1/24$ and solve for L.

$$\frac{L \div F}{(L \div F) - 1} = \frac{589}{588}$$

From this we find $L = 24.541$, which is very nearly equal to the required lead.

Calculations for Sixty-tooth Gear

By proceeding in the same way for the 60-tooth gear we have:

$$\frac{L \div F}{(L \div F) - 1} = \frac{785.568}{784.568}$$

We then factor the fraction $\frac{785}{784}$, thus:

$$\frac{785}{784} = \frac{5 \times 157}{4 \times 196}$$

As 157 is a prime number, and gives too large a number of teeth for any of the gears in the train, we try $\frac{784}{783}$ which ratio is very nearly equivalent to that required.

$$\frac{784}{783} = \frac{49 \times 16}{29 \times 27}$$

Multiply this value with the ratio of the gears for a 60-tooth spur gear:

$$\frac{49 \times 16}{29 \times 27} \times \frac{40 \times 48}{60 \times 80} = \frac{49 \times 32}{29 \times 135}, \text{ or } \frac{49 \times 32}{87 \times 45}$$

Possibly the 135-tooth gear is impracticable, on account of being too large, in which case the other combination must be tried.

If the lead resulting from the gears found is calculated in the same manner as in the previous case, we find that

$$L = 49.001$$

Influence of Small Changes in the Ratio on the Lead

It is interesting to note that a comparatively slight change in the ratio $\frac{L \div F}{(L \div F) - 1}$ makes a very decided change in the lead obtained. To illustrate, assume that in the first example given the ratio $\frac{589}{588} = 1.001701$ were changed to 1.002; let us see what effect this change would have on the lead obtained ($F = 1/24$):

$$\frac{L \div F}{(L \div F) - 1} = 1.002$$

If we solve for L in this equation we find $L = 20.875$, which is a very different lead from the one we wish to obtain.

DROP-FORGING A WRENCH BAR

B. L. E.—I desire to make drop-forging dies for the piece shown in Fig. 1. This piece is to be a steel forging and the principal point on which I desire information is the proper shaping of the breakdown in order to distribute the stock so

that I can get the head. Also advise me what size bar steel to use and to what length the bars should be cut for forging.

Answered by J. W. Johnson, Revere, Mass.

A.—For drop-forging the piece shown in Fig. 1 a pair of drop-forging dies fitted with forming and finishing impressions, breakdown and anvil will be required. The lower half of a suitable pair of dies is shown in Fig. 2. Fig. 3 shows the right-hand side elevation of the dies, giving an idea of the shape of the breakdown, and Fig. 4 is a left-hand side elevation to show the general proportions of the anvil required for drawing out the stock. The principal requirements of a pair of dies for drop-forging this piece are that the stock be so distributed by means of the breakdown and anvil that there will be little for the face impressions to do except to shape the sides of the piece. Referring to Fig. 2, the anvil shown on the left-hand side of the die should be given the first consideration. The function of this anvil is to draw the steel out for the handle of the wrench to such dimensions as will fill the face impressions when struck therein. Thus, as the size of stock to be used will be approximately 2 by ¾ inches, it is evident that a section of the two-inch width must be drawn down by means of the anvil to such size as will just fill the face impression of the wrench handle. Referring to Fig. 1, it will be seen that the section of the handle of this wrench measures approximately ½ by ⅞ inch. It is not necessary, however, that the stock be drawn to these exact dimensions but it must be drawn to a squared size whose section is about equal to ⅞ by ½ inch, which in this case would be

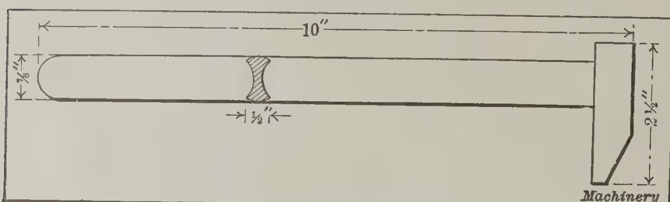


Fig. 1. Wrench Bar to be forged

about 11/16 inch. In making the anvil, therefore, the two faces should be shaped away until these faces are 11/16 inch apart when the dies meet. The removal of the stock back of the anvil faces is merely for clearance. As in all drop-forging operations, after the preliminary roughing down of the stock is accomplished by means of the anvil, it is necessary to strike the steel in the breakdown in order to approximately

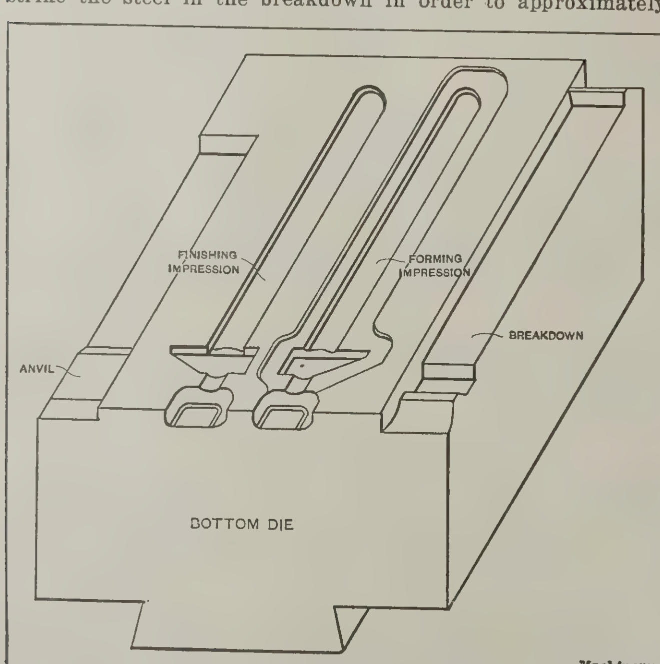

Fig. 2. Lower Half of Drop-forging Die

shape the forging. Referring again to Fig. 2 the lower half of the breakdown may be seen, and by referring to Fig. 3 the outline of the entire breakdown is seen. This breakdown should be about 1/16 inch smaller all around than the finished work is to be, in order to squeeze the stock so that it will lie in the impression for striking the final blows. All corners should be well rounded to avoid cold-shuts. It will be noticed that the width of the stock recommended is 2 inches while the height of the wrench bar head is 2½ inches. This is explained through the fact that the steel will spread the necessary amount to make up the difference. It would be possible to drop-forge this piece with but one face impression, but if many pieces are to be made it would be far more economical

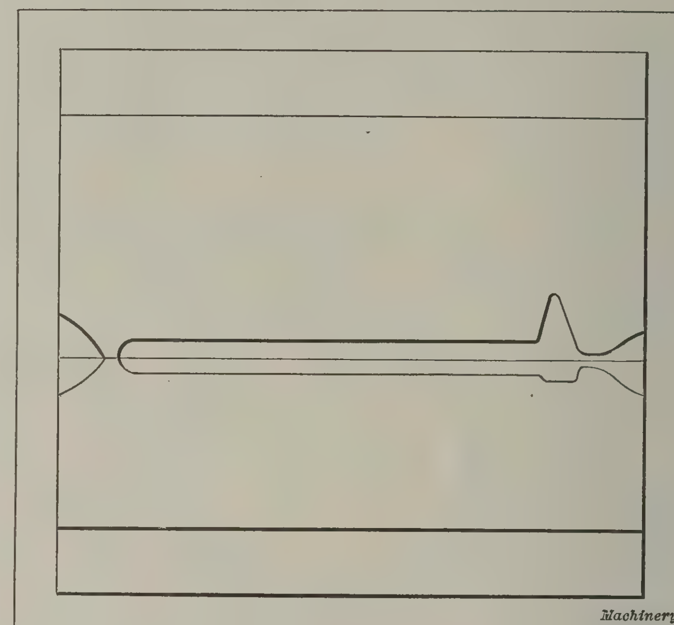

Fig. 3. Right-hand Side Elevation of Dies, showing Breakdown

to provide the dies with forming and finishing impressions as shown in Fig. 2. The forming impression should have all corners and edges well rounded in order to facilitate the flowing of the metal. This impression should be "flashed" and the upper die provided with both flash and gutter. For information in regard to cutting the flash and gutter, see "Drop-forge Die-sinking," Parts 1, 2 and 3, commencing in July, 1911,

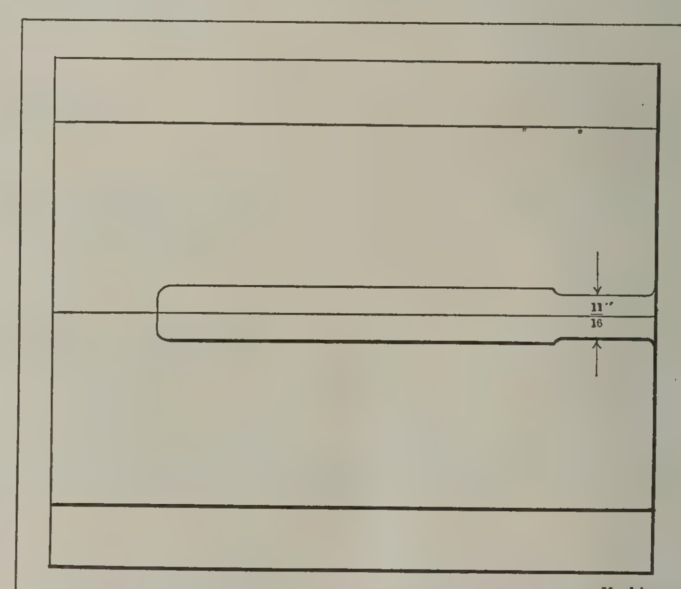

Fig. 4. Left-hand Side Elevation of Dies, showing Anvil

engineering edition of MACHINERY. The finishing impression is, of course, made exactly as the finished part must be shaped and is only used in striking the few final blows.

It is impossible to state the exact lengths to which the bars of steel should be cut for forging. This can best be determined by first cutting a length of stock from the bar as long as can be conveniently handled; say five or six feet in length. At the time of forging the last piece, it can then be seen if the bar could best be used slightly longer or shorter in order to come out with an even number of finished forgings.

Monel is said to be the only commercial metal that will resist the corrosive action of liquid soaps.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS
IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

WALKER "UNIMATIC" TOOL-ROOM GRINDER

The Walker Grinder Co., of Worcester, Mass., is now manufacturing a special grinder which is designed to meet all the requirements of modern tool-room practice. This machine, which is known as the "Unimatic" tool-room grinder, is not intended to replace the well-known No. 2 universal grinder built by this company, as it does not have as great a capacity. The new design embodies, however, all the universal features of the No. 2 size, with the addition of certain adjustments made possible by the novel construction.

The machine is very compact and entirely self-contained, no overhead works being required. The work-spindle is rotated by a flexible shaft, which is shown to the left of the

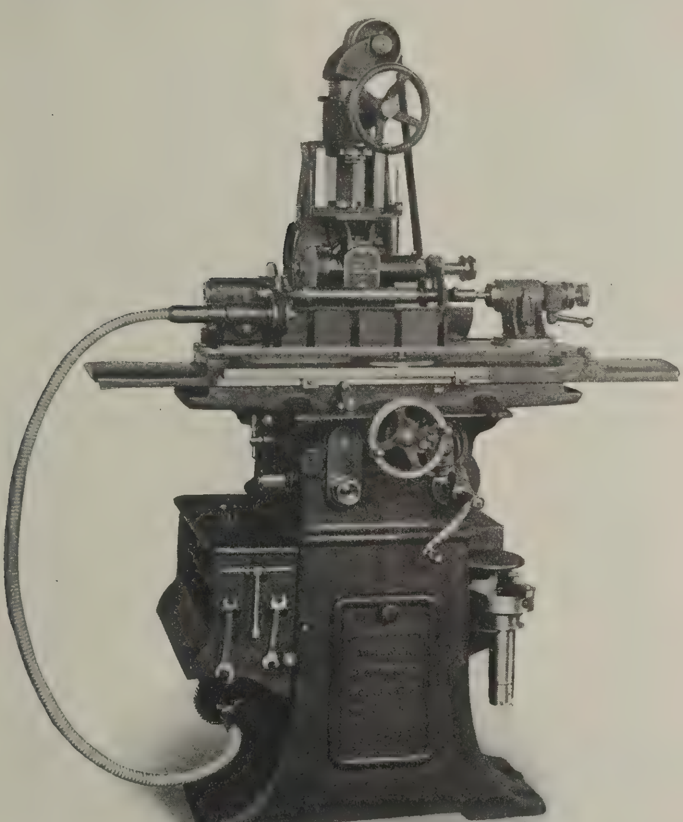

Fig. 1. Universal Tool-room Grinder, built by the Walker Grinder Co.

machine in Fig. 1, so that the overhead belt drum is eliminated. The initial drive is from a shaft in the base which transmits motion to the grinding wheel, the work-spindle and the table reciprocating mechanism. The arrangement of the interior shafts and driving belts, is shown by the end and front elevations, Figs. 4 and 5. The main shaft A carries tight and loose pulleys at the rear end (see also Fig. 2) and a three-step pulley in the center, which drives another three-step pulley mounted on shaft B. Shaft B also carries a large pulley C, which connects by a belt with the grinding-wheel spindle. Shaft A drives the intermediate feed shaft D by means of step pulleys, and shaft D, in turn, transmits motion to the table feed shaft E, which is also provided with step pulleys.

The initial driving shaft A connects with shaft F by means of step pulleys, and F is geared through fiber gearing to a second shaft G, which, of course, revolves in an opposite direction. The front ends of each of these shafts are recessed and arranged for attaching the flexible shaft H, which transmits motion to the work-spindle. This flexible shaft is clamped in

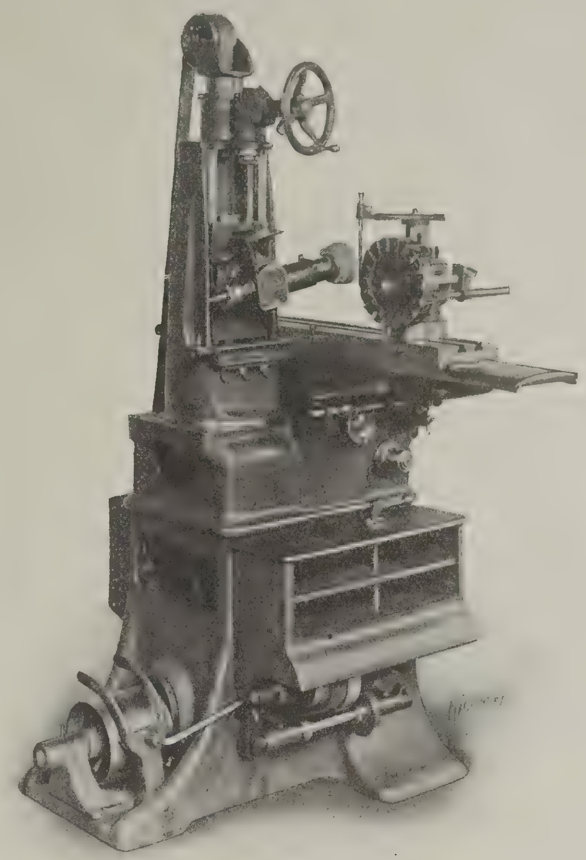

Fig. 2. Grinding an Inserted-tooth Cutter on Walker Grinder

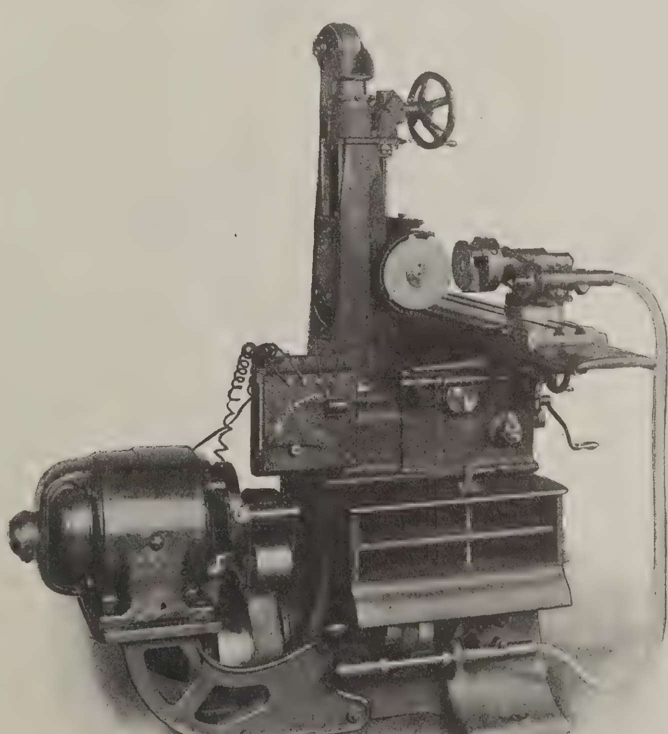

Fig. 3. Application of Motor Drive to Walker Grinder

place by screws and it can readily be attached to either F or G, according to the direction of rotation desired. The motion of the flexible shaft is controlled by handle I which connects with a friction clutch operated by a coil spring.

Hinged in the base of the column there is a frame J carrying an idler which is held against the belt connecting shafts A and B by a coil spring, so that constant tension is maintained. When it is desired to change the belt on the pulley, this tension is removed by withdrawing handle K; then the belt can easily be shifted through an opening in the side of the column. The driving belt operating on the tight and loose pulleys at the rear of shaft A, is shifted by a belt-shifter L, conveniently located at the front of the machine.

Upon the main base of the machine there is a pedestal M carrying the feed gearing and supporting the grinding-wheel housing N, which, by simply loosening one screw, can be swiveled 90 degrees about a vertical axis in either direction. Upon housing N is mounted the wheel-slide O, which is raised or lowered by a vertical screw, operated through bevel gears and the handle seen near the top of the machine. On the top of housing N is mounted an idler bracket P, which is provided at its lower end with a sleeve of large diameter through which the driving belt passes. This sleeve is threaded upon its exterior with a square thread of coarse pitch and the outside of this thread centers the sleeve in housing box Q when the housing is swiveled.

The grinder carriage R is mounted upon the pedestal M and slides on elongated V tracks which are lubricated automatically with rollers operating in oil wells. This method of lubrication is also provided for the platen S, upon which is mounted the swiveling platen S_1. This swivel platen, which carries the headstock and tailstock, can be set for tapers up to three inches per foot and has a fine screw adjustment. Upon the headstock, there is mounted an adjustable bracket T, which carries the pulley that connects with the upper end of the flexible shaft. This bracket is held by three cap-screws passing through slots and providing an adjustment for the short belt which rotates the driving faceplate.

The headstock has a universal chuck-spindle which can also be driven from pulley U. This chuck-spindle is interchangeable with the spindle which carries the revolving faceplate. The chuck-spindle, the driving faceplate and the flexible-shaft bearing are reversible in heads, so that the drive can be from whichever end is most convenient. This feature is found desirable when, for instance, the machine is set up for face grinding, as illustrated in Fig. 3. In this case, both the chuck-spindle and the flexible-shaft bearing have been reversed.

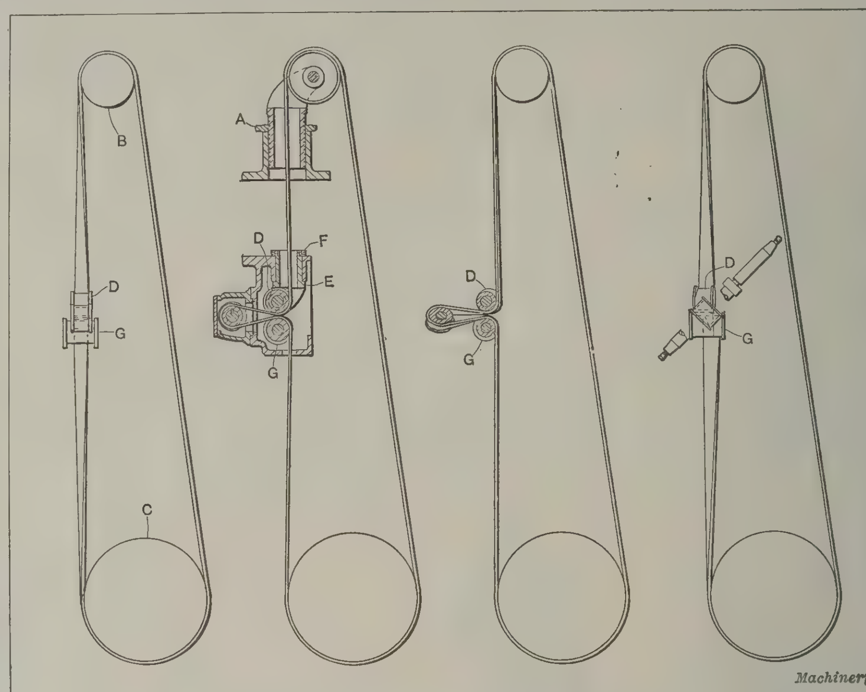

Fig. 6. Showing Course of Spindle Driving Belt for Various Positions of Grinder Head

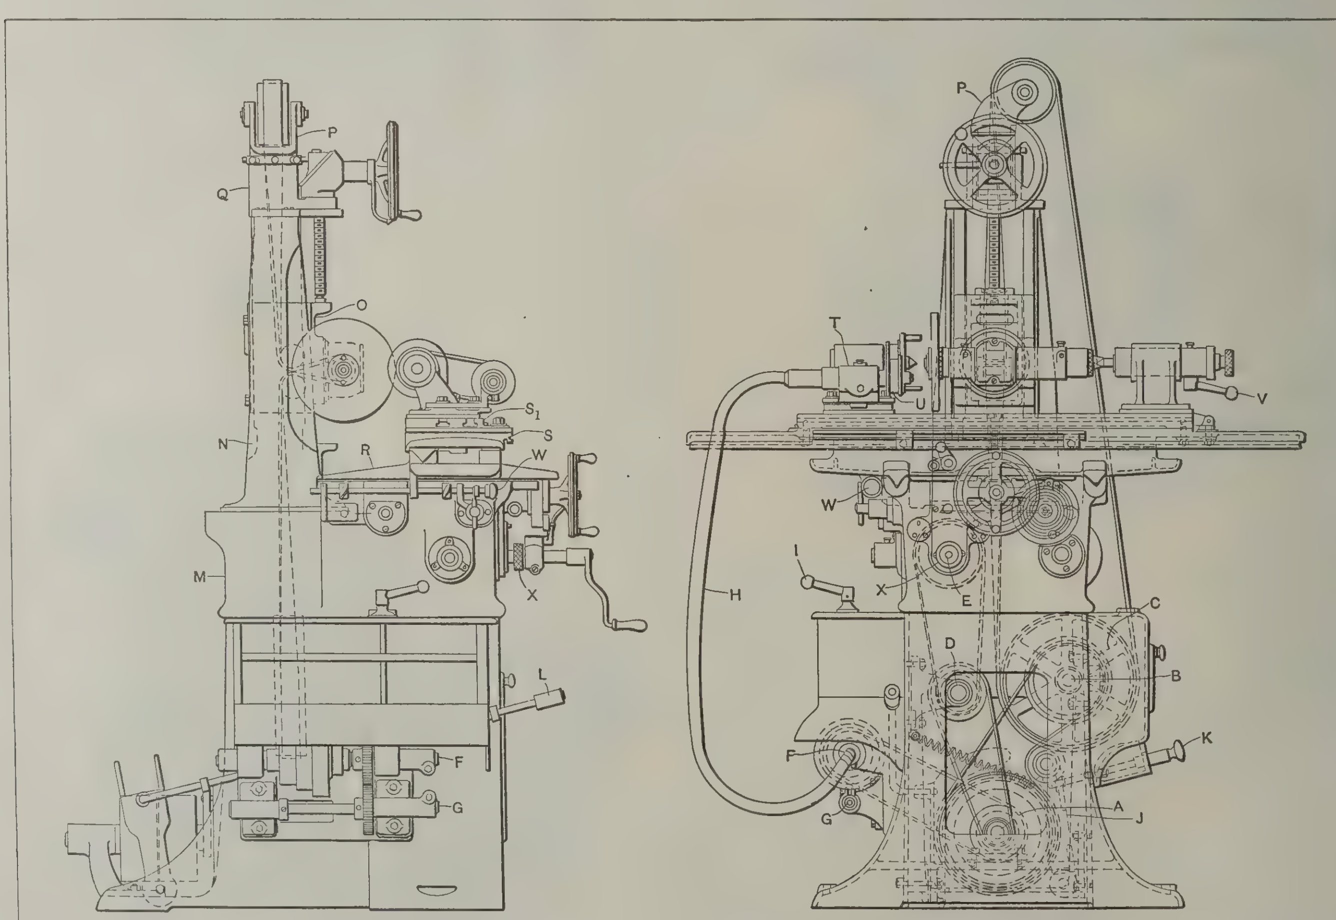

Figs. 4 and 5. Endand Front Elevations of Walker Tool-room Grinder

The tailstock spindle is provided with an adjustable spring to allow for any expansion of the work.

This grinder is not arranged for wet grinding but sectional shields or guards are provided for the top of the platen to take care of the dust. These shields are shown in position in Fig. 1, which illustrates the machine set up for a cylindrical grinding operation. The machine is equipped with an automatic stop mechanism located at the left side of the carriage as shown in Figs. 4 and 5. The knob *W* is attached to a horizontal rod carrying adjustable collars, which can be set to disengage the automatic cross-feed at any desired point. An instantaneous hand stop is also provided. The hand stop is operated by knob *X*, conveniently placed at the front of the machine, as shown in Fig. 5.

The diagrams in Fig. 6 show the course of the spindle driving belt for various positions of the grinder head. It will be noted that the pulleys *B* and *C* always remain in the same position, and that the various adjustments affect only the vertical side of the belt. The belt idler *D* is mounted in a swivel bracket *E*, which is held in place by nut *F*, and can swivel when the grinding spindle is tilted in a vertical plane. This swiveling action is largely automatic and the various positions are indicated by the diagrams. It will be seen that the part of the belt passing through the idler bracket is vertical, and only one side of the belt is affected by the swiveling action. The belt simply runs in a twist above and below the spindle when it is swiveled in a vertical plane. Bracket *E* turns so that the belt leads in the proper direction towards the periphery of the grinding-spindle pulley, thus obviating the tendency of the belt to crowd on the flanges that would develop if the bracket were not swiveled.

The idler pulley *G* is much wider than idler *D*, so that the belt, when leaving the spindle pulley, finds its own position. It has been found that with this construction, the grinding spindle can, if necessary, be run at a vertical angle of 45 degrees without any distortion. Figs. 2 and 7 illustrate the advantages of the vertical spindle adjustment. Fig. 2 shows the operation of grinding a milling cutter, and Fig. 7 illustrates an application of the tilting head to the grinding of the beveled edge of a machine part.

Fig. 3 shows the method of driving the machine with an electric motor. The latter is mounted on a bracket rigidly attached to the machine base, and the tension of the grinding belt is maintained by a spring-actuated idler. Fig. 8 shows the machine arranged for grinding the beveled seat of gasoline engine poppet valves. The swivel platen is set at an angle of 45 degrees, in which position it could not be operated by an overhead drum, but is readily driven by the flexible shaft. At first thought, it might seem that this flexible shaft would cause vibration of the work, but this has not proved to be the case. Any vibration in the shaft itself is not transmitted to the work, on account of the belt connection. Moreover, the overhang of all parts of the machine has been reduced to a minimum so that the construction is very rigid and the grinding smooth and even.

Fig. 9 shows the machine arranged for surface grinding. An extension to the spindle is provided for work of this kind. Another application of the machine is illustrated in Fig. 10, which shows the internal attachment in use. This grinder is, of course, applicable to a very large range of work, and on account of its rigidity, has proved efficient for all the different operations within its range.

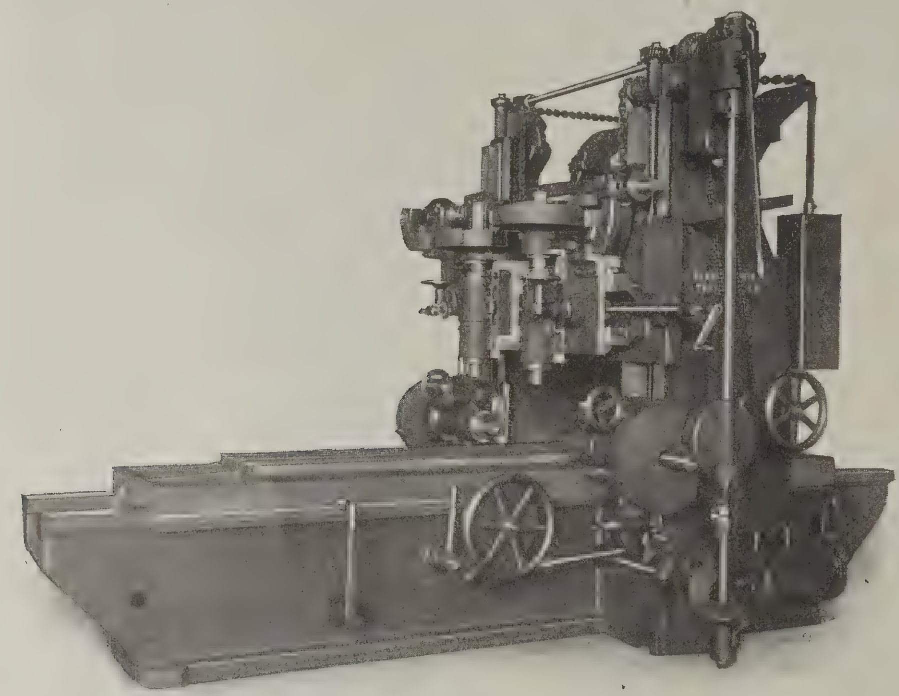
BEAMAN & SMITH FOUR-SPINDLE MILLING MACHINE

The Beaman & Smith Co., Providence, R. I., has developed an improved design of four-spindle milling machine. One of the advantages of this machine is the independent control of the spindles, it being possible to operate the spindles singly or in unison. The vertical spindles can be run at twice the speed of the horizontal spindles and *vice versa.* Provision is also made for reversing the spindles, and there is a second feed-box which gives a reverse feeding movement to the table when the spindles are reversed, thus making it possible to feed the work to the cutters from either direction.



Beaman & Smith Four-spindle Milling Machine

The general construction of this improved design is clearly shown by the accompanying illustration. There are two horizontal spindles carried by the uprights or housings, and two vertical spindles on the cross-rail. The table is of the square-lock construction with one side gib and two under gibs, which provide means of compensating for wear. The automatic feeds can be varied independently of the spindle speeds, and there is a quick power movement in either direction ranging from 7 to 14 feet per minute. The table has a working surface 30 inches wide and 10 feet long and a movement of 11 feet on the bed. There are five T-slots for the reception of clamping bolts and two rows of holes for stop-pins.

The automatic feeds to the table are positive in either direction and are obtained through a geared feed-box. There are nine changes varying from 2 to 12 inches for any spindle speed. As previously mentioned, there is a second feed-box, the gearing of which is so arranged that feeds can be reversed when the rotation of the spindles is reversed.

The spindles are of crucible steel and run in phosphor-bronze boxes. The front bearings are 4 inches in diameter and 6 inches long, and the rear bearings, 3⅝ inches in diameter and 4¾ inches long. Both the front and rear bearings are tapered and means are provided for taking up wear. The speeds vary from 6½ to 50 revolutions per minute. The ends of the spindles are made to fit cutters according to specifications.

This machine can be arranged for either a belt or motor drive. When a motor is used, one capable of developing 15 H. P. is employed. The cross-rail is raised or lowered by power, and it also has a hand adjustment. The spindles have a 6-inch independent longitudinal adjustment, effected by the handwheels shown, by means of worm gearing and a rack-and-pinion movement.

The centers of the vertical spindles are 6 inches in advance of those on the uprights. The minimum distance from the ends of the vertical spindles to the top of the table is 1 inch, and the maximum 30 inches, whereas the minimum and maximum distances between the centers of the vertical spindles are 12 and 30 inches, respectively. The horizontal spindles have a minimum distance between the ends of 18 inches, and they can be adjusted longitudinally to give an opening of 30 inches. The minimum height from the top of the table to the center of the horizontal spindle is 1 inch, and the maximum height, 26 inches. The weight of this machine is approximately 28,000 pounds.

STANDARD PORTABLE ELECTRIC DRILLS AND GRINDERS

The Standard Electric Tool Co., Cincinnati, Ohio, is placing on the market a line of high-power electric tools. One of the portable electric drills is shown in Fig. 1. This machine has ball bearings throughout and the bearings are dust-proof. The gears are generated from chrome-nickel steel, case-hardened, and are mounted on ball bearings packed in grease. The motors have a strong series winding which gives an excess of power over the rated capacity, thus preventing overloads and "burn-outs." The mechanical construction is high grade

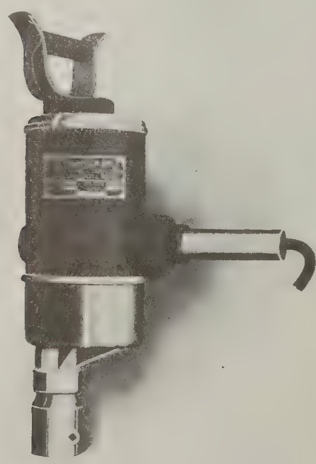


Fig. 1. Portable Electric Drill

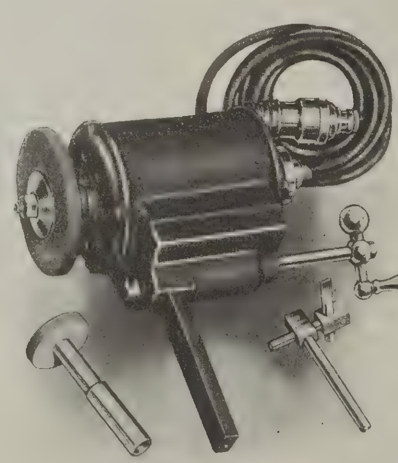

Fig. 2. Grinder with Toolpost Attachment

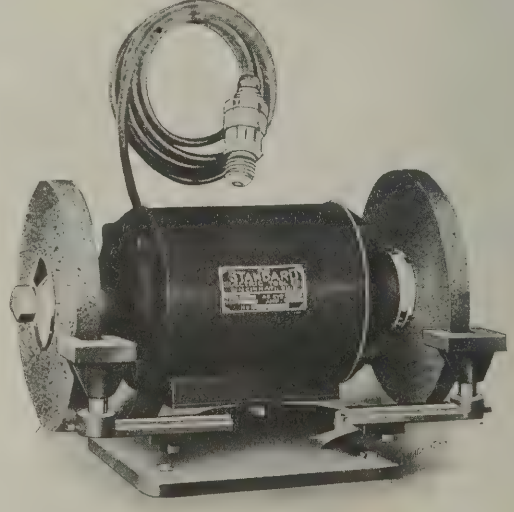

Fig. 3. Grinder shown in Fig. 2 converted into Bench Grinder

throughout. The drills are built in ⅜- and ½-inch sizes for direct or alternating current. The ½-inch direct-current drill is guaranteed to ream metal up to a thickness of 7/16 inch. This company also manufactures a universal drill of ⅜-inch capacity that will operate on either direct or alternating current.

The grinders are made for toolpost and bench work. The toolpost or center grinder, illustrated in Fig. 2, can be converted into a bench machine by removing the dovetail slide and placing the motor on top of a suitable base having a corresponding dovetail groove, as shown in Fig. 3. This feature greatly increases the range and utility of the tool.

All motors in both drills and grinders have forced ventilation by means of fans of a special design. The armatures and poles in both drills and grinders, are made of the best soft electrical sheet steel and are uniformly insulated. The grinders are equipped with ball bearings, when specified, instead of adjustable phosphor-bronze bearings.

ROCKFORD UNIVERSAL MILLING MACHINE

The universal milling machine illustrated in the accompanying halftone Fig 1 is manufactured by the Rockford Milling Machine Co., Rockford, Ill. This new machine is known as the No. 2 size. The table has a working surface of 38 by 9 inches, an automatic longitudinal travel of 25 inches, an

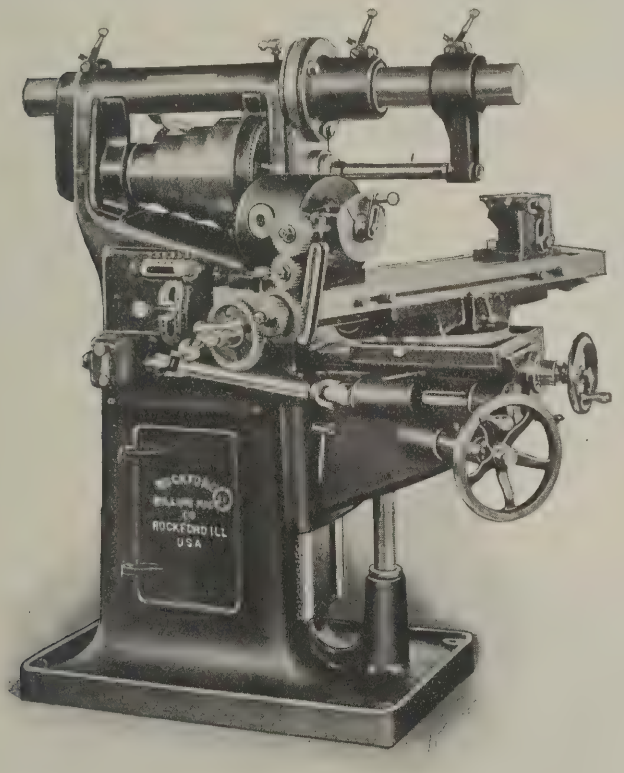

Fig. 1. Rockford No. 2 Universal Milling Machine

automatic transverse travel of 7½ inches, and a vertical power movement of 18 inches. The feeds are all positively driven through gearing and 14 changes are available. The levers for changing and reversing the feeds are conveniently located on the left side of the column, as shown in the illustration. The gears in the feed-box are cut from machine steel and the bearings are of bronze. The automatic feeds can be changed or reversed while the machine is in motion.

The main spindle of the machine has taper journals which run in bearings fitted with felt oil retainers. The wear of the spindle bearings can be quickly taken up by means of a nut at the rear of the spindle. The overhanging arm is equipped with a flanged support which reduces vibration and increases the cutting capacity. The knee has an extended top and an extra long bearing on the column, and the telescopic elevating screw is fitted with ball thrusts. The handwheels for the cross and vertical feeds are fitted with disengaging clutches.

Sixteen spindle speeds are available (with a two-speed countershaft) which range from 22 to 309 revolutions per minute. The equipment includes a two-speed countershaft, a swivel vise, an arbor, a flanged support for the overhanging arm, a dividing head and center-rest, a universal chuck, the necessary change gears, index plates, wrenches, etc.

The new dividing head is illustrated in Fig. 2. This head has been designed to combine rigidity and accuracy with simplicity and convenience. The worm-wheel, which is securely keyed to the spindle inside the head-block between the front and rear spindle bearings, has a diameter of 5⅜ inches on a 10½-inch head. The worm runs in oil, and there is an eccentric adjusting screw on the outside to take up wear

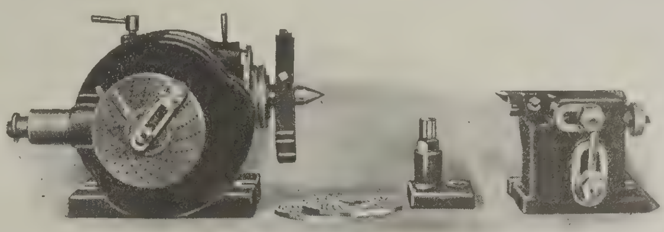

Fig. 2. Universal Dividing Head and Tailstock

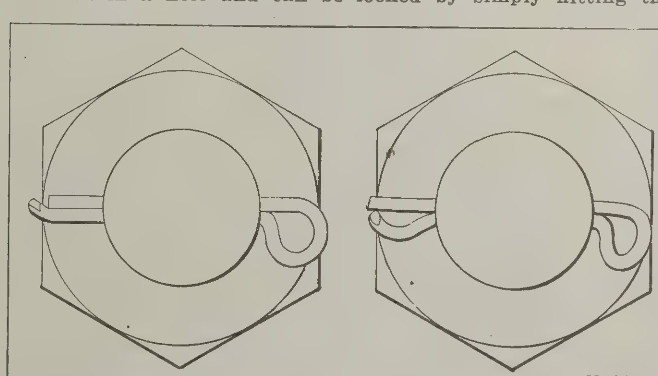
between the worm and wheel. The worm can easily be disengaged from the worm-wheel for rapid indexing.

Three index plates are regularly furnished, providing standard divisions up to 380. The spindle has adjustable taper bearings and is provided with a powerful and simple locking device. The front end has a No. 10 B & S taper hole and the nose is threaded to receive a chuck. The taper hole and threaded nose correspond in size to the main spindle so that tools can be interchanged. The swivel block carrying the spindle, swings from a position 10 degrees below the horizontal to 10 degrees beyond the perpendicular.

The center of the tailstock is held at an angle in order to locate the center close to the rear side and top, thus permitting the use of large end-milling cutters for squaring shafts, etc. The center is easily and quickly adjusted and is elevated for milling tapers by a cam. Ten change gears are supplied for spiral milling, and the worm is driven direct from the change-gear shaft.

CAMPBELL SELF-LOCKING COTTER-PIN

A. C. Campbell of Waterbury, Conn., has placed on the market an ingenious form of cotter-pin designed to replace the well-known spring cotter. This new cotter-pin is easily inserted in a hole and can be locked by simply hitting the



Campbell Self-locking Cotter-pin before and after Locking

loop or eye with a hammer; it is also removed easily. The cotter is made of half-round stock, the same as the ordinary type, but it is bent to a different shape. The eye is offset instead of being central, and the two limbs forming the body of the pin are of unequal length, as will be seen by referring to the left-hand view in the accompanying illustration. The long half of the pin is bent at an angle across the tip of the short member, in order to form a lock for the pin. This

bent end also forms what is practically a conical point, which makes it easy to enter the pin in a hole.

The method of using this pin is indicated by the illustration, which shows its application to a nut and bolt. The pin is placed in the hole as far as the head or eye will permit, as shown to the left, and then the head is flattened to about half its original height by striking it with a hammer. This forces the straight half of the pin farther into the hole which causes the bent end to be pushed downward, as shown by the view to the right. When the ends are forced apart in this way, the pin is securely locked so that it cannot work out of the hole.

This pin is not only easily inserted, but quickly and easily removed by the use of a common screw-driver, the tang of a file, or any tool having a thin, flat point which can be inserted in the loop or eye. After the point of the tool is inserted, it is twisted in the proper direction to draw back the straight half of the pin to its original position. This releases the bent or locking end and the pin can readily be withdrawn with the fingers. These pins can be inserted, locked and removed from the same side, so that they can be used in places quite difficult of access.

DIFFERENTIAL RECORDING GAGE

The Industrial Instrument Co., Foxboro, Mass., is now manufacturing a new differential recording gage which is illustrated in Fig. 1. This gage can be used for recording the differences between pressures, and it is also adapted for recording the flow of fluids by means of venturi or pitot tubes. The moving element consists of a patented pressure-

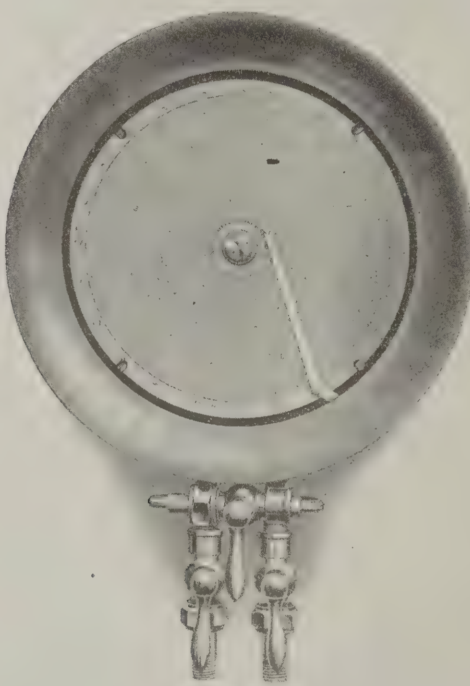


Fig. 1. Differential Recording Gage made by Industrial Instrument Co.

tube movement, which, for pressures below 10 pounds per square inch, is similar to the diaphragm tube shown in Fig. 2; whereas, for differential pressures exceeding 10 pounds per square inch, the helical tube movement shown in Fig. 3, is used.

The pen arm is attached directly to the shaft in both of these movements, which gives a rigid support. A friction joint in line with the shaft, makes adjustment possible without affecting the length of the pen arm. A pressure tube is employed having a range sufficient to cover the differential pressure desired. One of the two pressures, the difference between which is to be recorded, is applied internally to the pressure tube, and the other externally, the principle being the same as in ordinary practice except that one pressure, instead of being atmospheric, is replaced by some other pressure. Transmission from the movement to the pen arm is obtained by means of a special bearing passing through the wall of the chamber enclosing the movement.

This gage can be employed to advantage for recording the height of water in a boiler. When so used it is applied to the water column and gives a record not only of the height of the water, but an accurate record of the time the water column or gage glass is blown, the time the boiler blows off, or of any other disturbance affecting the height of the

Fig. 2. Diaphragm Tube Movement

Fig. 3. Helical Tube Movement

water in the gage glass. This continuous record will result in keeping a more uniform water level and will be an efficient check against unsafe high or low water, thus insuring greater economy and safety. The recorder can be placed at a distance from the boiler, if so desired, so that in case of an explosion, the responsibility can be placed where it belongs.

SHADOWLESS DRAFTING TABLE

The drafting table shown in the accompanying illustration has a plate-glass top beneath which is an illuminating chamber containing three electric lights. Among the advantages claimed for this construction are, the elimination of shadows and a good light regardless of the position of the windows or the time of day. The light can be intensified to any desired degree and it can also be subdued, either by the addition of tissue sheets or by reducing the electric lamp power.

The illumination from beneath makes it possible to easily trace from blueprints or drawings of any kind. Tracings can

Ulrich Shadowless Drafting Table

also be made on stiff drawing paper or bristol board, by intensifying the light, as may be required. The glass top has a cork pine frame to which the drawings may be attached with either ordinary thumb-tacks or a special suction clamp furnished with the table. The construction of the table is such that the angular position or height can be quickly adjusted, and it is rigidly held in position.

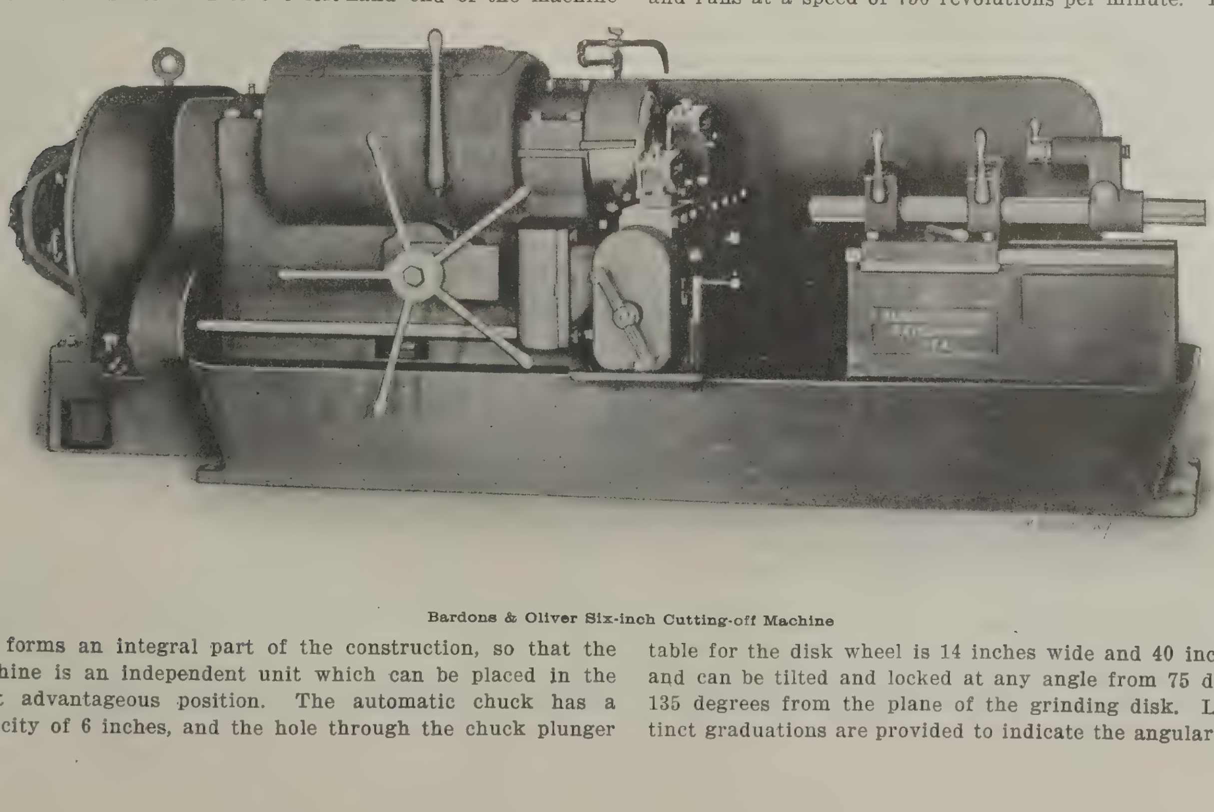
By adjusting a ventilator beneath the drawing board, the warmth from the electric lamps under the plate-glass top, can be so regulated that the ink will dry as rapidly as it is applied, thus making it possible to work over these lines immediately. There is a shelf on the left side of the table and a cabinet on the opposite side, which are very convenient for holding drawing instruments and other equipment. This table is manufactured in five different sizes by Eugene Dietzgen Co., 166 W. Monroe St., Chicago, Ill.

BARDONS & OLIVER CUTTING-OFF MACHINE

The cutting-off machine shown herewith is a 6-inch size built by Bardons & Oliver, Cleveland, Ohio. This is an exceptionally heavy and compact machine designed for rapid and efficient operation. The spindle speeds vary from 20 to 152 revolutions per minute with 10 per cent speed increments. The changes are obtained by means of a geared head and a Westinghouse 15-horsepower, adjustable-speed motor having a variation of from 300 to 1200 revolutions per minute. The motor is regulated by a drum controller having 16 points. This wide range of speeds makes it possible to use the most economical cutting speed.

The time required for inserting and removing the stock has been reduced to a minimum by means of the automatic chuck, the adjustable stop and the drum controller. The cutting-off tool-slides are so designed that all interference from chips is avoided. The support for these slides is fastened to the front of the head which has an extension on the side, as the illustration shows. This support or bracket has openings between the slide and head, thus allowing the chips to fall directly into the pan without interfering with the operation of the slides. This construction also permits shortening the main bed. There is an open space to the right of the cutting-off tool-slide which makes it convenient to remove the chips. An ample supply of oil for the cutting tools is furnished by a suitable pump, and there is a pan to catch the lubricant.

The motor is attached to the left-hand end of the machine and forms an integral part of the construction, so that the machine is an independent unit which can be placed in the most advantageous position. The automatic chuck has a capacity of 6 inches, and the hole through the chuck plunger is 6⅜ inches, whereas the hole through the spindle is 7 1/16 inches. The front spindle bearing has a diameter of 9¼ inches and is 8 inches long. The rear bearing has a diameter of 8⅝ inches and a length of 6¾ inches. The cutting tools measure ⅜ x 2½ inches. The weight of the machine, including the motor, is about 16,000 pounds.



Bardons & Oliver Six-inch Cutting-off Machine

BESLY PATTERNMAKERS' DISK GRINDER AND DRUM SANDER

The patternmakers' combination disk grinder and drum sander shown in Fig. 1 is manufactured by Charles H. Besly & Co., Chicago, Ill. All gear guards have been removed in order to show the arrangement of the driving mechanism. The machine is driven by a 3 horsepower motor mounted on a bracket bolted to the rear of the bed. This motor connects with the main spindle through sprockets and a Link-Belt silent chain.

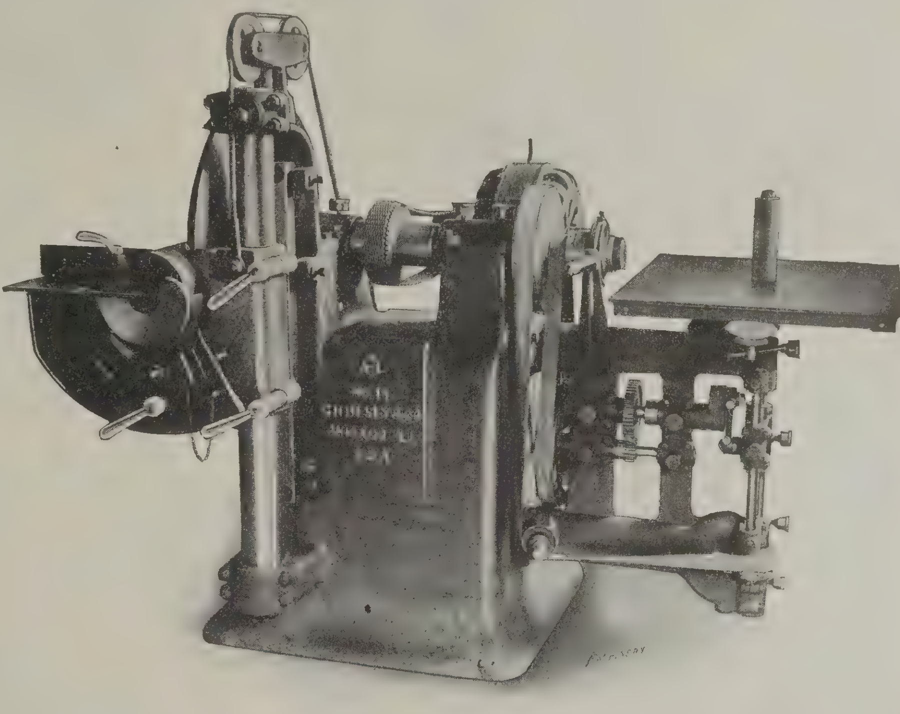


Fig. 1. Besly Combination Disk Grinder and Drum Sander for Wood Patternmaking

The steel disk wheel is 30 inches in diameter, ¾ inch thick and runs at a speed of 750 revolutions per minute. The work-table for the disk wheel is 14 inches wide and 40 inches long, and can be tilted and locked at any angle from 75 degrees to 135 degrees from the plane of the grinding disk. Large distinct graduations are provided to indicate the angular position.

The work-table is so arranged that the inside or working edge remains within 1/32 inch of the grinding disk, regardless of the angular position, and the supporting mechanism is back of the disk wheel and below the face of the work-table, so that there are no obstructions to interfere with the work. The work-table has a vertical adjustment of 25 inches and is supported by a round vertical shaft which permits swinging the table away from the grinding disk for convenience when re-setting a wheel or facing off extra large patterns.

The machine is equipped with four work-table attachments which include a sizing circle gage for cylindrical and conical grinding, a sliding bevel gage for simple and compound angle grinding, a sizing bevel gage for simple and compound angle grinding to dimensions, and an angle-plate for the free-hand cornering of thin work. There is a telescoping dust hood which may be piped to an exhauster for withdrawing the grinding dust.

The drum sanding attachment at the right is driven through a Johnson self-oiling friction clutch which enables the operator to stop the drum sander independently of the disk wheel. This is very essential, as the disk wheel is usually allowed to run continuously, whereas the drum sander must be stopped in order to attach drums of various sizes for different classes of work. The work-table of the drum sanding attachment measures 24 by 28 inches. It can be tilted and locked at any angle from 85 degrees to 105 degrees from the axis of the sand drum, and the position of the table is shown by large graduations which can easily be seen.

Fig. 2. View illustrating Use of Drum Sanding Attachment

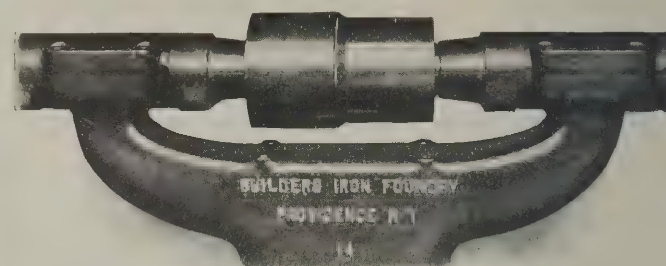
The sand drum illustrated is 2½ inches in diameter and 8 inches long, but drums varying from 1 to 6 inches in diameter and of any reasonable length can be used. The work-table has a central annular opening 8½ inches in diameter into which are fitted circular plates with center holes to accommodate drums of different sizes. The sand drum runs at 2250 revolutions per minute and when in operation, it is given a vertical reciprocating movement to equalize the wear of the abrasive. This reciprocating movement is obtained from the crank seen beneath the table, and it is adjustable from 0 to 4 inches. The sand drum spindle is driven by a 2-inch quarter-turn belt, and the reciprocating crank is driven by a 1½-inch belt, which transmits power to the crankshaft through the intermediate shaft and gearing shown.

Fig. 2 illustrates how the sand drum attachment is used for finishing straight and curved inside surfaces. The table is tilted to an angle of 1½ degree, in this particular instance, to give the required draft.

This machine occupies a floor space of 54 by 84 inches and weighs 2800 pounds. It is made with either 30- or 40-inch disk wheels and for a belt or motor drive.

IMPROVED POLISHING MACHINE

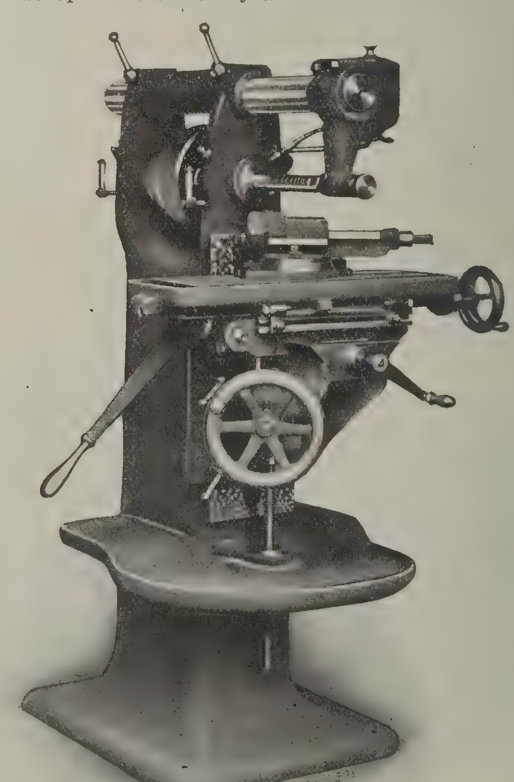
The accompanying illustration shows an improvement which has recently been made on the 12- and 14-inch ring-oiling polishing machine manufactured by the Builders Iron Foundry, Providence, R. I. The loose pulley has a diameter ½ inch less than the diameter of the tight pulley in order to relieve the tension on the driving belt when the spindle is stationary. This well-known feature permits the use of an extra-tight belt without subjecting the loose pulley to excessive strain; consequently there is less wear on both the belt and pulley. The loose pulley has a beveled flange on the tight pulley side, so that the belt can be shifted easily. This polishing machine has a positive method of lubrication which permits it to be run at very high speeds without lubrication troubles.



Spindle Mounting and Belt Pulleys of Polishing Machine made by Builders Iron Foundry

STEPTOE HAND MILLING MACHINE

The hand milling machine illustrated herewith is of a recent design now being built by the John Steptoe Shaper Co., 2951 Colerain Ave., Cincinnati, Ohio. The table of this machine can be operated either by a lever feed or a screw feed.



Steptoe Hand Milling Machine

The lever feed is intended for the rapid milling of small parts, but when desirable, either because of accuracy or for some other reason, the screw feed can be employed. This screw feed has a collar accurately graduated to thousandths of an inch.

This machine is also built with a lever elevation for the knee, when so ordered, and it will be manufactured later

with a power feed for the table. The vise has a graduated base for setting it to any angle. The pan seen below the knee prevents chips and oil from falling on the floor, and it is also convenient as a tool rest. The bearings are of high-grade phosphor-bronze and are tapered and threaded on the ends to take up wear. The bearings are thoroughly oiled by means of felt oilers.

DALLETT PNEUMATIC TOOLS FOR PATTERNMAKING

In view of the fact that pneumatic tools have proved so efficient for chipping metals, carving stone, etc., it seems rather strange that they have not come into general use in woodworking establishments. In the pattern shops, for instance,

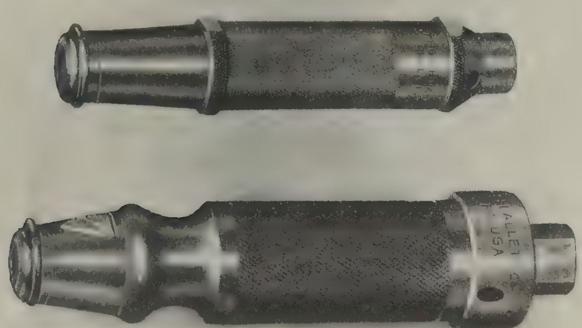


Fig. 1. Dallett Pneumatic Tools for Wood Carving and Patternmaking

there is always more or less hand carving which could doubtless be done easier and quicker with the aid of pneumatic tools. The Thomas H. Dallett Co., York and 23d Sts., Philadelphia, Pa., has placed on the market pneumatic tools for wood carving which are an adaptation of the pneumatic stone-working tools which this company has been manufacturing for years.

Fig. 2. Sectional View of One-inch Pneumatic Wood-carving Tool

These tools for wood carving are made in two sizes, which are illustrated in Fig. 1. The upper tool is a ¾-inch size intended for fine carving and finishing, whereas the 1-inch size below is more powerful and is adapted for gouging and heavy roughing work.

It is claimed that these tools enable one man to accomplish a great deal more than would be possible by the old method of hand carving. They can be regulated to give a light or hard blow, either by placing the thumb over the exhaust hole or cutting down the air supply by means of a stop-cock in the hose. Both tools are of the valveless type and operate on the same principle, although there is a slight difference in the design. The head of the ¾-inch tool is locked by a pin and spring, whereas, in the 1-inch "finger grip" design, the head is locked by a ratchet and pawl.

The sectional view, Fig. 2, shows the construction of the larger size. The tool-steel piston is the only moving part, and it strikes as high as two or three thousand blows per minute, the rate depending upon the pressure. The cylinder is of hardened steel and, in the case of the "finger grip" design, it is one solid piece. A renewable hardened bushing is inserted in the end of the barrel for the reception of a shank having a special "quarter-octagon" shape instead of being round. With this arrangement, the chisel can be held steady and secure without any effort on the part of the workman. Furthermore, by having a shank of this shape, the chisel can be twisted when gouging or roughing, in order to split or pry off a chip, which could not be done with a round bushing.

As wood chisels are made with both tang and socket ends, three fittings known as a plug, shank and socket shank are

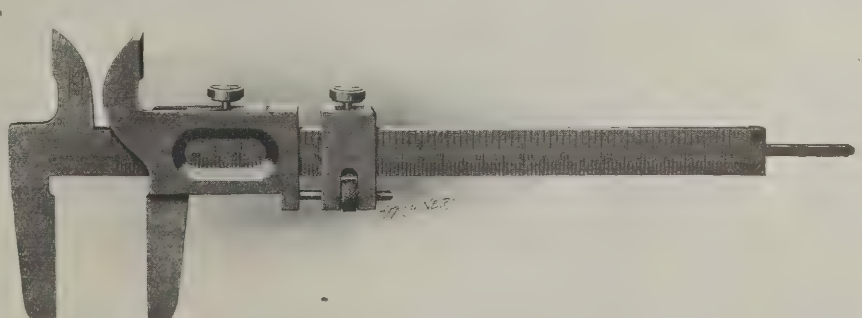
Fig. 3. Using the Dallett Pneumatic Tool for Patternmaking

furnished to adapt the pneumatic tools for any style of chisel. The shanks are provided with a recess on one side which is engaged by a locking spring to prevent the shank from dropping out when the tool is in operation. This feature makes it unnecessary for the workman to hold the chisel in place.

Fig. 3 illustrates the application of this tool to patternmaking. The air consumption of the ¾-inch size is approximately four cubic feet of free air per minute, and that of the 1-inch size, about five cubic feet. The air pressure required depends entirely upon the character of the work and the kind of wood being operated upon. The pressures range from 40 to 100 pounds, but pressures between 70 and 90 pounds are most commonly used for general work.

SCHUCHARDT & SCHUTTE VERNIER CALIPER

Schuchardt & Schutte, Cedar & West Sts., New York, has placed on the market the improved form of vernier caliper shown herewith. This is a combination tool which can be used for measuring inside and outside diameters and also as a depth gage. The extension jaws seen above the regular caliper jaws, are used for internal measurements, and the depth gage slides in a groove on the rear side and projects



Combination Vernier Caliper for Inside, Outside and Depth Measurements

beyond the end of the bar or scale, as shown to the right. The jaws and depth gage move together, so that all three measurements are obtained at one setting, and the scales give a direct reading.

The general arrangement of this caliper is similar to the type formerly sold by this company, but the construction is

quite different. The fixed jaws for internal and external measurements are integral with the bar instead of being riveted in place, and the sliding jaw completely encircles the bar, instead of being retained by a flat spring, as with the older design. This construction makes the tool much stronger and adapts it for hard usage in machine shops.

The bar is 6 inches long and is graduated on the upper and lower edges. Two sets of graduations can be furnished. The upper and lower scales of one set are graduated to sixteenths and twenty-fifths of an inch with verniers reading to one-hundred twenty-eighths and one thousandths inch, respectively. The other set has one-sixteenth-inch graduations on the upper scale and millimeters on the lower scale with verniers reading to one-hundred twenty-eighths inch and one-tenth millimeter, respectively.

BATH GRINDING MACHINE FOR MULTIPLE KEY-SHAFTS

The grinding machine illustrated herewith has been designed for grinding integral multiple key-shafts or sliding-gear shafts for automobile transmission cases. A formed grinding wheel is used and the sides of two keys as well as the circular surface between them, are ground simultaneously. This machine is built by the Bath Grinder Co., Fitchburg, Mass. Fig. 1 is a front view showing the water guards in place; Fig. 2 is an end view illustrating the construction and arrangement of the grinding wheel head; and Fig. 3 shows a key-shaft in place and the wheel in position for grinding. Before taking this latter view, the water guards were removed to expose the details of the machine.

The vertical column has two wide bearing surfaces upon which the grinding wheel head is mounted. The column is strongly ribbed internally and firmly bolted to the base of the machine. The wheel-head is rigidly constructed and careful attention has been paid to the oiling system. The wheel-spindle is made of tool steel, hardened and ground, and runs in adjustable phosphor-bronze bearings, which are thoroughly protected from grit. The handwheel for feeding the grinding wheel vertically, is graduated to read to 0.00025 inch, and it is equipped with a stop for grinding duplicate parts. The thrust of the vertical feed screw is taken by ball thrust bearings.

The machine is provided with an indexing work-head, firmly bolted to the table. The indexing mechanism consists of an index dial, a tooth ratchet wheel and an index plunger-bolt, all of which are protected from water and grit. The index plunger-bolt is released by a slight backward movement of the handle shown; then by a forward movement, the work is revolved and the plunger-bolt engaged in the next taper notch. This mechanism is so designed that the dial cannot revolve backwards when free of the plunger, which insures a positive indexing action. The number of divisions on the dial are determined by the number of keys in the shaft to be ground.

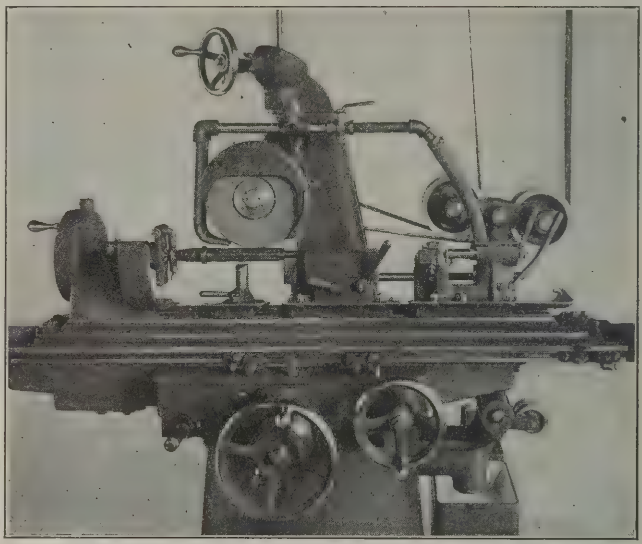


Fig. 3. View of Bath Grinder with Water Guards removed

The footstock furnished on this machine is very compact and rigid in construction. The center carrier is flat and is set into the base at an angle, thus bringing the center within one-half inch of the top and one-half inch of the inner side of the footstock. This allows the grinding wheel to pass the footstock, without disturbing its position. The center carrier is operated by a spring controlled by the lever seen at the right-hand end of the footstock. The carrier may be locked firmly in position by the handle at the left. All operating parts are thoroughly protected from water and grit.

Fig. 1. Bath Multiple Key-shaft Grinding Machine

Fig. 2. End View of Bath Grinding Machine

The wheel truing device, which is illustrated in Fig. 4, is provided with three black diamonds. One is for forming the radius of the wheel and is operated by the short lever seen at the end of the fixture. The other two diamonds are for forming the sides of the wheel and are operated simultaneously by the long lever shown at the end of the fixture. The diamond for forming the radius is carried by a steel spindle which

revolves in a taper bearing, and is provided with a very sensitive adjustment. The alignment of the side forming diamonds is insured by adjustable taper keys. These bearings are carefully protected from grit and water.

After this device has been properly located at the back of the footstock, it should not be disturbed. When truing the grinding wheel, the table is moved so as to bring the center of the grinding wheel over the center of the diamonds, the

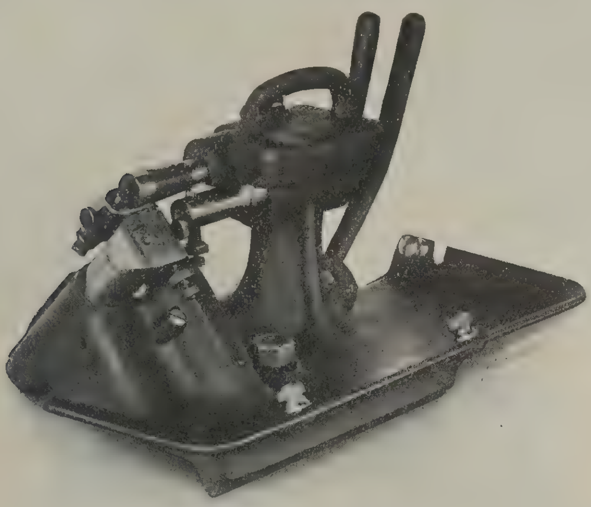

Fig. 4. Device for Truing Sides of Wheel and Forming Radius

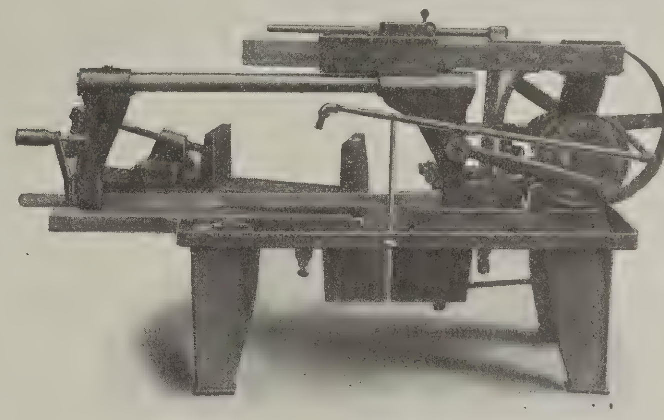
table being provided with a twin stop for locating it in the correct position. The master block for setting the diamonds is clamped on top of the wheel truing device base, which is provided with a dovetail to insure alignment. The master block carries a hardened tool steel plug, to which the diamonds are set. A shield is furnished to cover the bearing on the wheel truing device when the master block is not in use.

A combination centering and rest base is furnished for centering work rapidly, and also for supporting slender work. This fixture is clamped to the table and is provided with a plunger, the top of which is formed to fit between two keys on the shaft to be ground. The plunger is actuated by a spring, and is controlled by a lever which has a cam cast integral and engages the plunger. A slight turn of this lever to the left relieves the plunger, and, when used as a support, the plunger may be clamped firmly in position by moving the lever in the opposite direction.

The table is controlled in the usual manner by adjustable dogs operating against a reversing lever which actuate a clutch of the "load-and-fire" type. The table can also be controlled by a hand-reversing lever, which provides means for automatically stopping it at the end of its traverse, by simply giving the lever part of a turn at any time during the traverse of the table. All operating levers, handles and adjustments are within easy reach of the operator from the front of the machine. The water tank is separate from the machine, thus making it convenient for cleaning.

ROBERTSON POWER HACKSAW

In the June, 1912, number of MACHINERY a power hacksaw, known as No. 2, manufactured by the W. Robertson Machine & Foundry Co., 32 Greenwood Place, Buffalo, N. Y., was illustrated and described. The accompanying illustration shows a larger size of hacksaw, known as No. 5, built by the same company. This machine is designed for cutting off structural shapes and solid stock, round or square, the maximum capacity being 8 by 15 inches. The saw frame is adjustable and allows the use of a 10-inch blade for cutting small stock, which involves a great saving when large stock is not being cut continually. The vise has strong wide jaws and is provided with a quick adjustment so that the operator can open or close it instantly to take stock from 1 to 15 inches. The vise swivels to a 45-degree angle, and is graduated.



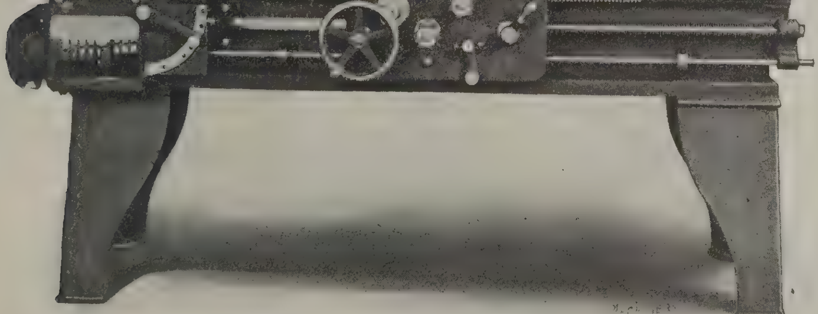
"Economy" Power Hacksaw

The saw cuts on the draw stroke, and is raised on the return stroke by an arrangement which is very simple mechanically, yet positive and durable. The saw stops automatically when the cut is completed. The tank shown under the bed is for cooling liquid, which is pumped to the blade by a rotary pump connected to the driving gear at the rear of the head.

The maximum length of the blade is 24 inches, the minimum being 10 inches; the stroke is 6 inches. The driving pulley speed is 140 R. P. M., and the net weight of the machine is 360 pounds.

GREAVES-KLUSMAN 17-INCH LATHE

Greaves, Klusman & Co., Cincinnati, Ohio, have added to their line of lathes, a 17-inch quick change-gear type having a three-step cone and friction double back-gears. The bed is a new form designed to minimize twisting strains by means of heavy reinforcements under the V's, which extend below the top of the girths. The headstock is massive and the spindle is made of high-carbon steel and runs in self-oiling phosphor-bronze bearings. The front spindle bearing is hardened and ground in position. The self-adjusting, friction, double back-gears can be engaged by the operator in any position along the bed, by simply shifting the horizontal bar shown.



Greaves-Klusman Quick-change 17-inch Engine Lathe

With the two-speed, friction countershaft regularly furnished with this lathe, eighteen speeds are obtainable. As six of these speeds are secured without shifting the belt, it is convenient to obtain the proper speed for roughing and finishing.

The frictions of the double back-gear mechanism are of simple construction and have two rings which engage recesses in the gears. There are two toggles fitted in each ring which expand the frictions when the longitudinal bar is shifted. These frictions are self-adjusting for wear and have ample strength to transmit the maximum belt pull.

The tailstock has an extra-long spindle which is gripped by two sets of double-plug clamps at both ends of the barrel. This clamping device is operated by a single handle. The carriage has a full length bearing on each V and a flat bearing inside the front V, which shortens the bridge and gives a direct support under the tool-rest. The apron is the double-plate box form. The quick-change gear-box at the left is a simple, compact design having but two handles which control the entire range of threads and feeds. The lathe is fitted with a chasing dial for "catching" threads, and all threads from two to fifty-six per inch can be cut, including the 11½ pipe thread. There is a clutch for independently engaging or disengaging the lead-screw on the feed-rod. This clutch is operated by a handwheel on the gear-box.

This lathe has a swing over the bed of 18⅜ inches, a swing over the carriage of 13⅛ inches, and it takes 31 inches between the centers, with a 6-foot bed. The front spindle bearing is 3 3/16 inches in diameter and 5⅛ inches long, and the rear bearing is 2⅝ inches in diameter and 4 5/16 inches long. The back-gear ratios are 3.5 to 1 and 12 to 1.

BLISS TOGGLE DRAWING PRESS

The accompanying illustrations show the front and rear views of a toggle drawing press recently designed and built by the E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y. This is said to be one of the largest drawing presses of this type ever built. This press is intended for drawing and forming sheet metal automobile parts made of thick stock, such as brake drums,

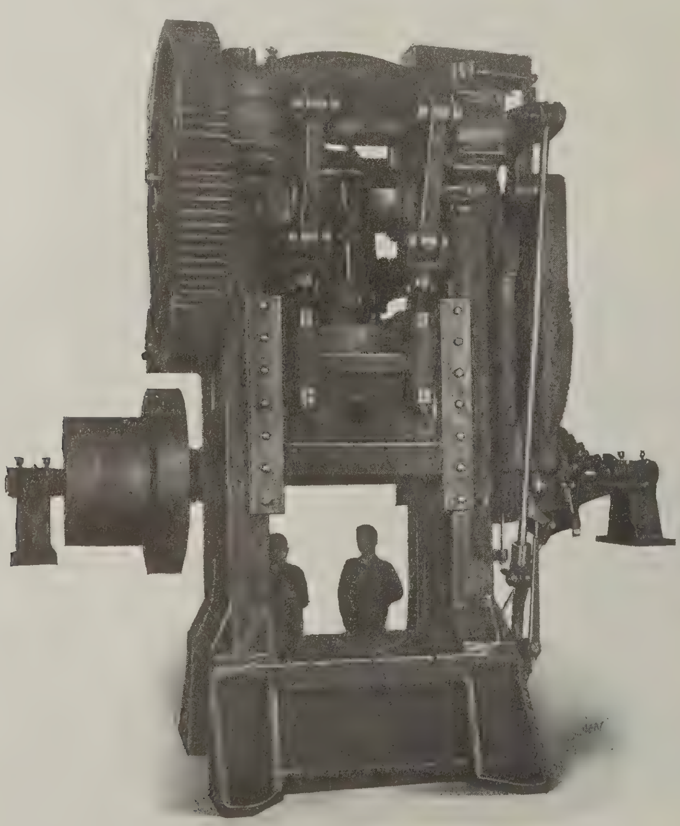


Fig. 1. Large Toggle Drawing Press built by E. W. Bliss Co.

rear axle housings, etc., but it is equally well adapted for other lines of manufacture in which very heavy stock is drawn.

The construction is of the built-up type, the bed, the crownpiece and uprights being separate and bound together by four 7-inch steel tie-rods, which take all the working strain. These tie-rods are heated and shrunk into place. The frame columns are of cored box section, and impart great rigidity to the entire structure. The main crankshaft is 12 inches in diameter and has a stroke of 24 inches. The stroke of the blankholder slide is 16 inches.

The entire construction of the machine is in proportion to the 12-inch crankshaft and 7-inch tie-rods, and the calculations were based on the bending strength. With a factor of safety of 2½, the machine has a safe working capacity of 600 tons. Attention is called to the basis of the calculations, because in many instances, the capacity of presses is figured on the shearing strain. If the latter method were adopted in this case the press shown would have a capacity of 1000 tons, but to have this capacity with the bending strength taken as a basis, would require 9-inch tie-rods and a 16-inch crankshaft.

The Bliss toggle movement is applied to the press and all pressure on the blank is transferred through straightened

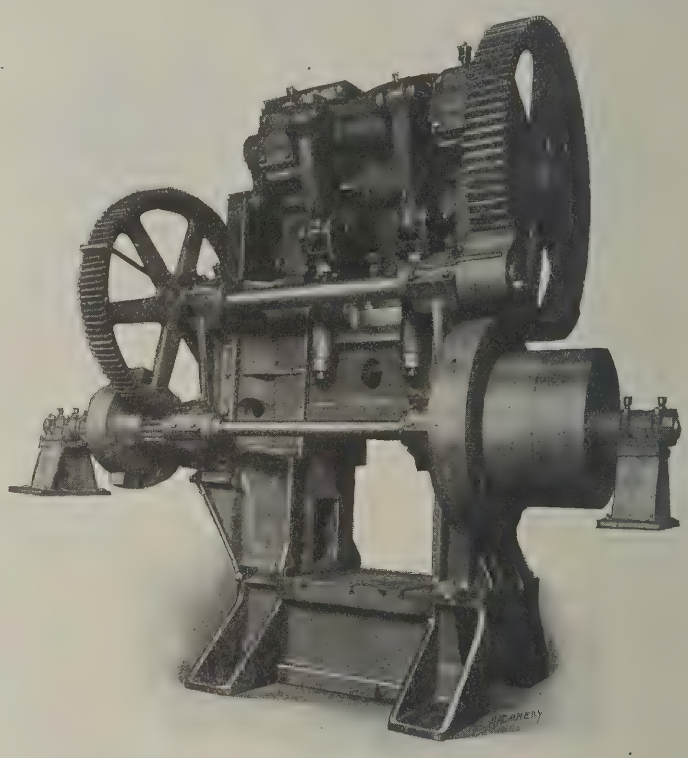

Fig. 2. Rear View of Bliss Toggle Press

toggles directly to the frame, relieving the bearings from all friction and wear due to blank-holding, with a consequent reduction in power consumption.

The press is double geared, and the entire train of gears are of steel castings, and machine cut. The press is controlled by a powerful hand-actuated friction clutch of the double-grip type, the action of which is practically instantaneous. This clutch, in connection with the semi-automatic brake, places the movements of the press entirely under the control of the operator, so that it can be started or stopped at any point.

It will be noted that the bottom of the outboard bearing standards are very high from the base of the press. This arrangement was necessary because of the low ceilings in the building at the place of installation, which requires the press to be placed in a pit of considerable depth. The actual shipping weight is 170,000 pounds.

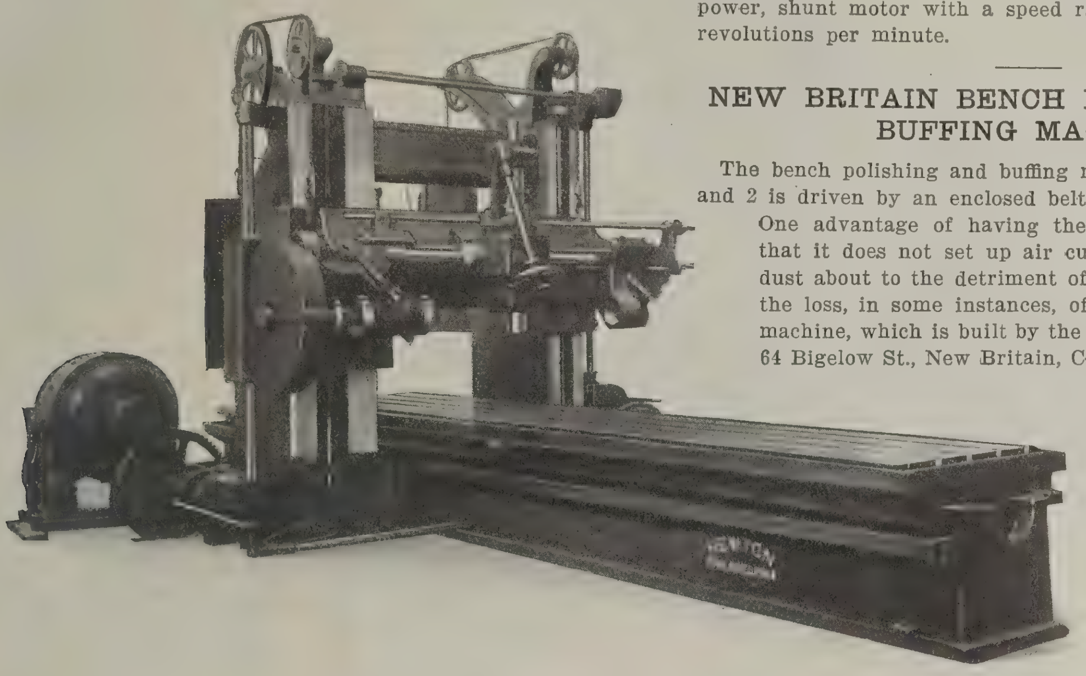
NEWTON HORIZONTAL MILLING MACHINE

The Newton Machine Tool Works, Inc., 24th and Vine Sts., Philadelphia, Pa., has recently designed a heavy type of horizontal milling machine for forge work. The bed of this machine is of an extra-heavy, double-ribbed, box-type construction having oil pans cast integral and bearings with square gibs for the table. The sides of the bed are fitted with tongues for attaching the uprights which extend to the floor line. The work-table is also exceptionally heavy, of double-ribbed box-type construction, and has an angular steel rack bolted to the bottom which is engaged by a bronze worm-gear of steep lead and large diameter.

The rail is of the inclined face type and is of large propor-

tions. It is fitted to the uprights with square lock bearings. Adjustments are made by taper shoes, and the alignment is maintained by the narrow guide bearing on the left-hand upright. The bearing of the rail on this upright, for alignment, is on both sides of one shear, to prevent any distortion of the bearing surfaces. The bearing for the driving worm-wheel sleeve and the driving worm are cast solid with the rail, which gives a strong resistance to thrust and tends to eliminate chatter.

The spindle revolves in a bronze bushed capped bearing, which has a hand side adjustment on the rail for convenience in setting cutters. The rail is of sufficient length to permit removing the cutters without taking off the outer support. The spindle is arranged to drive the cutter arbor by means of a broad face key, and the arbor is held in place by a through retaining bolt. The outer end of the cutter arbor is supported in bushings that have parallel internal and taper external bearings, fitted with adjusting nuts to compensate for wear. Individual screws fitted with micrometer measuring collars



Newton Horizontal Milling Machine for Forge Work

are furnished for moving both the horizontal spindle and the vertical spindle saddles. The outer support is adjusted rapidly by means of a rack and pinion. The cross-rail elevating screws have a top and bottom bearing, and as the counterweights are heavier than the rail, tension is always maintained and lost motion eliminated.

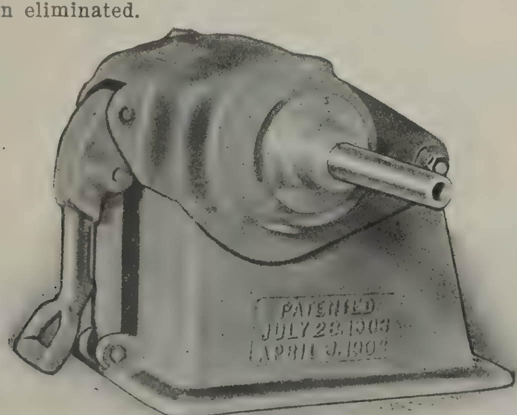


Fig. 1. The New Britain Bench Polishing Machine

As many forgings, such as large driving shafts, require feather keyways, this machine has been equipped with a vertical spindle to mill the ends of the keyways. The vertical spindle is five inches in diameter, and is arranged to drive the cutters by a broad face key. It is fitted with a No. 6 Morse taper, retaining and drift key slots, and a micrometer measuring shoulder. The vertical spindle is driven from a spur gear placed beside the worm-wheel for the horizontal spindle. The motion is transmitted through a clutch so that the vertical spindle can be disengaged when not needed.

This machine has a reversing fast power traverse, positive geared feeds with nine changes, and a reversing fast power elevation for the cross-rail, in addition to hand adjustment for the table and rail. One handwheel controls the hand movement of the rail and table, and the lever controlling the direction of the rapid traverse for the table always controls the movement of the cross-rail.

The diameter of the horizontal spindle is 6⅜ inches; side adjustment of the spindle by hand, 12 inches; distance from the center of the spindle to the under side of the cross-rail, 4 inches; independent hand adjustment of the vertical spindle, 9 inches; width of work-table on the working surface, 42 inches; length that can be milled, 12 feet; width between the uprights, 48 inches; maximum distance from the center of the spindle to the top of the work-table, 52 inches.

This machine is driven by a General Electric 50–60-horsepower, shunt motor with a speed range of from 400 to 1200 revolutions per minute.

NEW BRITAIN BENCH POLISHING AND BUFFING MACHINE

The bench polishing and buffing machine shown in Figs. 1 and 2 is driven by an enclosed belt from beneath the bench. One advantage of having the driving belt enclosed is that it does not set up air currents which would carry dust about to the detriment of the worker's health, and the loss, in some instances, of valuable material. This machine, which is built by the New Britain Machine Co., 64 Bigelow St., New Britain, Conn., has been designed to facilitate cleaning, there being plain, smooth surfaces with rounded corners, so that all valuable material that is polished and buffed off can be recovered.

The drive from beneath keeps the spindle down in the bearings, which is said to give a smoother running head than when the pull of the belt holds the spindle against the box cap. The drive from beneath also makes possible a simple means of starting and stopping without any loose pulleys. This is accomplished by swiveling the upper portion of the head which is hinged at the rear and is held by a toggle lever. When the head is lifted by pushing the lever down, as in Fig. 1, the belt is tightened and the spindle set in motion.

Fig. 2. Starting Toggle raised to disengage Belt from Driving Pulley

On the other hand, when the lever is raised, as in Fig. 2, the spindle is dropped onto a brake-block which stops it quickly, and the belt sags away from the driving pulley beneath the bench. The toggle lever is so designed that as the belt tightens, the leverage increases, and, at the end of its downward movement, the toggle becomes self-locking.

The machine is equipped with either a double- or single-end

spindle. The boxes are self-aligning and have a ball section in the center which allows the bearings to adjust themselves, if the shaft is sprung either by heavy belt pull or excessive polishing pressure on the end of the spindle. The spindle is oiled by solid internal collars which dip into the oil and carry it up to the strippers above, which distribute it to each end of the bearings. This collar also serves to take up end motion.

GORTON HEAVY-DUTY CUTTING-OFF MACHINE

The accompanying illustrations show a 16-inch heavy-duty, high-speed cutting-off machine recently built by the George Gorton Machine Co., Racine, Wis. This machine has been under development by the Gorton company during a period of several years, the various details being covered by numerous patents both in the United States and abroad. The special feature of the machine is its great capacity; it will sever round, 30 to 40 point carbon open hearth steel bars, 6 inches in diameter, in thirty seconds, and 12-inch bar can be cut off in one minute; but the working speed recommended is one minute for a 6-inch bar of the material mentioned, other sizes being operated upon in the same proportion.

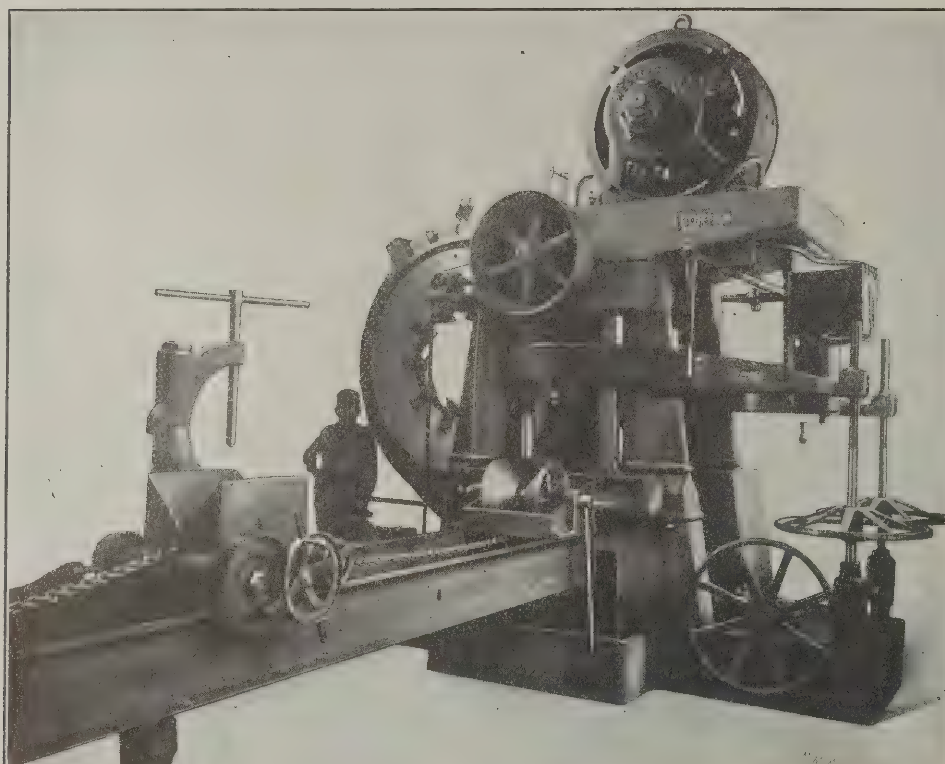

Fig. 1. Gorton Sixteen-inch Cutting-off Machine with Drum raised to provide Access to Cutters

The machine is driven by a 40 H. P. variable-speed motor. The main driving gear is 72 inches in diameter with a 4½-inch face, and is made of semi-steel. It meshes with a main driving pinion, integral with its shaft, made of a crucible steel forging. The diameter of the pinion is 5 inches, and as the cutter points are 10 inches from the center of rotation of the saw drum, this arrangement makes an exceedingly powerful drive. The outside clutch gear, shown in Fig. 3, is 36 inches in diameter and is driven directly from the motor through an intermediate gear as indicated. The cutter travel can be varied from 17 feet per minute up to 51 feet per minute, according to the kind of stock being cut. The cutter blade is ¾ inch thick, and the opening between the cutter points is 20 inches in diameter. To avoid accidental breakage of cutters, the main clutch is provided with a shearing pin which will release the driving mechanism when undue strain is placed upon the cutter. This shearing pin is so located that the cutter is disconnected from all parts of large diameter which continue to revolve until the motor is shut down. This arrangement avoids any flywheel effect which would tend to continue to rotate the cutter after the shearing of the pin.

The stock is fed through the machine by means of a stock carriage, as indicated in Fig. 2. The amount of stock fed may be measured off accurately by means of a measuring bolt. The stock severed is forced on through the V-block at the rear of the machine, indicated in Fig. 3. Simple and powerful clamping arrangements are provided. These may be operated either by hand, or by hydraulic or pneumatic means.

An important feature of this machine, as well as of other Gorton cutting-off machines, is that the cutter blade with its drum is driven through spur gearing, as this means of driving is most economical in power consumption, most durable, and

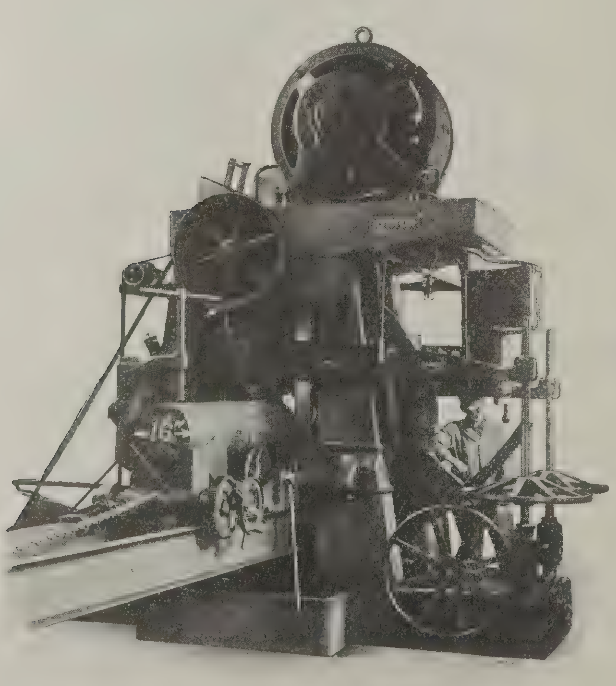

Fig. 2. Cutting-off Machine with Bar in Place ready for Cut

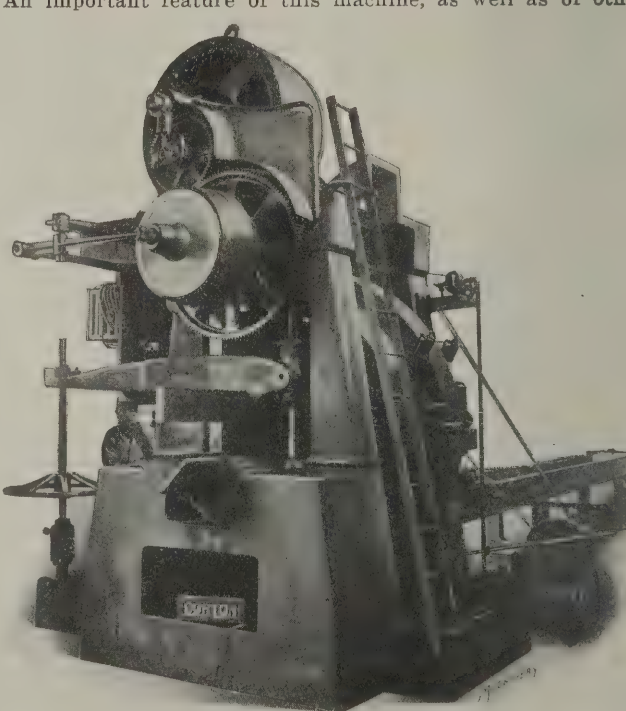

Fig. 3. Rear View of Gorton Cutting-off Machine

least expensive to manufacture and to maintain. The feed is by means of a worm and worm-gear segment.

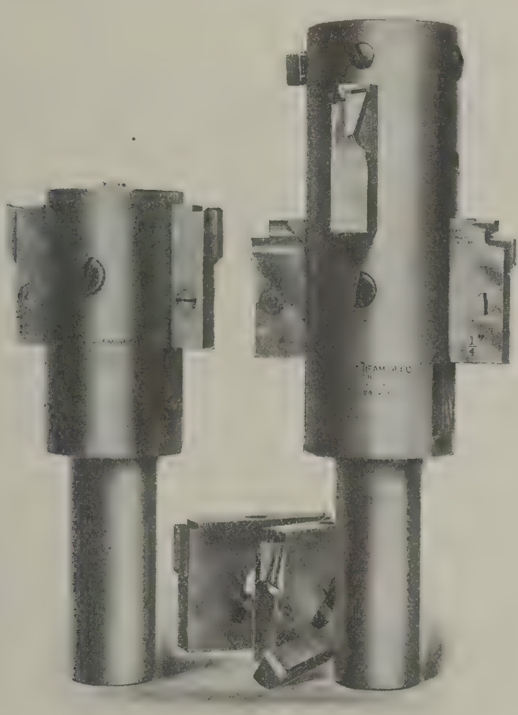
The question of lubrication has been given special attention. The saw drum bearings operate in a flood of oil, and the construction is such that it is impossible for the cutting compound, chips or dirt to enter these bearings. The main pinion bearings, which are 3½ inches in diameter, also operate in a flood of oil. The feed work cases are also flooded with oil, and the main driving clutch is partially so lubricated. A pump is provided for flooding the cutters with lubricating compound when in operation.

The total net weight of the machine, as shown in the illustrations, exclusive of the stock rack, is 55,000 pounds. The total height of the machine, including the motor, is 12 feet, the shipping height, with motor removed, being 9 feet 6 inches. The length of the base on the floor line is 9 feet 6 inches, the width being 7 feet.

KELLY AUTOMOBILE HUB REAMERS

The accompanying illustration shows a boring and reaming outfit for automobile wheel hubs made by the Kelly Reamer Co., Cleveland, Ohio, the tools as shown being especially intended for use on the Jones & Lamson turret lathe. The tool shown to the right is the boring tool used for roughing only, while that shown to the left is the finishing reamer. The tools shown at the bottom, between the shanks of the holders, are exchange-tools used for the small end of the hub.

One of the improvements introduced in these tools as compared with the ordinary design of Kelly reamers, illustrated



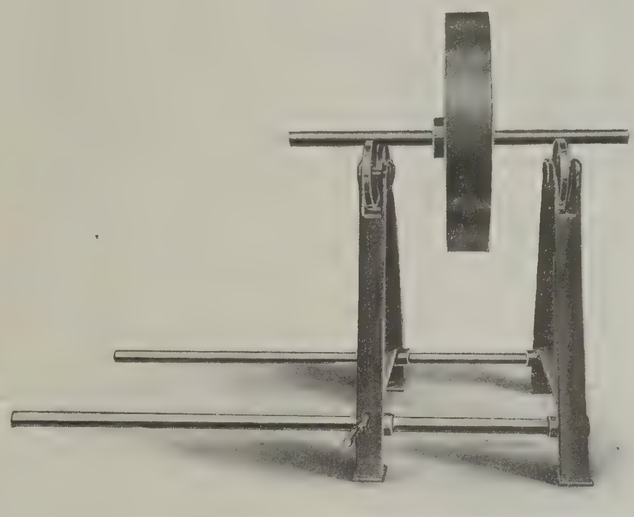
Kelly Roughing and Finishing Reamers for Automobile Wheel Hubs

and described in the July, 1908, number of MACHINERY, is that the reamer blades do not extend outside of the flat reamer holder body in the lengthwise direction. Thus the tools can be easily slid in and out of the holder and rapidly exchanged. This feature is especially valuable for crankcase work, where it is imperative that the boring and reaming be done at one setting of the work, to insure alignment. The special construction then permits the change from boring or roughing reamer bodies to floating finishing reamers to be made rapidly and without difficulty.

TWENTIETH CENTURY BALANCING STAND

The balancing stand shown in the accompanying illustration has been brought out by the Rockford Tool Co., Rockford, Ill., and is designed for balancing pulleys, flywheels, armatures, etc. It will swing wheels 8 feet in diameter, and has a carrying capacity of 5 tons. The distance between the standards is adjustable, the maximum distance being 8 feet and the minimum distance 2 feet. The adjustment is by means of a rack and pinion, the hand-crank shown in the foreground being used for this purpose.

The size of balancing stand shown in the illustration is known as No. 4. Besides this one, four other sizes are built, known as Nos. 1, 2, 2A and 3. Size No. 1 is intended for bench use and is 20 inches between the standards. It will swing 22 inches, and carry a weight of 1000 pounds. No. 2 and 2A both swing 46 inches and have a distance of 30 inches be-



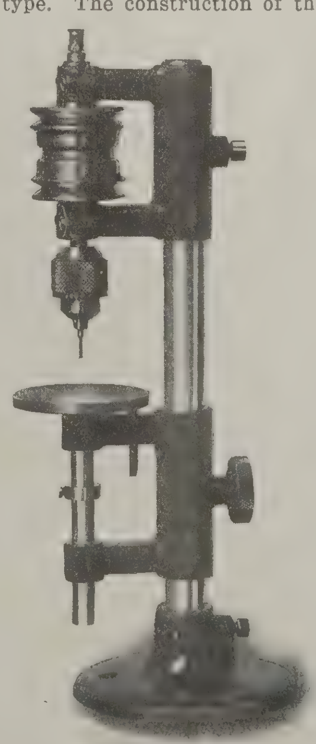
Twentieth Century Balancing Stand, built by the Rockford Tool Co.

tween standards. No. 2 has a carrying capacity of 1000 pounds, while No. 2A will carry one ton. Size No. 3 has a carrying capacity of 2½ tons with a maximum distance of 6 feet between standards, and a swing of 6 feet.

The rotating disks which carry the shaft of the wheel to be balanced run in ball bearings. The disks on stands Nos. 1 and 2 are made from steel, hardened and ground, while the disks on sizes 2A, 3 and 4 are made from chilled cast iron and ground.

ELGIN BENCH TAPPING MACHINE

The Elgin Tool Works, Elgin, Ill., has brought out a new tapping machine of the bench type. The construction of this machine is very simple, as will be seen by referring to the engraving. The two heads which carry the tapping spindle and the work table respectively, are mounted on a vertical column or shaft which can be furnished in different lengths so that holes in the side of a box or frame can be tapped. The tap spindle is driven through a friction clutch interposed between the belt pulleys shown. One of these pulleys carries an open belt, and the other a cross belt for obtaining a reverse movement.



Elgin Bench Tapping Machine

To operate the machine, the work is placed on the table and is lifted up until the tap enters the hole. A stop-collar on the table spindle is set for the required depth, and when this collar comes against the under side of the table bracket, the upward movement is arrested and the tap spindle is drawn downward, thus disengaging the friction clutch from the upper driving pulley. A slight downward pressure then

engages the reversing clutch, and the tap is backed out of the hole.

SANDERSON PORTABLE BORING-BAR

The accompanying illustrations show a portable boring-bar for straight and taper holes, which has been brought out by the Sanderson Tool Sales Co., 438-439 Brown-Marx Bldg., Birmingham, Ala. Fig. 1 shows the general appearance of the tool, while the line engraving, Fig. 2, shows the details of the design. The special features of the boring-bar are that it is readily adjusted, easy to operate, and simple in construction; it can be applied to ordinary drill presses, radial drills, lathes, electric or air motors, and in fact to any machine or appliance having a revolving element.

Fig. 1. Sanderson Portable Boring-bar

The tool consists, as shown in Fig. 2, mainly of a tool carriage *A*, a tool bar guide *D*, and a driving bar *I*. The tool carriage consists of a rack and worm, and a holder with a graduation segment. The rack holds the cutting tool *B* which is inserted at right angles to it at the bottom end. The tool is operated by a star feed at *C*. The rack is guided by the tool bar guide *D* which is dovetailed so as to hold the rack and tool firmly and prevent the tool from chattering or vibrating. Adjustment for different tapers is easily obtained by loosening the nuts *E*, *F* and *G*. If a straight hole is to be bored, the tool is merely set over by means of the nuts and slots to any diameter within the capacity of the bar.

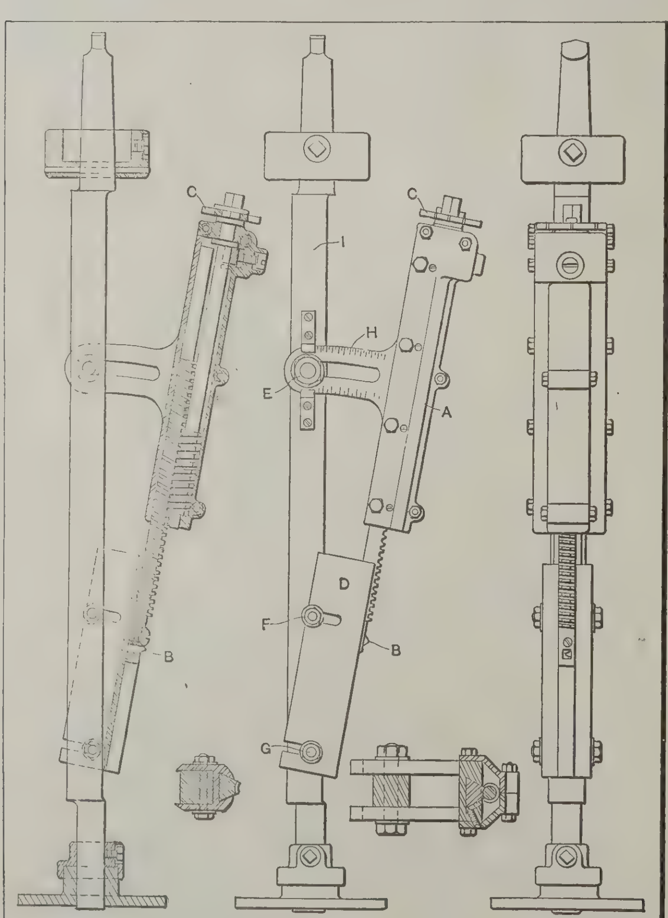


Fig. 2. General Design of Portable Boring-bar for Straight and Taper Holes

The length over-all of the device is 32 inches. The taper shank fits a No. 4 Morse taper socket. The tool has a capacity for boring holes varying from 2½ to 5 inches in diameter, straight or taper, to a depth of 8 inches. The taper adjustment allows tapers up to 6 degrees to be bored. Special bars can be made to take care of holes of other dimensions and tapers.

* * *

NEW MACHINERY AND TOOLS NOTES

Knurling Tool: A. B. Campbell, Fairport, N. Y. Hand-operated knurling tool having three knurls. The part to be knurled is placed in a vise and the tool, which is turned like a die, feeds itself along the surface of the work.

Die-head: Pottstown Machine Co., Pottstown, Pa. Die-head having a machinery steel body and four chasers which are securely held in internal slots, the angle of which conforms to Briggs standard pipe tapers. These heads are made in several sizes having capacities from 1 to 6 inches.

Radial Drilling Machine: Cincinnati Bickford Tool Co., Oakley, Cincinnati, Ohio. Plain radial drilling machine of an improved design. This machine is equipped either with a cone drive, speed-box drive, variable-speed motor drive, or a motor and speed-box drive. All gearing is enclosed and the construction throughout is along modern lines.

Sensitive Drill Press: Francis Reed Co., Worcester, Mass. Sensitive drilling machine which is provided with six spindle speeds. Three speeds are obtained from cone pulleys and this number is doubled by shifting the position of the quarter-turn idler at the top of the column. This idler is controlled by a lever and is automatically locked in position.

Electric Welders: Geuder, Paeschke & Frey Co., Milwaukee, Wis. Automatic electric spot-welders made in four sizes, ranging from 10 to 50 kilowatts capacity. The machine is set in motion by a foot pedal, and all welding operations are entirely automatic. The capacity is from 100 to 200 welds per minute when operating on sheets of from 19 to 31 gage thickness.

Tap Grinder: Wells Bros. Co., Greenfield, Mass. Machine for grinding taps correctly. The tap to be ground is held between centers and it is kept in the proper position by an adjustable spring-finger which regulates the clearance. The grinding is done by a cup wheel. The machine has a self-contained countershaft, and will take taps up to 12 inches in length.

Bench Lathe Attachments: Elgin Tool Works, Elgin, Ill. Auxiliary equipment for the bench lathe, including a filing attachment, two milling attachments and cylindrical and surface grinding attachments. One of the milling attachments has a horizontal spindle carried upon a vertical slide, and the other a vertical spindle which can be set in any desired position.

Turret Lathes: Warner & Swasey Co., Cleveland, Ohio. Hollow hexagon turret lathes of recent design, known as Nos. 2A and 3A machines, respectively. The 2A size has a capacity for bar stock up to 2¼ inches in diameter and, with a chucking outfit, will take castings or forgings 12 inches in diameter. The 3A machine has a capacity for bar stock up to 3¼ inches in diameter and for chuck work up to 15 inches.

Drilling, Boring and Milling Machine: Detrick & Harvey Machine Co., Baltimore, Md. Heavy drilling, boring and milling machine of the horizontal type, having a box-shaped runway on which a large vertical column is mounted. The latter has a traverse of 168 inches and the saddle a vertical movement of 144 inches. Power for traversing the column and saddle is obtained from a 7½-horsepower motor, and the spindle is driven by a 20-horsepower motor.

Drilling Machine Vise: Easton Tool & Machine Co., Easton, Pa. Vise for use on table of drilling machine. The front jaw has a travel of 3½ inches and the rear jaw can be turned to present different sides to the clamping or front jaw. One side of the rear jaw corresponds to the clamping jaw; another side serves as an angle-plate, and the two remaining sides are provided with V-grooves for holding cylindrical work, one groove being vertical and the other horizontal.

Bevel Gear Shaper: Browning Engineering Co., Cleveland, Ohio. Automatic bevel gear shaper having a revolving templet which gives the proper shape to the teeth, so that epicycloidal, involute or any special form of tooth can be cut by providing the proper templet. Twenty-five templets are supplied with the machine. When the shaper is in operation two tools plane opposite sides of the same tooth, alternately, and a gear is finished complete in one revolution of the blank.

Automatic Bevel Gear Shaper: Fred Mill, 622 William Ave., Detroit, Mich. When this shaper is in operation, cuts are taken from first one tooth and then the next, and so on around the blank. The arbor bearing is then moved on its horizontal axis to give a new depth of cut, and the teeth are planed successively as before. This operation is repeated until the teeth are formed to the required depth. The tool is relieved on the backward stroke and all movements are automatic.

Spring Coiling Machine: F. H. Sleeper, 12 Shafner St., Worcester, Mass. Universal coil-making machine which will

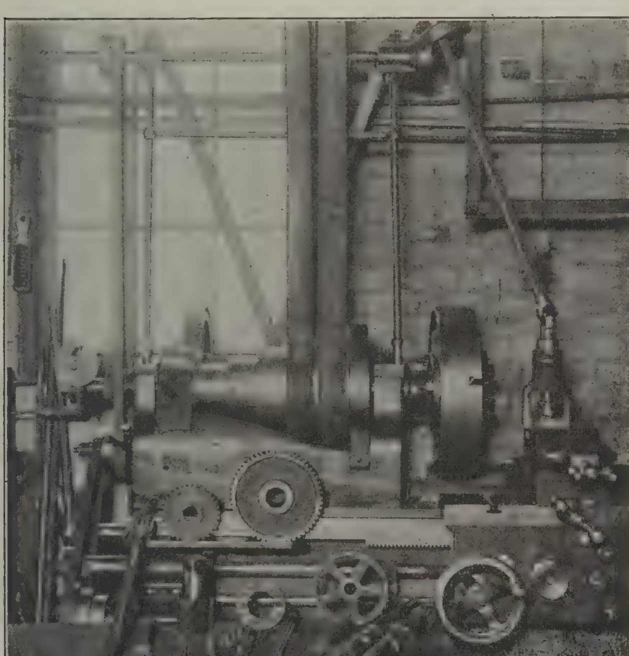
coil and cut springs of various shapes, and has a capacity for diameters varying from ¼ to 2 inches. The wire enters the machine between rolls and it is pushed through guides to the coiling and cutting-off mechanism. The rolls have two grooves for receiving either large or small stock. On the main shaft of the machine there are three cams; one of these varies the diameter of the coil, another gives the pitch or opening between the coils, and the third is for cutting off. The output of this machine varies from 35 to 100 springs per minute.

Inverted Spindle Drilling Machines: Foote-Burt Co., Cleveland, Ohio. One machine is a special design for drilling oil holes ¼ inch in diameter and 8 inches long. It is a 4-spindle inverted type, the spindles projecting through the table and the work being held in the upper heads. When drilling, the heads are fed downward either by hand or power. This company has also built two other machines of the inverted type, each of which has six spindles. One is designed for machining 6-cylinder automobile engine castings, and the other is for drilling long oil holes in cast-iron belt conveyor brackets. One of the advantages of this inverted construction is the absence of overhang and the ease with which chips may be disposed of.

* * *

LATHE MILLING ATTACHMENT

The Haase Machine Works, 411 Fifth Ave., So., Minneapolis, Minn., is manufacturing an attachment for converting a lathe into a milling machine, whenever milling operations can be performed to advantage in connection with turning. This attachment is shown applied to a lathe, in the accompanying illustration. The milling spindle is vertical and is carried by a housing clamped to the toolpost. The drive to the spindle is through a square, universal-jointed shaft connecting through gearing with an overhead countershaft, which, in turn, is driven by a belt from the headstock cone. The feeding movement for the milling cutter is also obtained from the overhead countershaft, which connects by belt with the regular carriage feeding mechanism, as the illustration shows.

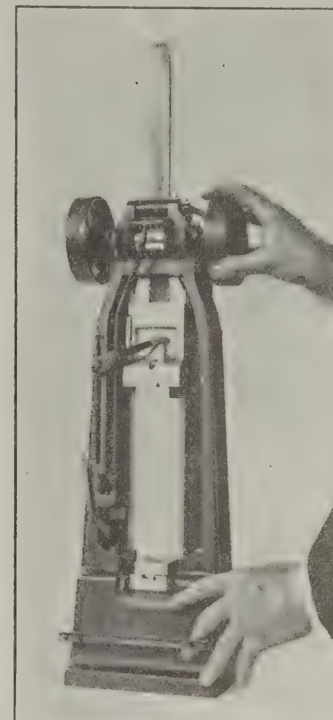


Haase Lathe Milling Attachment

This attachment is intended for cutting teeth in spur and bevel gears, fluting taps and reamers, splining, etc. When the lathe is to be used for milling, the cone pulley is disengaged from the face-gear, so that the spindle remains stationary. The spindle is indexed for gear cutting, fluting, etc., by the index-plate and worm-gearing seen attached to the left-hand end of the spindle. This indexing mechanism is held stationary by the yoke extending from the lathe, and it is expanded in the end of the hollow spindle by a bolt which holds it in position. The overhead driving mechanism for this attachment does not interfere with the regular operation of the lathe, and it can be attached without drilling any holes. The countershaft has, in addition to the two vertical supports, diagonal braces at the rear, which are attached to the back-gear spindle. Some examples of the work done by this milling attachment are shown in front of the lathe in the illustration.

DROP-HAMMER MODEL FOR SALESMEN

When selling or attempting to sell any machine or tool, it is often difficult to make a prospective customer fully appreciate the good points of the design by a verbal description, even though photographs and drawings are used for illustrating the noteworthy features. The Billings & Spencer Co. has adopted a novel plan of using a model in connection with the selling of drop-hammers, for demonstrating the advantages. This miniature drop-hammer, which is illustrated in the accompanying illustration is an exact duplicate of the 3000-pound hammer built by this company. The model only weighs sixteen pounds, whereas the large hammer has a base weighing approximately 5000 pounds and has a height of about twenty feet. This working model is shown to every prospective customer called upon, and it enables the salesman to back up his claims in a very forceful way.



Miniature Drop-hammer used by Billings & Spencer Salesmen

The Billings & Spencer Co. also uses one of these models in the plant at Hartford for instructing new workmen in the proper operation of drop-hammers. This makes it unnecessary to use a large hammer for purposes of instruction.

* * *

PORTABLE MOTOR OUTFIT

The portable motor outfit shown herewith is used in a printing press manufacturing plant for testing presses on the assembling floor. The motor is carried on a four-wheeled truck so that it can be moved about easily, and the starter is mounted on top of the motor, which makes a very compact arrangement.

Reliance Adjustable-speed Motor and Starter mounted on Truck for Testing Printing Presses

A 7½-horsepower Reliance adjustable-speed motor of the armature-shifting type, is used. The motor has a speed range of from 470 to 1880 revolutions per minute, and, in addition, the starter is provided with a special heavy resistance which gives a further speed reduction of 50 per cent for very slow speeds. The main line switch and fuses are mounted on the rear of

the starter. An insulated cable of any desired length may be used for connecting the motor to line plugs at different points about the shop. A similar outfit in another printing press plant is equipped with a flexible shaft and is used for certain boring, drilling and facing operations which can be done to better advantage while the press is being assembled.

* * *

BAR AND CHUCK WORK IN CLEVELAND AUTOMATICS

Automatic and semi-automatic machines are employed at the present time for doing such a large variety of work that a study of the tool equipment used in the production of different machine parts should be of value to the designer and shop man, as well as educational to the builder who is interested in economical manufacturing methods. Fig. 1 of the accompanying illustrations shows three interesting examples of work recently done on some of the machines built by the Cleveland Automatic Machine Co., Cleveland, Ohio.

Sectional and end views of a phosphor-bronze bearing for a gas engine are shown at *A*, and Figs. 2 and 3 illustrate the method of turning this part in a standard model turret machine, which is fitted with a tilting magazine attachment. The part is finished in two operations. The rough castings are taken from the magazine and placed in the chuck by means of conveyer *B*. Fig. 2 shows the position of the turret just after the conveyor has received the casting from the magazine, and Fig. 3 shows the conveyor after it has been indexed in line with the chuck.

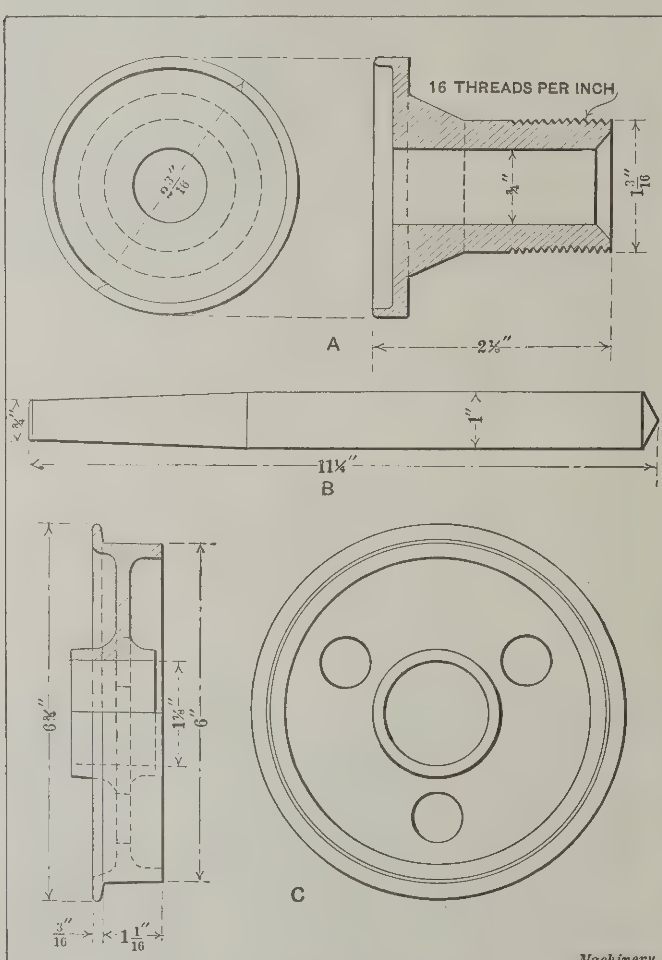


Fig 1. (A) Phosphor-bronze Bearing. (B) High-speed Steel Drill Blank (C) Cast-iron Flanged Wheel

The end of the casting is faced and the hole drilled and chamfered by the tools shown at *C*, which include a three-fluted drill, a chamfering tool for the mouth of the hole and a facing tool for the end. The center turning tool *D* carries a cutter for roughing the taper part next to the flange (see Fig 1), and there is also a cutter for roughing the straight part and a chamfering tool for the corners. These outside roughing operations are performed at the same time that the tools at *C* are in operation, so that six tools are working simultaneously.

Tool *E*, mounted on the tool-block at the rear of the cross-slide, finishes the taper part next to the flange and also the side of the flange. The boring tool *F*, which is mounted in an adjustable tool-holder in the turret, next comes into operation, after which the hole is accurately finished by a floating reamer *G*. While the reaming operation takes place, an overhanging tool which is mounted in the same holder with the reamer finishes the outside diameter of the flange.

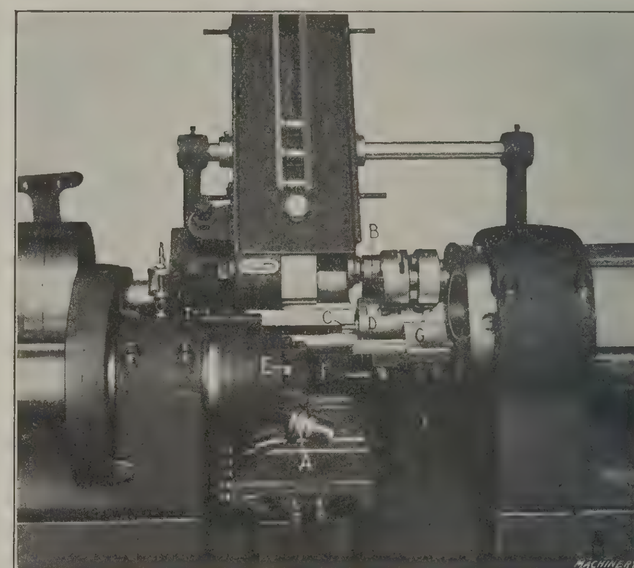

Fig. 2. Cleveland Standard Model Turret Machine equipped with Magazine for Turning Part shown at A, Fig. 1

The thread on the end of the casting is cut by a button die. At the time the thread is being cut the peripheral speed of the work is 59 feet per minute, whereas the speed while the other tools are in operation is 90 feet per minute. This completes the first operation, which requires 2 minutes and 30 seconds.

The second operation is that of recessing the flanged end (see Fig. 1). This work is done on the same machine and with the same magazine, but there is a cross-slide tool held in the turret for finishing the flange and counterbore. The second operation requires 50 seconds, so that the casting is finished complete in 3 minutes and 20 seconds. The rough casting weighs 17 ounces, and the finished piece 9 ounces. The principal dimensions are given in Fig. 1.

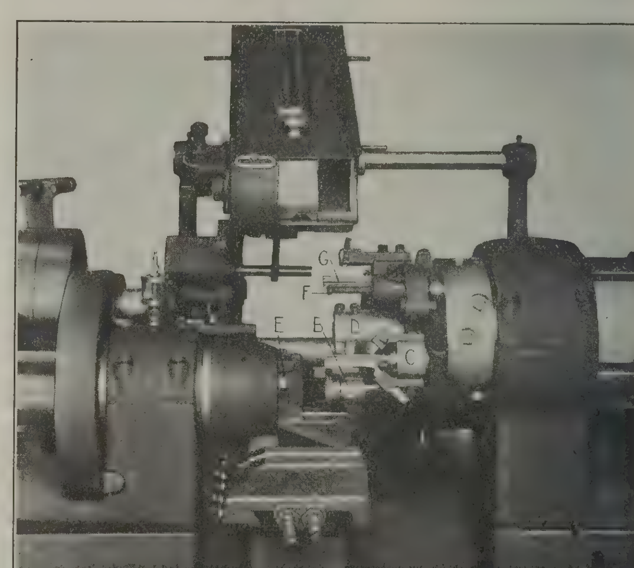

Fig. 3. Conveyor in Position to insert Rough Casting in Chuck

Another example of work done on the automatic is shown at *B*, Fig. 1. This is a high-speed steel drill blank which is finished in 6 minutes 35 seconds. It is 1 inch in diameter, 11¼ inches long and has a No. 3 Morse taper shank. The machine used for this work is a regular plain screw machine which is

cammed double, one drum being used to operate the box turning tool, and the other the longitudinal slide and tool for turning the taper shank.

The bar stock is fed through the spindle against a swinging gage stop; then a roller-rest box-tool *A* (Fig. 4) which is mounted on the tailstock spindle, advances and starts turning the body of the drill blank. On the front cross-slide there is another slide *B* which moves in a longitudinal direction and is set at an angle for turning the taper shank of the drill blank. This slide is operated by the cams *H* and *I* on the large cam drum. These cams control the movement of a sliding guide *D*, which moves independently upon the tailstock spindle and connects with slide *B* by connecting-bar *C*. The tool which turns the taper shank of the drill is shown at *E*. This tool and the box-tool for turning the straight part start and finish their cuts at the same time. The taper shank is considerably shorter than the straight part of the drill blank, so that a slower feed can be used, which is desirable owing to the gradual increase in the depth of the cut. The slide *B* is adjustable so that it can be set for different tapers.

At the rear of the roller-rest box-tool *A* there is a holder carrying another set of steadying rolls and a tool *F* which finishes the point of the drill to the correct angle. A combination tool *G* on the rear of the cross-slide rough-turns the point of the next drill and breaks the corner of the taper shank end of the finished blank as the latter is being cut off. The actual labor cost for producing this drill blank is about 7 mills per blank.

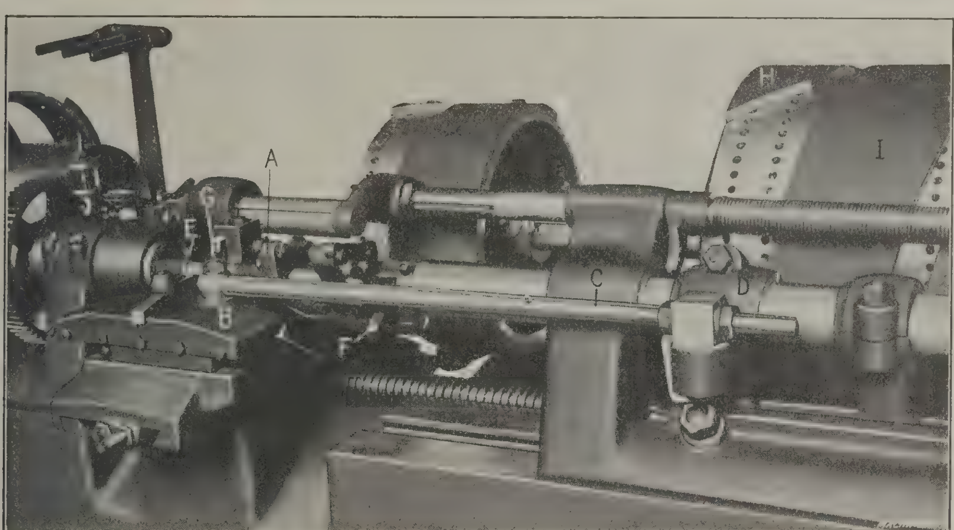

Fig. 4. Cleveland Plain Automatic fitted for Turning Drill Blanks

An example of chuck work is shown at *C*, Fig. 1. This is a cast-iron flanged wheel having a diameter of 6 inches. These wheels are turned in a standard-model, convertible automatic turret machine having a special equipment for this particular job, as illustrated in Fig. 5. The outside of the wheel is turned to within 0.0015 inch of the given size, and because of the accuracy required, a single-pointed tool is used instead of a forming tool, and two cuts are taken. The machine is fitted with a three-jaw universal chuck which has special jaws that engage the three cored holes in the web of the casting. The work is chucked by hand as in any ordinary chucking machine.

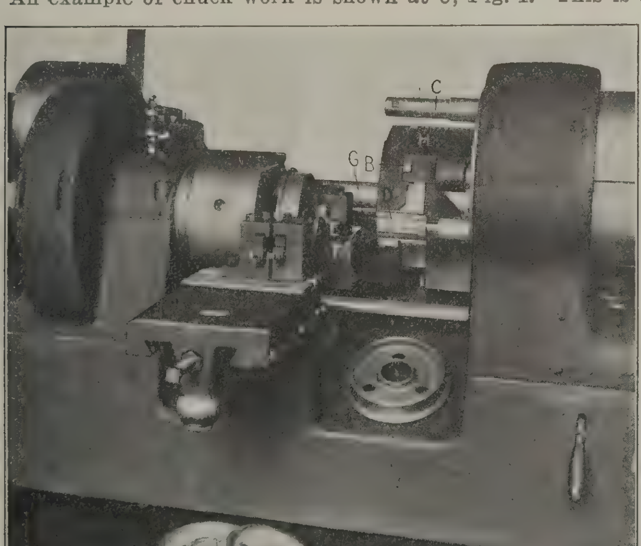

Fig. 5. Cleveland Convertible Automatic Turret Machine having Special Equipment for Turning Flanged Wheel C, Fig. 1

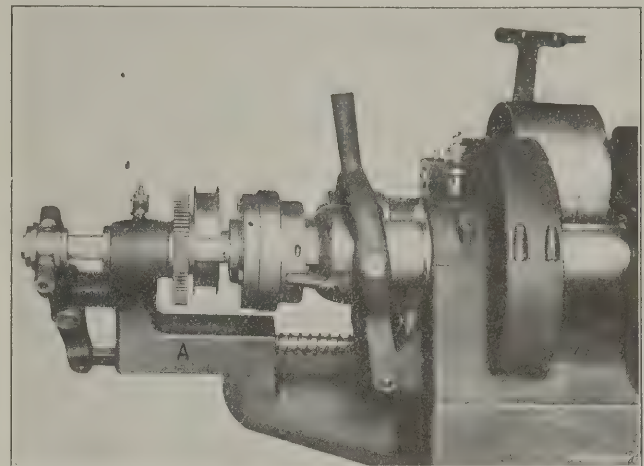

Fig. 6. Driving Mechanism for Boring and Back-facing Attachment

There is a boring and back facing attachment having an independent drive mounted at the left-hand end of the spindle head. The rear end of this bar and the driving mechanism are supported by a framework *A*, as illustrated in Fig. 6. The bar extends through the spindle and, in this particular case, carries a boring tool for roughing and a facing cutter which faces the rear end of the hub. At the same time, tool *B*, which is mounted in the turret, rough-faces the front end of the hub, and a tool on the rear cross-slide rough-turns the outside diameter of the wheel and also the top of the flange, so that five tools are working simultaneously at this time. The outside of the wheel has a peripheral speed of 50 feet per minute, and the boring cutter is operated at the rate of 80 feet per minute by the independent driving mechanism previously referred to. By changing the driving pulley on the countershaft, the speed of the bar can be varied to suit different classes of work.

The next tools which come into operation are the two held in bar *C*, which is mounted in the turret. These are finish-boring and facing cutters. While these cuts are being taken, the spindle speed is increased to give a peripheral speed inside the hole of 80 feet per minute. After the finish-boring cut is taken, the speed is reduced to 50 feet per minute on the outside diameter. The hole is then accurately sized by reamer *D*, and the tread of the wheel is finished by tool *E* on the rear cross-slide. The flange of the wheel is finished by one of the two tools mounted on the front cross-slide, while the other faces the rim of the wheel.

The tools on the rear cross-slide move in a longitudinal direction, and the slide upon which the rear tool-block is mounted can be seen at *F*. The longitudinal movement is obtained by cam drum *H* which imparts motion to the slide through connecting-bar *G*. A bell and stop-motion attachment stops the machine after each piece is completed. One of these castings is finished in 3 minutes 45 seconds. This operation shows the adaptability of this machine for chucking operations, as well as for handling bar work of various kinds.

* * *

Always have all bearing surfaces for nuts or heads of cap-screws spot-faced.

THE ABILITY OF BILL

By A. P. PRESS

Bill came in to see us the other day. Bill was one of our apprentice boys five years ago, and he was noted more for what he didn't do than for what he really accomplished—not but that his ability to turn off work was good enough, but his inherited ability to get clear of doing it was greater still. So putting the two together his abilities seemed to be largely of the last described order.

When Bill came in looking pretty prosperous, and seated himself in the best chair in the office, and took out a fat cigar with a gold band around it, and offered us one of the same brand, we knew that we were right.

"Yes," said Bill, as he got warmed up a little, "I was down to Baltimore one day last week, and as I was strolling around, I wandered into a big machine shop, that had just gone into the assignees' hands. The auctioneer was showing off the machinery in the usual manner, and, of course, I was interested. I did not have any money, but I had on a good suit of clothes, good friends, and a pocket full of these same cigars (which, by the way, are some that my wife gave me at Christmas), pretty good aren't they?

"I was inspecting a big boring mill which was a fine machine, when I noticed a little bunch of buyers over in the corner. When I had sized up the mill, and some of the other large tools pretty well, one of the bunch came over to me."

"Say, Mister, are you interested in this outfit?"

"Sure I am."

"Well, how high do you think you could go?"

"The sky is my limit."

"Now say, stranger, we are making up a little pool on this to buy the whole shop. Do you want to come in?"

"No, I think I had better stick by my lonesome."

"Now see here, that's going to queer the whole thing. What will you take to keep out?"

"Well, I have come quite a ways. I don't like to go home with an empty pocket. What is it worth to you?"

He went back and the bunch got together and back he came.

"Now then if you will keep out of it entirely we will give you an even $500."

"Yes, $500 is all right, but it looks to me as though there was more than $500 in it. Is that cash?"

"No, we will have to give you a check."

"I don't seem to see that. Make it $500 cash and it is a bargain."

Back he went and there was a great taking out of pocketbooks for a few minutes, and then he came back.

"We have got just $450. If you will take it we will make it cash."

"And take it I did," said Bill, "and that is where these good clothes came from, and the vacation too."

Bill has gone, although the flavor of that cigar still lingers in the office, and our opinion of Bill is that he will be noted all his life, not for the things he does, but for the things that others think he is going to do.

And there are others.

* * *

In a paper entitled "The Effect of the Relation of Stroke and Bore in Automobile Engines," presented by Mr. John Wilkinson, before the summer meeting of the Society of Automobile Engineers, at Detroit, June 27-29, 1912, the author stated that as a pure thermal question there is no apparent reason why the stroke to bore ratio cannot be carried up to and even exceed a ratio of 2. In the mechanical design, however, difficulties begin to appear when the ratio exceeds 1.33, and when the ratio exceeds 1.5 the objections become so strong that there appear to be no compensating features for the increase in weight and expense. An excessively long stroke involves too much weight in the valve mechanism. It might, therefore, be fair, according to the author, in placing general limits on the stroke to bore ratio, to say that it is limited in one direction to 1 by the cooling limit of the piston, and in the other direction to 1.5 by the limits of mechanical adaptability.

COLORING ALUMINUM

A process for coloring aluminum is described in the *Brass World*. This process has been patented by S. Axelrod of Oberschoneweide, Germany. It consists in treating the aluminum surfaces with a solution of cobalt nitrate and then heating the object. The heat changes the color of the surface, and gradations ranging all the way from steel gray to brown and finally black may be obtained, according to the temperature to which the article is heated. The salts should be either neutral or alkaline. The aluminum article is dipped in the salt solution, or the solution may be applied with a brush, the salt having been dissolved in water previous to application. The exact temperature to be used is not stated, but it is rather low, as aluminum melts at a comparatively low heat. It is stated that the colors thus produced will not rub or scale off, and that they are permanent. The inventor also claims that zinc, tin and other metals may be colored by cobalt nitrate or other cobalt salts in the same manner.

* * *

During the first week in August, the centenary of the great Krupp works at Essen, Germany, will be celebrated. The celebration will be attended by the Emperor and many other German rulers, military officers, admirals and civil officials. The festivities will be largely military in nature in order to give emphasis to the important part that the Krupp works have played in military and naval armaments. One feature will be a series of sham battles. Men armed with weapons of the era of the Emperor Maximilian will fight with an army equipped with modern rifles and artillery.

PERSONALS

John Bath, designer of the Bath grinder and formerly manager of the Bath Grinder Co., Fitchburg, Mass., has been made sales manager of the Reed-Prentice Co., Worcester, Mass.

Robert H. Lasch has resigned his position of chairman and managing director of the Selson Engineering Co., Ltd., London, England, and Mr. Henry M. Sonnenthal has been appointed in his place.

Ira J. Peat has resigned as assistant foreman of the Simplex Time Recorder Co., Gardner, Mass., to take the position of general superintendent of the Long Mailing Machinery Co., of Minneapolis, Minn.

Edward Rivett of the Rivett Lathe Mfg. Co., Boston, Mass., who sailed for Europe in June, will return in October to resume his duties as president of the reorganized company now known as the Rivett Lathe & Grinder Co.

H. A. S. Howarth, a valued contributor to MACHINERY, who for the past year has been assistant professor of mechanical engineering of the Lehigh University, South Bethlehem, Pa., has been appointed assistant professor of machine design at the Carnegie Technical Schools, Pittsburg, Pa.

Edwin Rust Douglas, mechanical and electrical engineer, has resigned the position of works manager of the Hero Mfg. Co., Philadelphia, Pa., and is now acting as consulting engineer with that company and with David Lupton's Sons Co., and S. L. Allen & Co., all of Philadelphia. Mr. Douglas will be able to serve others also, to a limited extent, in problems concerning manufacturing and factory organization.

Joseph E. Martin, formerly in charge of the estimating and boring mill department of the Bullard Machine Tool Co., Bridgeport, Conn., has resigned his position to take that of superintendent of the Foster Engineering Co., Newark, N. J. Mr. Martin was with the Bullard Machine Tool Co. for eight years. His friends in Bridgeport and associates in the Society of Mechanical Foremen, of which he was president, gave him a farewell reception.

Gilbert H. Pearsall has been made vice-president of the Jacobs-Shupert U. S. Firebox Co., and will be in charge of the Eastern sales office of that company with headquarters at Room 732, 30 Church St., New York City. Mr. Pearsall will retain his position as secretary of Joseph T. Ryerson & Son with which concern he has been identified since May, 1901. He has been in general charge of the sales of the Ryerson company since January 1, 1905. Prior to that connection he held positions in the traffic and transportation departments of several railway companies.

Charles B. Moore has resigned as vice-president of the American Arch Co., and has been elected vice-president of the Jacobs-Shupert U. S. Firebox Co. Mr. Moore will be in charge of the Western sales department of the company with offices in the Railway Exchange Bldg., Chicago, Ill. Mr. Moore organized the Columbia Boiler Co. in 1900 for the

purpose of manufacturing house heating apparatus and boilers. In 1902 he organized the American Locomotive Equipment Co., and was general manager and a director of that company until 1911, when he was elected its president. He assisted in the organization of the American Arch Co. in 1910 and was elected vice-president and a director of that company in 1911. He also organized the Boss Nut Co., of which he is a director. Mr. Moore is the inventor of a number of locomotive devices, the best known of which are his locomotive brick arches.

* * *

COMING EVENTS

August 20.—Annual convention of the International Railroad Master Blacksmiths' Association at Hotel Sherman, Chicago, Ill. J. E. Carrigan, Rutland Railway, Rutland, Vt., chairman of the executive committee.

September 2-7—Sixth congress of the International Association for Testing Materials at the Engineering Societies Building, 29 W. 39th St., New York. H. F. J. Porter, secretary, 1 Madison Ave., New York.

September 9-11.—Ninety-third meeting of the National Association of Cotton Manufacturers at the Griswold, Eastern Point, New London, Conn. C. J. H. Woodbury, secretary, Boston, Mass.

September 24-26.—Annual convention of the American Foundrymen's Association and allied bodies, in Buffalo, N. Y.; Hotel Statler, headquarters. Richard Moldenke, Watchung, N. J., secretary.

September 30-October 4.—Autumn meeting of the Iron and Steel Institute at Leeds, England. G. C. Lloyd, secretary, 28 Victoria St., London.

October 4-26.—International Machinery Exhibition at Olympia, London, England, organized by the Machine Tool and Engineering Association. Ltd.

October 7-11.—Annual convention of the American Electric Railway Association and allied associations in Chicago, Ill. The exhibit will be at Dexter Pavilion, 43d and Halstead Sts. H. C. Donecker, secretary-treasurer, 29 W. 39th St., New York.

SOCIETIES, SCHOOLS AND COLLEGES

Upper Iowa University, Fayette, Iowa. Catalogue for **1911-1912**.

University of New Mexico, Albuquerque, N. M. Catalogue 1911-1912, and announcements for 1912-1913.

Working Men's College, Melbourne, Australia. Prospectus for 1912. Frederick A. Campbell, director.

Louisiana State University, Baton Rouge, La. Catalogue for 1911-1912, and announcements for 1912-1913.

New Mexico School of Mines, Socorro, N. M. Annual Register for 1911-1912 with announcements for 1912-1913.

Delaware College, Newark, Del. Catalogue of the officers and students for the year 1911-1912, and announcements for the year 1912-1913.

University of Utah, Salt Lake City, Utah. Catalogue of students for 1911-1912 and announcements for 1912-1913 in the schools of arts and sciences, education, mines and medicine.

Iowa State College of Agricultural and Mechanic Arts, Ames, Iowa. Directory of graduates of the division of engineering, giving the individual records of between 1100 and 1200 graduates.

NEW BOOKS AND PAMPHLETS

The Polytechnic Engineer. Volume XII, 1912. 129 pages, 6 by 9 inches. Published by the undergraduates of the Polytechnic Institute of Brooklyn.

Personal Efficiency. By Charles Frederick Loweth. 16 pages, 6 by 9 inches. Published by the University of Illinois, Urbana, Ill., as No. 5 of the College of Engineering Series.

Organization in Engineering. By Henry Marison Byllesby. 14 pages, 6 by 9 inches. Published by the University of Illinois, Urbana, Ill., as No. 4 of the College of Engineering Series.

Molding Concrete Fountains and Lawn Ornaments. By A. A. Houghton. 56 pages, 5 by 7⅜ inches. 14 illustrations. Published by Norman W. Henley & Son, New York. Price 50 cents.

Molding Concrete Flower Pots, Boxes, Jardinieres, etc. By A. A. Houghton. 52 pages, 5 by 7¾ inches. 7 illustrations. Published by Norman W. Henley & Son, New York. Price 50 cents.

Report of the Commissioner of Education for the Year ended June 30, 1911. Vol. I. 675 pages, 6 by 9 inches. Published by the Bureau of Education of the United States, Washington, D. C.

A Rapid Method for the Determination of Vanadium in Steels, Ores, etc. Published by the Department of Commerce and Labor, Washington, D. C., as No. 8 of the Technologic Papers of the Bureau of Standards.

On the Measurement and Division of Water. By L. G. Carpenter. 48 pages, 6 by 9 inches. Illustrated. Published by the Agricultural Experiment Station of the Colorado Agricultural College, Fort Collins, Col., as Bulletin No. 150.

Conference Committee Methods in Handling Railway Legislation on Mechanical Matters. By Charles Arthur Seley. 15 pages, 6 by 9 inches. Published by the University of Illinois, Urbana, Ill., as No. 2 of the College of Engineering Series.

A New Analysis of the Cylinder Performance of Reciprocating Engines. By Paul Clayton. 104 pages, 6 by 9 inches. Illustrated. Published by the University of Illinois Engineering Experiment Station, Urbana, Ill., as Bulletin No. 58.

The Strength of Reinforced Concrete Beams; Results of Tests of 333 Beams. By Richard L. Humphrey and Louis H. Losse. Published by the Department of Commerce and Labor, Washington, D. C., as No. 2 of the Technologic Papers of the Bureau of Standards.

The Effect of Added Fatty and Other Oils Upon the Carbonization of Mineral Lubricating Oils. By C. E. Waters. Published by the Department of Commerce and Labor of Washington, D. C., as No. 4 of the Technologic Papers of the Bureau of Standards.

Tests of the Absorptive and Permeable Properties of Portland Cement, Mortars and Concrete, together with Tests of Damp-Proofing and Water-Proofing Compounds and Materials. By Rudolph J. Wig and P. H. Bates. Published by the Department of Commerce and Labor, Washington, D. C., as No. 3 of the Technologic Papers of the Bureau of Standards.

Lectures Delivered at the Centenary Celebration of the First Commercial Gas Company, to sell Gas as an Illuminant. 174 pages, 6 by 9 inches. Illustrated. Published by the American Gas Institute, 29 W. 39th St., New York.

This interesting series of lectures is prefaced with the chronology of the development of gas lighting, beginning 1450 B. C. The importance of gas as an illuminant and fuel, and the growing importance of producer gas in the industrial field, makes this series of lectures of historical and commercial value.

Analysis of Metallurgical and Engineering Materials. By Henry Wysor. 82 pages, 8½ by 10½ inches. Published by the Chemical Publishing Co., Easton, Pa. Price, $2.

This manual, which is the outcome of an effort to raise the efficiency of the students' work in the laboratory, is a systematic arrangement of laboratory methods, compiled by the assistant professor of analytical chemistry and metallurgy in Lafayette College. Each page of text is accompanied by a blank page for the insertion of notes and data by the user. The condensed, step-by-step directions for making analyses should be appreciated by all chemists and students of chemistry.

The Effects of Cold Weather upon Train Resistance and Tonnage Rating. By Edward C. Schmidt and F. W. Marquis. 24 pages, 6 by 9 inches. Published by the University of Illinois Engineering Experiment Station, Urbana, Ill., as Bulletin No. 59.

The bulletin presents the results of tests made to determine the amount of increase in train resistance in cold weather, and the tests show that even in moderately cold weather there is a very definite increase in train resistance over the resistance which prevails at air temperatures above 30 to 40 degrees F. This increased resistance is chiefly due to the lower temperatures of the car journals, and the tests show that the temperature rises very slowly, requiring twelve to fifteen miles travel from the starting point before the resistance has reached its minimum value.

Modern Illumination, Theory and Practice. By Henry C. Horstman and Victor H. Tousley. 273 pages, 4⅝ by 6¾ inches. Published by Frederick J. Drake & Co., Michigan Ave., Chicago, Ill. Price $2.

This is a handbook of practical information for users of electric light, contractors, electricians, etc. It treats of light, principles of vision, reflection, refraction and diffusion, photometry, calculation of flux from photometric curves, illumination calculations, characteristics of electric illuminants, shades and reflectors, location and height of lamps, color of light, choice of lamps, choice of fixtures, indirect lighting, practical considerations, table of intensities in foot candle for various classes of service, plans and specifications, illumination tables, incandescent light wiring and other tables, glossary of terms and phrases, etc.

Engineering Valuation of Public Utilities and Factories. By Horatio A. Foster. 345 pages, 6 by 9 inches. Published by D. Van Nostrand Co., New York. Price, $3 net.

The demand for information regarding the valuation of public utilities has been growing rapidly during the last few years mainly because, with the increase in supervision of public utilities by commissions which require valuations of properties when permission is asked to change rates or to add to securities for any purpose, engineers have extended their field of activity to include problems of ratemaking. This fact and the public demand that corporations shall receive a fair return on the fair value only of their properties, make it important that those in charge of appraisals shall be familiar with the elements which courts and commissions will consider in passing upon the merits of a valuation. The investigation leading to a decision as to a satisfactory schedule of rates requires the services of a technical expert. Mr. Foster, who has been extensively engaged in appraisals, has produced an excellent work on a subject which is now of broad public importance. After a short discussion of "value," the purposes of its determination, and the directions for obtaining it, an important court opinion by Judge Savage of Maine is given in full, as embodying the best instructions for valuation yet pronounced. An excellent feature of the book is the compilation of forms to be used in making an appraisal, and there are included also extended depreciation tables at various percentages and for various terms of usefulness, which will be found of much service in making valuations. After a short chapter devoted to the cost of appraising a property, the value of "good will" and "going concern value" are defined and discussed, and the opinions of commissions, courts, and individuals are given at some length. Considerable space is devoted to the subject of depreciation, which, like the author's treatment of "intangible value," contains a number of original views. The chapters on amortization, handling of depreciation, and appreciation are interesting. The study of the court decisions as to franchises should go far toward elucidating this complex subject. A clear discussion of capitalization and the control of public utilities follows, and the book closes with copies of some of the decisions of the courts and the syllabuses of a large number of others. In one volume are thus brought together the gist of virtually all important rulings bearing on the subject of valuations, so that not only the engineer but the layman may learn their application in any given case. Mr. Foster's work is distinctly of value.

The Human Factor in Works Management. By James Hartness. 159 pages, 6 by 9 inches. Published by McGraw-Hill Book Co., New York. Price $1.50 net.

The views on works management of a manufacturer who is a mechanic and inventor, and the president of a well-known and highly successful concern would attract attention, and when those views are on the neglected human factor element, they become extraordinarily interesting. This work by Mr. Hartness sets forth some of the essential principles of industrial economics as represented by his experience and that of many who regard some of the theories of scientific management laid down by its leading exponents with doubt and misgivings. In the discussion of habit the idea is brought out that success depends more on the man than the plan, and that systems are but a means and not the end. Repetition forms habit, and is necessary for success. Contrary to the popular idea, repetition does not degrade, but simplifies and makes work easy. The mere size of an organization does not give it strength; but whether the organization is large or small the advantage lies with that one in which each operation is repeated the most times per individual. Skill is due to continued application. A lathe hand does the most and best work with his own lathe and tools under the conditions with which he has become familiar. But there are all kinds of minds, and not all have the same ambitions and aspirations. There is often lack of sympathy and understanding between those who would lift the masses to what they conceive to be a better plane of thought and living. Inertia of habit and consequent dislike of change of methods is characteristic of workers generally. When the conditions of work are such that methods must be continually changed, inefficiency results. The notorious inefficiency of plumbers on repair work is attributed by the author largely to the strange surroundings of each job and the new conditions that must be met. To make a business pay in the long run, it must be conducted so as to build up those conditions most conducive to the well-being of the workers as a whole; hence the folly of trying to "make a business pay" from the financial side alone. Space will not permit quoting or paraphrasing many more interesting statements bearing on the human factor element in business. The chapters "Some of the Non-Technical Phases of Machine Design" and "Machine Building for Profit." deal with some of the intangibilities of manufacturing. Courage to

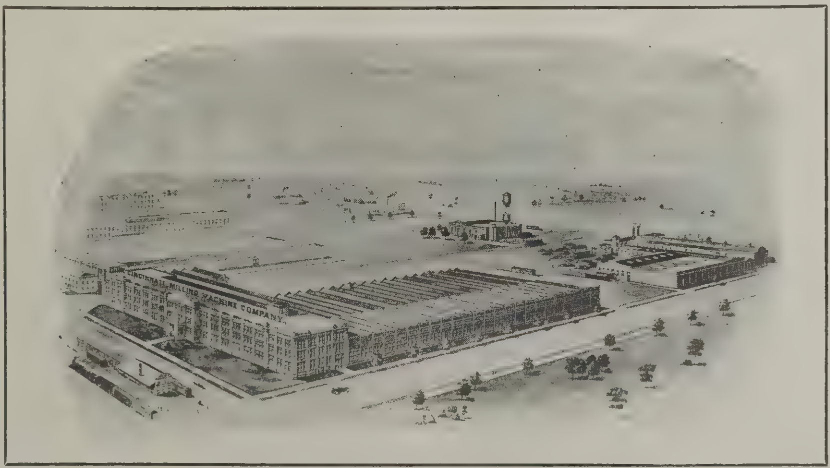
COME AND SEE OUR NEW PLANT

SOME OF OUR VISITORS

This is part of a group of Superintendents and Foremen who made a trip from Chicago especially to see our new plant. When are you coming? It will pay you to visit us, because you will see one of the most up-to-date machine tool plants in the world. It contains more than 6¼ acres of floor space. The buildings have all been constructed to provide as nearly as possible ideal conditions as to lighting, heating, ventilation, sanitation and the routing of materials. We would like to show you how we accomplish these things.

Our equipment includes many special machines for individual operations requiring a high degree of accuracy and special devices for manufacturing in large quantities. Our advanced foundry practice produces iron castings of the highest quality for the service required of each important part of our machines.

These are some of the things that make it possible for us to supply you with Milling Machines of the highest quality in all particulars.



THE PLANT DRAWN TO AN EXACT SCALE

The Cincinnati Milling Machine Company

Cincinnati, Ohio, U. S. A.

EUROPEAN AGENTS—Alfred H. Schutte, Cologne, Berlin, Brussels, Milan, Paris and Barcelona. Donauwerk Ernst Krause & Co., Vienna, Budapest and Prague. Sam Lagerlofs, Stockholm, Sweden. Axel Christiernsson, Abo, Finland. Chas. Churchill & Co., London, Birmingham, Manchester. Newcastle-on-Tyne and Glasgow. CANADA AGENT—H. W. Petrie, Limited, Toronto, Montreal and Vancouver. AUSTRALIAN AGENTS—Thos. McPherson & Son, Melbourne. JAPAN AGENTS—Andrews & George, Yokohama. CUBA AGENT—Krajewski-Pesant Co., Havana. ARGENTINE AGENTS—Robert Pusterla & Co., Buenos Ayres.

discard is as desirable as courage to accept and use. The hero of the drafting-board is the one not afraid to use the eraser, and the hero manufacturer is he who sticks to one thing and makes it successful. The weakness of many concerns and a prolific cause of failure is a constantly changing policy and product. The tendency of individuals to be jacks-of-all-trades is exemplified by manufacturers who will not concentrate on one line long enough to become proficient in its production. "The manufacturer of a great variety of machines in response to a demand by the selling organization is a relic of other days", expresses the perception of the author. His own experience has amply demonstrated the value of developing a specialty and then sticking to it. The book is full of interest and value for manufacturers and students of industrial economics.

NEW CATALOGUES AND CIRCULARS

GREEN FUEL ECONOMIZER Co., Matteawan, N. Y. Catalogue No. 142 on the Green boiler economizers.

INTERNATIONAL GAS ENGINE Co., Cudahy, Wis. Catalogue No. 12 of "Ingeco" engines operating on gas, gasoline, oil and producer gas.

J. FAESSLER MFG. Co., Moberly, Mo. Bulletin No. 28 illustrating and describing "Faessler" safety sectional boiler tool expander with quick-acting knockout.

SANDERSON TOOL SALES Co., Brown Marx Bldg., Birmingham, Ala. Circular of Sanderson adjustable portable boring-bar for boring straight and taper holes.

C. W. HUNT Co., West New Brighton, N. Y. Catalogue No. 12-1 on industrial narrow gage railways for handling raw and finished materials in foundries, iron mills, power plants, factories, etc.

CHICAGO PNEUMATIC TOOL Co., 1010 Fisher Bldg., Chicago, Ill. Instruction booklet for operating the "Little Giant" car, containing directions for the operation of gasoline engines and motor cars.

WESTINGHOUSE ELECTRIC & MFG. Co., E. Pittsburg, Pa. Circulars 1516, on Baldwin-Westinghouse Electric Locomotives; 1155, on Series Arc Lighting Systems, with Westinghouse Cooper-Hewitt Rectifiers.

WATSON-STILLMAN Co., 192 Fulton St., New York. Catalogue No. 85 on hydro-pneumatic wheel presses, listing and describing over seventy variations in types and sizes of from 60 to 600 tons capacity.

ELECTRIC CONTROLLER & MFG. Co., Cleveland, Ohio. Bulletins 1022 on Automatic Motor Starters for Non-Reversing Direct-Current Motors; 1023, on Type A Knife Switches; and 1024, on Type MC Solenoids.

JOSEPH DIXON CRUCIBLE Co., Jersey City, N. J. Booklet entitled "Painting the Smokestack," setting forth the qualities of Dixon's silica-graphite paint that meet the trying service demanded of a smokestack paint.

CROCKER-WHEELER Co., Ampere, N. J. Bulletin No. 151 on "Remek" distributing transformers. The bulletin is well printed on pebbled paper which brings out very clearly the characteristics of the halftone illustrations.

FORT WAYNE ENGINEERING & MFG. Co., Fort Wayne, Ind. Circular of Paul pumping machinery, air compressors, water supply systems, suction pressure systems, deep well pressure systems and pneumatic displacement systems.

BECKER MILLING MACHINE Co., Hyde Park, Mass. Catalogue of carbon and high-speed steel standard cutters, form cutters, hobs for spur and spiral gears, saws, shell end-mills, T-slot cutters, arbors, spring collets, inserted tooth cutters, etc.

FOSDICK MACHINE TOOL Co., Cincinnati, Ohio. Circular illustrating and describing new style 2½-foot and 3-foot National radial drills having back gears and tapping attachment, and adapted for belt, variable speed motor or constant speed motor drives.

F. B. SHUSTER Co., New Haven, Conn. Catalogue of automatic wire straightening and cutting machinery and sheet metal straightening and cutting machinery for straightening and cutting wire and sheet metal to exact lengths from the coil; elastic blow riveting machines; etc.

THOMAS H. DALLETT Co., York and 23rd Sts., Philadelphia, Pa. Bulletin No. 304 describing the Dallett pneumatic wood carving tools. These tools are useful in any branch of the woodworking industry where gouging, roughing and carving work of any description is being done in the usual manner with hand chisels.

AMERICAN VANADIUM Co., 325 Vanadium Bldg., Pittsburg, Pa. Pamphlet on vanadium steels and classification of heat-treatment with directions for application to iron and steel. This valuable treatise should be of great interest to all concerned with the use of steels required to withstand repeated shocks without crystallization.

MONTGOMERY & Co., 105-107 Fulton St., New York. Price list of Grobet Swiss files, illustrated. These are the original Swiss files made by F. L. Grobet, the business of which was originated over 100 years ago. The catalogue shows a large variety of toolmakers' files, and should be in the hands of everyone ordering fine files.

LAMSON CONSOLIDATED STORE SERVICE Co., Boston, Mass. Bulletins of pneumatic tubes, wire cash carriers, cable cash carriers, parcel carriers, message carriers, pickup carriers, sweep-off carriers, selective carriers, tray conveyors, library conveyors, mail conveyors, belt conveyors, special conveyors, small lifts, and light elevators.

GENERAL ELECTRIC Co., Schenectady, N. Y. Bulletins 4953, Large Shell Type Transformers; 4959, The Electrical Operation of Railroad Shops; 4960, Lightning Arresters for Electric Railways; 4962, Electric Power in the Lumber Industry; 4963, Small Direct and Alternating Current Motors Drawn Shell Type; and 4966, Hydro-Electric Power Development.

INDUSTRIAL INSTRUMENT Co., Foxboro, Mass. Bulletin No. 65, of Foxboro improved recording gages, listing nearly 2000 ranges in three sizes covering all purposes and pressures from full vacuum to 10,000 pounds per square inch. Lists are arranged to facilitate quick and easy selection of instruments, and each instrument is assigned a code word for convenience in identification.

UNITED STEEL Co., Canton, Ohio. Booklet on vanadium steel, giving the results of tests on chrome-vanadium steel, demonstrating that this steel has unusually valuable properties. Illustrations show the results of tests on springs, gears, axles, bars, etc. The company is a pioneer in the manufacture of chrome-vanadium steel, and has specialized in its production ever since its introduction.

VANADIUM-ALLOYS STEEL Co., Latrobe, Pa. Booklet on vanadium steel for all purposes, giving characteristics of "Red-cut" high-speed steels; price list of "Red-cut" disks suitable for milling cutters, and information on "Vasco" special steel, etc. The general effect of vanadium on steel is discussed, and, altogether, the booklet will be found of much interest to users of steels.

KELLY REAMER Co., 1547-65 Columbus Road, Cleveland, Ohio. Catalogue of Kelly adjustable reamers, with high-speed steel blades, for boring automobile cylinders, connecting-rods, jigs and all holes requiring accuracy and smoothness of finish. The Kelly reamer has floating cutters which compensate for errors of alignment by "floating" to the center of holes previously bored true.

WATSON-STILLMAN Co., 192 Fulton St., New York. Catalogue No. 86 on the Chambersburg throttle valve, which is claimed to be superior to the ordinary throttle valve in the following particulars: single seat; regrind without removal; no lost motion; internal boiler inspection without removal; provision of inlet for steam at highest point in dome; perfect balance; easy operation; screw or lever control.

FORT WAYNE ELECTRIC WORKS OF GENERAL ELECTRIC Co., 1616 Broadway, Fort Wayne, Ind. Bulletins 1140, on Single-Phase Repulsion Induction Motors, Type SR; 1137, on Belt-Driven Revolving Field Alternators, Form B; 1136, Direct-Connected Type MPL Direct-Current Generators; 1139, on Motor Drives; also instruction book No. 3053 on Multi-Phase Revolving Field AC Generators and Belted Exciters.

JOSEPH DIXON CRUCIBLE Co., Jersey City, N. J. Circular on graphite products comprising flake graphite, heavy graphite, machine greases, waterproof graphite grease, "Graphitoleo," "Everlasting" axle grease, pipe joint compound, traction belt dressing and leather preservative, solid belt dressing, automobile lubricants, silica-graphite paint, stove cement, plumbago crucibles, graphite brushes for motors and generators, etc.

TREADWELL ENGINEERING Co., Easton, Pa. Colored card illustrating the coloring of patterns to indicate finished surfaces, rough surfaces and core prints. The standard colors adopted are those recommended at a joint meeting of the Steel Founders' Society and the American Society for Testing Materials, for use on patterns in steel foundries, and are: red for finished surfaces, yellow for rough surfaces, and black for core prints.

CURTIS & CURTIS Co., 8 Garden St., Bridgeport, Conn. Catalogue of Forbes patent pipe cutting and threading machinery for hand, belt, or electric power. The catalogue is a very complete production, giving full data on all of the many sizes and styles of portable machines built. The largest machine cuts off and threads pipe from 2½ to 12 inches diameter, and its approximate net weight is 3650 pounds, while the smallest is adapted for ¼-inch to 2-inch pipe, and weighs 155 pounds.

GOULD & EBERHARDT, Newark, N. J. Catalogue of high-duty shapers and attachments, illustrating details of construction and giving full data of 14-inch, 16-inch, 20-inch, 24-inch and 34-inch sizes. These shapers are regularly furnished with four-step cone pulleys and are also provided with electric motor drive for either direct or alternating current. A large variety of shaper attachments is illustrated, including tilting base for shaper vises, circular or cone mandrel, automatic vertical feed, traverse head, index centers, circular table, concave attachment, convex attachment, auxiliary front cross feed, etc.

NATIONAL TUBE Co., Frick Bldg., Pittsburg, Pa. Booklet entitled "The Modern Boiler Tube," containing the story of its evolution and development and some expert opinions on its efficiency. The booklet is a valuable contribution to the literature on boiler tubes, briefly tracing their development since the patent of Henry Osborn of Birmingham was granted in 1812 for the manufacture of gun barrels by bending wrought-iron plates over a circular and tapered mandrel and welding the heated metal under a tilt hammer. Illustrations show the tests applied by the National Tube Co. to boiler tubes, and the data of tests supplied by the American Society for Testing Materials are included.

TRADE NOTES

REED-PRENTICE Co., Worcester, Mass., requests manufacturers' catalogues for the Prentice Bros. department, 667 Cambridge St.

BLAKESLEE FORGING Co., Plantsville, Conn., is about to erect a three-story machine shop, 30 by 160 feet, and a forge shop 220 by 50 feet; also an annealing room 32 by 76 feet.

TATE-JONES & Co., INC., Empire Bldg., Pittsburg, Pa., report that orders were recently received for large oil burning furnaces from the Falls Hollow Staybolt Co., of Cuyahoga Falls, Ohio, and the Pennsylvania Steel Co., of Steelton, Pa.

TAYLOR IRON & STEEL Co., High Bridge, N. J., has opened an office in Pittsburg at 301 Oliver Bldg., in charge of Mr. James S. Morrison. The office was opened to meet the increased demand for manganese steel castings in Pittsburg and vicinity.

RHINELAND MACHINE WORKS Co., 140 W. 42nd St., New York, will open a place of business in Cologne or Frankfort, Germany, in the near future for the purpose of selling American machinery and tools and other manufactured products. The company is interested particularly in articles which will be used by manufacturers in general, and especially patented devices.

W. M. PATTISON SUPPLY Co., 197-211 St. Clair Ave., Cleveland, Ohio, has purchased the real estate, buildings, factory and power equipment of the Long Arm System Co., of Cleveland, manufacturers of automobile engines, transmissions, axles, gears, etc. The factory equipment consists of 205 machine tools, 10 furnaces, 21 motors and a large assortment of smaller tools which will probably be offered in lots to suit purchasers.

H. W. JOHNS-MANVILLE Co., Madison Ave. and 41st St., New York, has applied the J-N "Line-O-Lite" electric light lamps with much success to showcases in hardware stores, especially those containing machinists' tools, cutters and other tools requiring bright illumination to bring out their characteristics. The "Line-O-Lite" lamp is made in tubular form, twelve inches long, which shape makes it a good light distributor, yet easily concealed.

TATE-JONES & Co., INC., Pittsburg, Pa., report that the Massillon Bridge & Structural Co., Massillon, Ohio, has placed an order with them for a complete oil burning furnace equipment for a new plant. The placing of this order is the result of long-continued and satisfactory use of Tate-Jones & Co's. furnaces by some of the officers of the Massillon Co., while connected with another bridge plant for which Tate-Jones & Co., Inc., installed furnaces several years ago.

HESS-BRIGHT MFG. Co., Philadelphia, Pa., has transferred its offices to its new factory at 17 E. Erie Ave. The old quarters at 21st and Fairmount Aves. have for the past two years been inadequate for the rapidly growing business of the company, and the new site, which covers about thirteen acres, affords ample room for a much-needed expansion. The factory buildings are one-story high and embody the most advanced ideas on modern factory arrangement and construction.

ALLEN MFG. Co., INC., 135 Sheldon St., Hartford, Conn., has moved into the old Henry & Wright Mfg. Co's. plant in order to be able to care for its rapidly growing business of manufacturing the Allen safety set-screw. The company has established a Canadian branch at 29 St. David's Lane, Montreal, Canada, which will manufacture safety set-screws for the Canadian trade. Safety set-screws are now made for lathe dogs, and special safety screws will be made to order from ¼ inch to 1 inch diameter.

WARNER & SWASEY Co., Cleveland, Ohio, has filed an application for an increase of capital stock from $500,000 to $1,000,000. The increase of capital is to be provided for making an extension of the company's business. During the past three years the company has doubled the capacity of the plant, and is now contemplating the construction of an additional building on the east side of its present structure. The new building will be used largely for shipping and storage purposes. The officers of the company are Ambrose Swasey, president; Worcester R. Warner, vice-president; and Frank A. Scott, secretary and treasurer.

MACHINERY

Railway Edition for Locomotive Construction and Repair Shops

SEPTEMBER, 1912

MACHINING A LOCOMOTIVE CROSSHEAD*

BY FRANKLIN D. JONES†

IN the construction of any piece of machinery or part of a machine there are usually several ways of obtaining the same result. To illustrate, a casting or forging that requires boring, turning and planing can, in some instances, be bored or turned prior to planing, and *vice versa*, it being possible to vary the order of the operations. There is one way, however, which is the best, and this is usually not only the easiest and quickest way, but the one which gives the most accurate results. To determine just what order should be followed when a number of different machining operations are required is often the most difficult part of the work. Accompanying this article there are a number of views which show how a locomotive crosshead of the "alligator" type is machined. None of the operations is especially difficult, but the successive order in which they are performed is well worth studying, especially by the apprentice or machinist who has had little or no experience in general machine work. These views were taken in the Pennsylvania Railroad's large locomotive shops at Altoona, Pa.

Fig. 1. Reaming a Crosshead in Horizontal Boring Machine

Fig. 2. Turning End of Crosshead

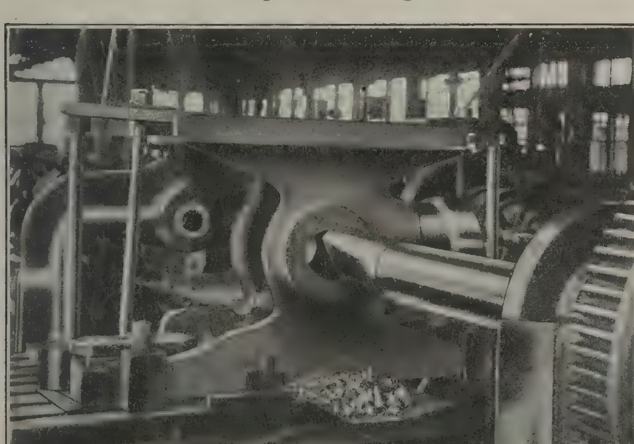


Fig 3. Drilling Wrist-pin Hole

Fig. 4. Drilling Key-slot

Before beginning a job of this kind the relation between the various finished surfaces should be carefully considered in order to determine the best method of starting the work and the successive order of the operations. The machine work includes boring taper holes for the piston-rod and wrist-pin, planing the bearing surfaces for the guides, planing the sides of the crosshead, turning the cylindrical end or "barrel," and cutting the slot for the piston-rod key. The principal requirements, in this case, are as follows: The axes of the piston-rod and wrist-pin holes should be at right-angles to each other; the axis of the piston-rod hole should be parallel to the guide bearing surfaces, as well as the flanges or sides, and the wrist-pin hole should also be parallel to the guide bearing surfaces.

Before the crosshead is machined, center lines are laid off on the ends, as indicated at *A*, Fig. 1. These center lines are used for setting the rough casting prior to boring the piston-rod hole, and they also serve as central points to work from when planing the guide bearing surfaces. The first machining operation is that of boring and reaming the taper hole for the piston-rod. A horizontal boring machine is used for this work, and the crosshead is clamped to the table with the cylindrical end or "barrel" toward the spindle, as shown in Fig. 1.

The latest practice is to bore this hole from the solid metal, although formerly a 2-inch hole was cored in the casting. Recent specifications require the ends of all crossheads to be cast solid, to insure castings free from shrinkage cracks and blow-holes, although the solid castings are, of course, more expensive to machine, as it is necessary to drill out the hole which was formerly cored. After the casting is clamped in the position shown, the table is adjusted vertically until the

† Associate Editor of MACHINERY.

center lines A coincide with the axis of the spindle. The required vertical position is obtained by inserting a center, similar to a lathe center, in the spindle and adjusting the table until the lines coincide with this center.

After a hole has been drilled in the solid end it is further enlarged to admit the reamer by using a boring-bar and cutters which are "stepped" down to correspond with the taper of the hole. In this way the hole is rough-bored so that the finishing reamer has about the same amount of stock to remove throughout its entire length. Fig. 1 shows this final operation of reaming. The hole has a taper of ¾ inch per foot, and it is reamed to conform to a standard plug gage.

After the piston-rod hole is finished, the crosshead is mounted on a taper arbor and the cylindrical end is turned as indicated in Fig. 2. This surface is finished more to give the work a neat appearance than anything else, although it provides a smooth surface for laying out the piston-rod key-slot.

The third operation in the regular order is that of planing. Two castings are planed simultaneously, and as the planed surfaces must be in line with the axis of the piston-rod hole, the work is chucked with reference to this hole by using tapered mandrels, as illustrated in Fig. 5. These mandrels are driven tightly into the crosshead and are mounted in V-blocks as shown. The V-blocks are aligned by tongue-pieces which fit into the platen T-slots, and the V's are, of course, so located as to hold the mandrels parallel both with the platen and the line of motion. A four-head planer is used, so that the flanges and pads at the sides can be machined simultaneously with the top surfaces. After the top and one side of each casting have been finished, the work is turned over for planing the opposite surfaces.

The wrist-pin hole is next bored and reamed by again using the horizontal boring machine, as indicated in Fig. 3. The casting is clamped in a crosswise position on the table, at right-angles to the spindle, and the hole is first rough-drilled and then finished to the right taper with a reamer. The adjustment for height is obtained by inserting the conical center previously referred to in the spindle and then adjusting the table vertically until this center coincides with lines laid off from the center of the piston-rod hole.

The next operation is that of laying out and machining a slot for the key which holds the piston-rod in place. This key is located, in a crosshead of this type, at an angle of 45 degrees, because when in this position it can be removed more easily. The method of laying out the key-slot is indicated in Fig. 6. The center of the piston-rod hole is first located by inserting a centered taper plug, as shown. The pointer of a surface gage is next set to coincide with this center, and the center line for the slot is then laid off and circles are scribed for drilling. As the illustration indicates, the diagonal location of this slot is obtained by simply placing the crosshead on a special angle-plate which holds it at an angle of 45 degrees with the table.

The drilling of the slot is shown in Fig. 4. The horizontal boring machine is used and the crosshead is held in the 45-

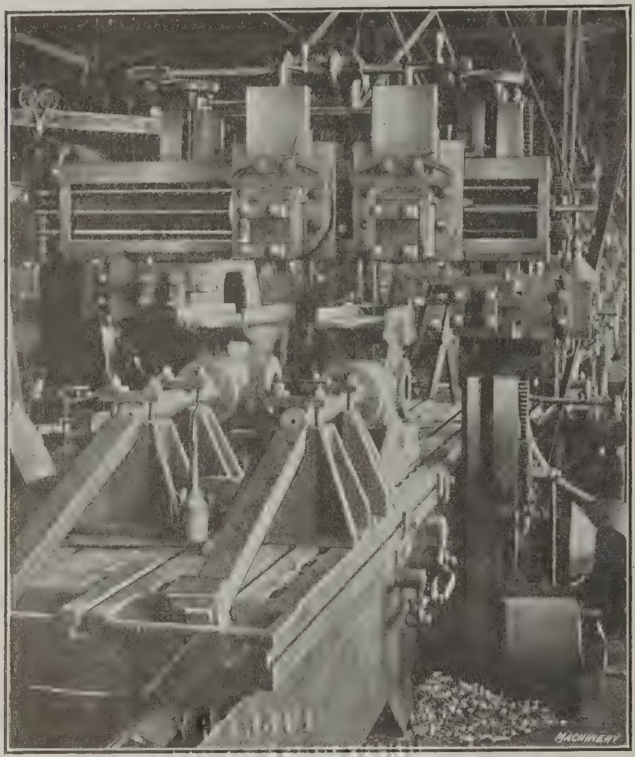

Fig. 5. Planing Two Crossheads Simultaneously

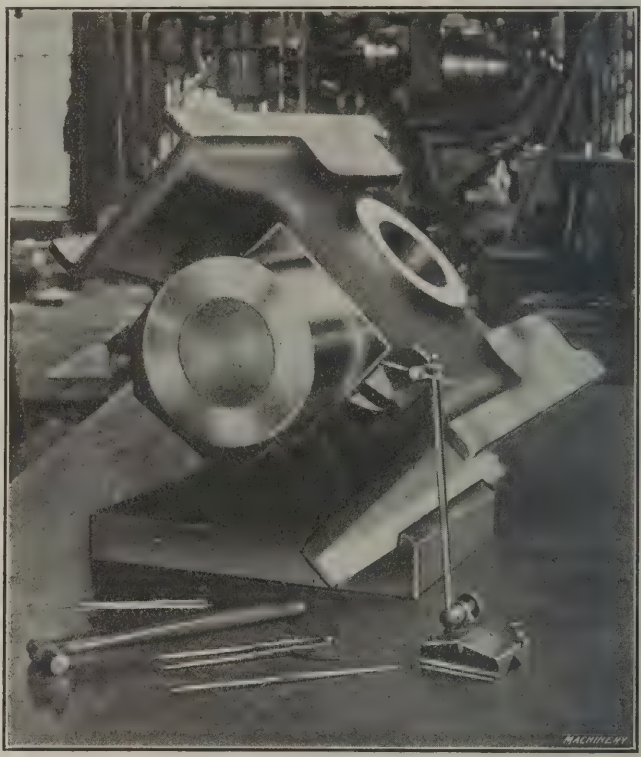

Fig. 6. Laying Out Piston-rod Key-slot

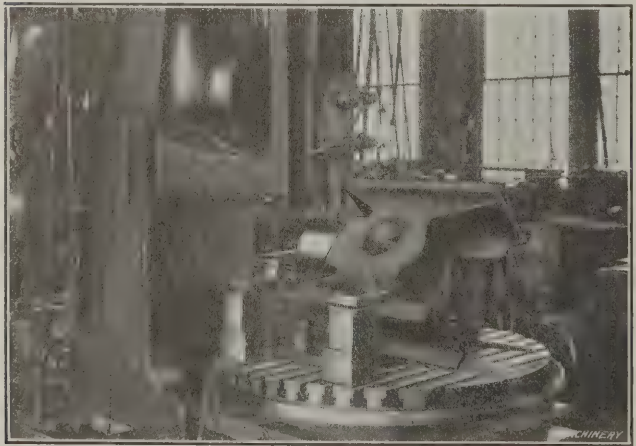

Fig. 7. Slotting Key-slot

Fig. 8. Planing Guide Bearing Surfaces in Open-side Shaper

degree position by employing the same angle-plate used for the laying-out operation. After the required number of holes have been drilled through one side, the crosshead is turned over to bring the opposite side into position.

The rough slot formed by drilling is finished in the slotting machine as shown in Fig. 7. The 45-degree angle-plate is also used for this operation, and when one side is slotted the work is located for machining the opposite side by simply turning it over. It will be noted that the slotter is equipped with a pump and piping for supplying lubricant to the cutting tool. This is a feature not generally found on slotting machines, although it can often be used to advantage, especially when slotting cast steel or forgings.

Before the crosshead can be finished, the top and bottom must be given a tin lining to form a good bearing for the guides. After tinning, the rough surfaces are planed smooth and to the required dimensions, as shown in Fig. 8. An open-side or Richards type of shaper is used for this work, and the crosshead is held on a taper mandrel mounted in V-blocks, the same as for the planing operation. The shaper is preferable to the planer for finishing the tinned surfaces, as it is quicker in operation and less cumbersome to handle. The lining is about 1/8 inch thick on the horizontal surface and 1/16 inch thick at the sides of the flanges, after being planed.

This completes the crosshead with the exception of one or two minor operations, such as drilling and tapping holes for the bracket which operates the "lead-and-lap" lever (sometimes called the combination lever) of the Walschaerts valve gear, cutting a key-seat in the wrist-pin hole, etc. This crosshead is made of cast steel, which is used on modern locomotives not only for crossheads, but for many other parts, because it makes possible a reduction in weight. This matter of weight is especially important in the case of a crosshead, as it is essential to keep the reciprocating parts of a locomotive as light as possible without sacrificing strength.

STATISTICS OF RAILWAYS IN U. S. FOR THE YEAR ENDED JUNE 30, 1911

The statements in this abstract are based upon compilations for the twenty-fourth annual statistical report of the Interstate Commerce Commission, covering the fiscal year ended June 30, 1911.

Mileage

Substantially complete returns were rendered to the Commission for 246,124.40 miles of line operated, including 11,006.86 miles used under trackage rights. The aggregate mileage of railway tracks of all kinds covered by operating returns was 362,710.18 miles. This mileage was thus classified: Single track, 246,124.40 miles; second track, 23,451.26; third track, 2,414.16; fourth, fifth, and sixth tracks, 1,747.10; yard track and sidings, 88,973.26. These figures indicate an increase of 10,943.59 miles over corresponding returns for 1910 in the aggregate length of all tracks, of which increase 3,391.33 miles, or 30.99 per cent, represent yard track and sidings.

Equipment

There were 61,327 locomotives in service on June 30, 1911, indicating an increase of 2,380 over corresponding returns for the previous year. Of the total number of locomotives, 14,301 were classified as passenger, 36,405 as freight, 9,324 as switching, and 1,297 were unclassified.

The total number of cars of all classes was 2,359,335, or 69,004 more than on June 30, 1910. This equipment was thus assigned: Passenger service, 49,818 cars; freight service, 2,195,511; and company's service, 114,006.

The average number of locomotives per 1,000 miles of line was 249, and the average number of cars per 1,000 miles of line was 9,586. The number of passenger-miles per passenger locomotive was 2,268,067, and the number of ton-miles per freight locomotive was 6,913,246.

Employes

The total number of persons on the pay rolls of the steam roads on June 30, 1911, was 1,669,809, or an average of 678 per 100 miles of line. As compared with returns for June 30, 1910, there was a decrease of 29,611 in the total number of railway employes. There were 63,390 enginemen, 66,376 firemen, 48,200 conductors, 133,221 other trainmen, and 40,005 switch tenders, crossing tenders, and watchmen. The total number of railway employes (omitting 93,718 not distributed) was apportioned among the six general divisions of employment as follows: To maintenance of way and structures, 493,926; to maintenance of equipment, 344,112; to traffic expenses, 22,246; to transportation expenses, 629,654; to general expenses, 52,201; and to outside operations, 33,952. The total amount of wages and salaries paid to railway employes during the year ended June 30, 1911, was $1,208,466,470.

Capitalization of Railway Property

On June 30, 1911, the par value of the amount of railway capital outstanding was $19,208,935,081. Of the capital outstanding, there existed as stock $8,470,717,611, of which $7,074,917,559 was common and $1,395,800,052 was preferred; the remaining part, $10,738,217,470, representing funded debt, consisted of mortgage bonds, $7,825,269,102; collateral trust bonds, $1,183,766,188; plain bonds, debentures and notes, $951,377,816; income bonds, $261,777,220; miscellaneous funded obligations, $195,430,395; and equipment trust obligations, $319,596,749.

Of the total capital stock outstanding, $2,740,467,285, or 32.35 per cent, paid no dividends. The amount of dividends declared during the year (by both operating and lessor companies) was $460,195,376, being equivalent to 8.03 per cent on dividend-paying stock.

Revenues and Expenses

For the year ended June 30, 1911, the operating revenues of the railways (average mileage operated, 243,433.61 miles) were $2,789,761,669; their operating expenses were $1,915,054,005. The corresponding returns for 1910 (average mileage operated 236,986.51 miles) were: Operating revenues, $2,750,667,435; operating expenses, $1,822,630,433. The following figures present a statement of the operating revenues for 1911 in detail:

Freight revenue	$1,925,950,887
Passenger revenue	657,638,291
Mail revenue	50,702,625
Express revenue	70,725,137
Excess baggage revenue and milk revenue (on passenger trains)	15,430,683
Parlor and chair car revenue and other passenger-train revenue	5,274,450
Switching revenue	27,665,997
Special service train revenue and miscellaneous transportation revenue	9,479,809
Total revenue from operations other than transportation	24,707,757
Joint facilities revenue—Dr	647,247
Joint facilities revenue—Cr	2,833,280
Total operating revenues	$2,789,761,669

The operating revenues stated above averaged $11,460 per mile of line.

Operating expenses, as assigned to the five general classes, were:

Maintenance of way and structures	$366,025,262
Maintenance of equipment	428,367,306
Traffic expenses	59,166,364
Transportation expenses	987,382,108
General expenses	73,689,373
Unclassified	423,592
Total operating expenses	$1,915,054,005

The foregoing operating expenses averaged $7,867 per mile of line.

Public Service of Railways

The number of passengers carried during the year was 997,409,882. The corresponding number for the year ended June 30, 1910, was 971,683,199. The increase in the number of passengers carried during the year over 1910 was 25,726,683. The number of passengers carried 1 mile, or the passenger mileage, as compiled for 1911, was 33,201,694,699. The corresponding return for 1910 was 863,198,370 less. The number of passengers carried 1 mile per mile of road was 139,191.

The number of tons of freight carried was 1,781,637,954, while the corresponding figure for the previous year was 1,849,900,101, the decrease being 68,262,147 tons. The ton

mileage, or the number of tons carried 1 mile, as shown for the year ended June 30, 1911, was 253,783,701,839. The decrease in the ton mileage for the year ended June 30, 1911, under the return for 1910, was 1,233,208,612. The number of tons carried 1 mile per mile of road for the year 1911 was 1,053,566. The number of tons per train-mile was 383.10.

The average receipts per passenger per mile were 1.974 cents; the average receipts per ton per mile, 0.757 cent. The ratio of operating expenses to operating revenues was 68.66 per cent.

METHODS USED IN ERECTING PLANERS

FOUNDATIONS, ALIGNMENT, SQUARING UP, ERECTING COUNTERSHAFTS, ETC.

BY EDWARD K. HAMMOND*

Edward K. Hammond†

DISAPPOINTMENT is sometimes experienced in the performance of new machinery, owing to its failure to produce work of the standard expected. In most cases, however, the machine itself is quite capable of properly doing the work for which it was sold, and an investigation by an expert will usually show the trouble to be due to one of two general causes; the machine is either improperly used, or it has been incorrectly set up. Either error will make production of accurate work impossible, and incorrect methods of setting up a machine will also often cause it to be seriously damaged. It is the purpose of this article to explain the correct methods of setting up a planer, the information presented being based upon methods developed by the Cincinnati Planer Co., Cincinnati, O.

In setting up machines of this type, the following requirements must be fulfilled. A solid foundation must be provided for the planer to rest upon. The bed must be true and set level upon the foundation and square with the lineshaft; it must bear evenly upon the foundation and be adequately supported by it. The cross-rail must be exactly parallel with the table. It will be evident to any machinist that a planer cannot give satisfactory results unless the table runs perfectly true and the cross-rail is parallel with it. The necessity for a solid foundation, upon which the planer bed is evenly supported, is just as important a factor in securing accurate work, although it is not so generally appreciated. Where a planer bed is not given adequate support, its weight will cause it to be sprung out of shape, and the inaccuracy of the ways which is produced in this way will manifest itself in the work produced on the machine.

The best practice is to set planers upon a concrete foundation and the Cincinnati Planer Co., in common with most reliable builders, furnishes foundation plans giving details for the construction which has been found suitable for the size of machine to be installed. Fig. 1 shows one of these foundation plans for a 62-inch x 62-inch x 14-foot Cincinnati planer. This plan calls for the use of leveling blocks between the planer bed and the foundation, one of these being illustrated in Fig. 2. The sliding members of these blocks are lubricated with graphite, to make sure that they will work smoothly, and by means

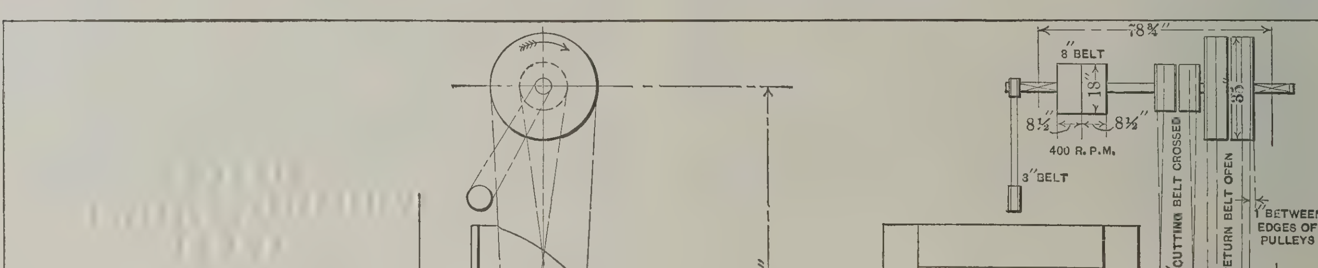

Fig. 1. Foundation Plan for a 62-inch by 62-inch by 14-foot Planer

*Address: 9620 Hoyne Ave., Chicago, Ill.

† Edward K. Hammond was born in Morgan Park, Ill., in 1885. He graduated from the Armour Scientific Academy and Armour Institute of Technology with the degree of bachelor of science. He worked for two years in the shops of the Western Electric Co. and was editor of *Modern Machinery*, Chicago. He is now in charge of one of four gas testing laboratories maintained by the city of Chicago. Mr. Hammond has contributed articles to several of the leading technical publications on various phases of machine shop practice and factory administration.

of the adjusting screws, each individual block may be set to exactly the required point to bring the planer bed to an accurate level. Where the planer has feet, these rest upon the leveling blocks, but where the bed extends right down to the foundation, the blocks are distributed in the way best suited to carry the weight of the bed and protect it from being strained at any point. Average conditions require leveling blocks in the foundation at intervals of four feet. These blocks not only provide a rapid and accurate method of leveling, but also make it possible to correct a considerable amount of error that may be found in either the planer bed itself or in the foundation, thus bringing the machine back to an accurate level in either case.

In preparing this type of planer foundation, the concrete is filled in to within about eight inches of the floor line. The

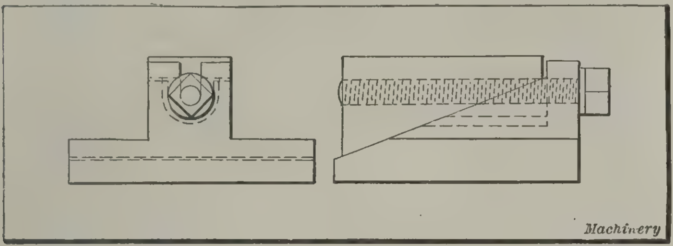

Fig. 2. Leveling Block of the Type used in a Concrete Foundation

leveling blocks are then placed in position and carefully adjusted with a long straightedge so that tissue paper will be held tightly on any block when the straightedge is passed from one position to another. After the blocks have been placed in position with the required degree of accuracy by this adjustment, the concrete is filled in almost to the level of their upper faces, spaces being left to allow access to the adjusting screws. These spaces should be provided with covers to keep chips and dirt away from the screws.

The use of heavy concrete foundations and leveling blocks of this type make the initial cost of installation rather high, but it is possible, in this way, to secure a higher degree of accuracy in planer work than is usually considered practical. This increased accuracy permits the saving of a great deal of time in scraping the work after it has been planed. The time required to keep the planers themselves in proper working condition is also reduced when they stand upon accurate founda-

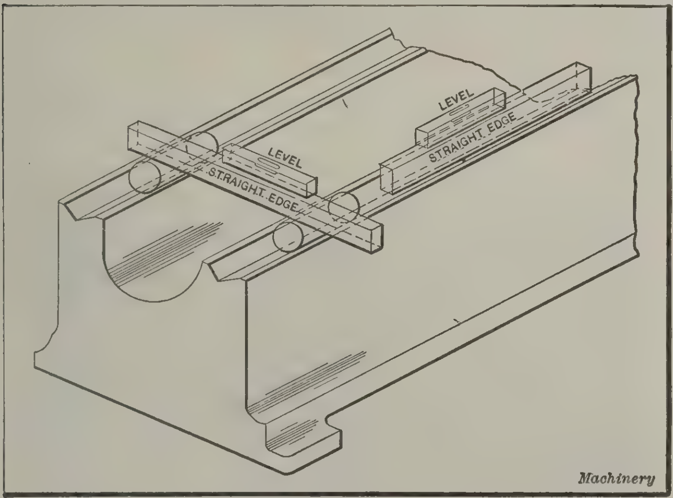

Fig. 3. Method of Testing the Level of a Planer Bed in Two Directions

tions, because all unnecessary strains upon the machines, due to lack of adequate support, are eliminated.

An idea of the efficiency of this form of foundation for a planer may be gathered from tests which have recently been made in the shops of the Norton Grinding Co., Worcester, Mass. After a year of constant use, the table of an 18-inch x36-inch planer with an 18-foot bed was tested with a 15-foot straightedge, and it was found that tissue paper could be held at any three points on the table, with the table in any position on the bed. When a planer is able to meet such a severe test, the claim for a greater accuracy in its output will be readily granted, as very few planers successfully meet such a test when mounted on any other form of foundation.

There has recently been considerable discussion concerning the advisability of bolting down planers to the foundation. The claim is made that a machine which is heavy enough to do its work well will not move at reversal, and the belt pull can never left it from the floor. Experience has shown that the only fastening necessary for a planer standing on a concrete foundation and leveling blocks, is to drill the plates and put in one-half-inch pins on each side of one or more pairs of legs, to prevent endwise sliding. In certain cases where this method of fastening was used, the pins were originally set so that they did not touch the planer feet, and the machine has never moved enough to bring them into contact. The use of foundation bolts was discarded on account of several objectionable features for which they are responsible. Among these the following may be mentioned: When a planer is bolted to a wooden floor and a heavy weight is placed near it, the planer is bound to follow any temporary settling of the floor which occurs; this sets up a strain in the entire planer. The same objection applies when permanent settling occurs in any form of planer foundation, and springing or deformation of the bed is bound to take place if it is bolted to the foundation at the time when the settling takes place. The pres-

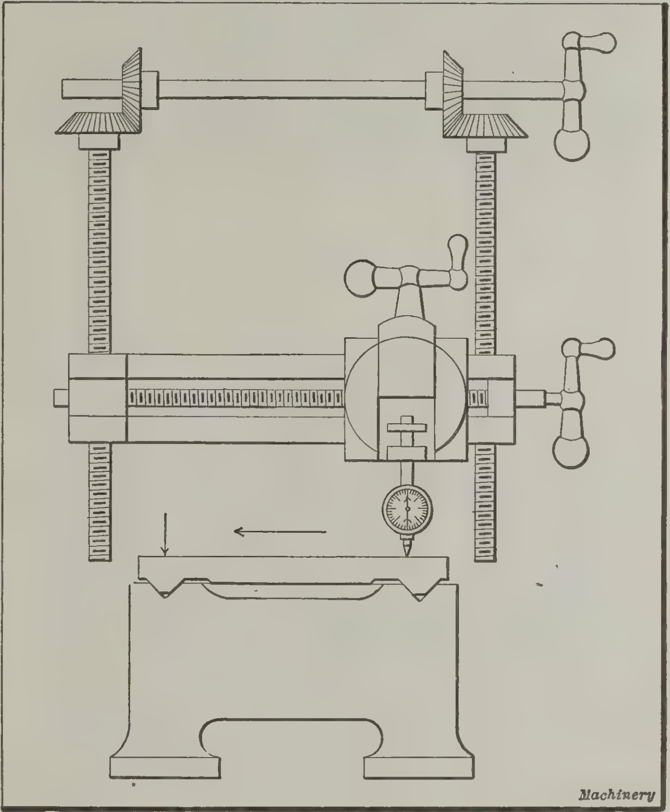

Fig. 4. Testing the Alignment of the Planer Cross-rail with the Table

ence of foundation screws also presents the possibility for careless workmen to attempt to use them to level the bed. This is obviously poor practice, because any leveling that is accomplished through the tightening of foundation screws, is done by springing the bed out of shape.

A More Simple Form of Foundation

A more simple method of supporting a planer consists of preparing a preliminary foundation upon which the machine is placed. Iron wedges or cedar shingles are then used to raise the bed to a height of about one inch above the level of the foundation, and also to bring it to a level position. A mortar is now made, consisting of one part of Portland cement to one part of sand, which is used to raise the foundation to the level of the bottom of the bed. Where this method of constructing a foundation is followed, care must be taken to tamp in the mortar firmly under the bed. A foundation of this kind is less expensive than the one previously described, but it is also far less serviceable in the long run.

Placing the Planer on the Foundation

In placing the planer on the foundation, care must be taken to have the bed set exactly square with the line shaft in order to provide for a proper operation of the driving belts. After this condition has been fulfilled, the bed must be ac-

curately leveled in both the lenghtwise and crosswise directions. This is done by removing the table and using a good spirit level to determine the direction in which the leveling blocks must be adjusted to bring the bed into the required position. If a level, which is long enough to reach across the bed is not available, a shorter instrument may be used on the top of an accurate straightedge which is parallel on both sides.

The beds of the planers built by the Cincinnati Planer Co.

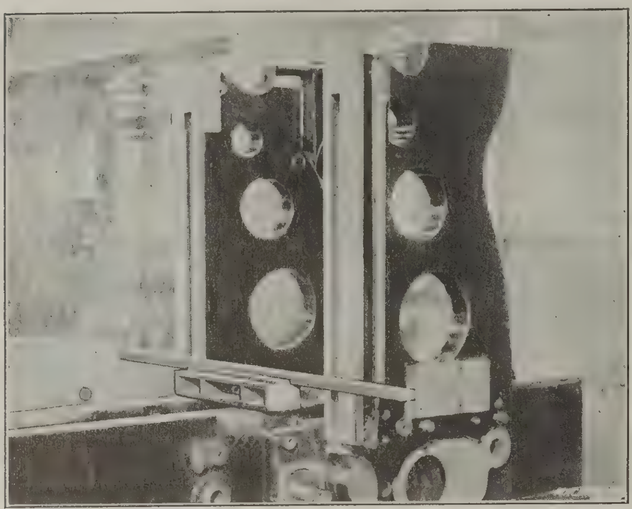

Fig. 5. Method of Bringing the Housings Square with the Ways

and many other firms, have the surfaces at the top of the Vs planed exactly parallel with the ways. If it is known that this method has been followed by the firm which built the planer that is being set up, these surfaces can be used as a support for the spirit level. Fig. 3 shows the proper method of procedure where the top surfaces of the bed have not been accurately lined up with the ways. In this case the ways themselves are used in leveling the bed. For making the crosswise adjustments, two cylindrical bars, of exactly the same diameter and of suitable size to fit in the Vs, are used as supports for the spirit level or straightedge. For the lengthwise adjustments, the level is set directly in the Vs. The bed is left a trifle high at the center, because the pressure of the tool and the weight of the housings come at this point; this causes a little more deflection and a slightly greater tendency for the foundation to settle. By observing the precaution of having the bed a little high at this place, the ways will, in the end, be brought to an accurate level.

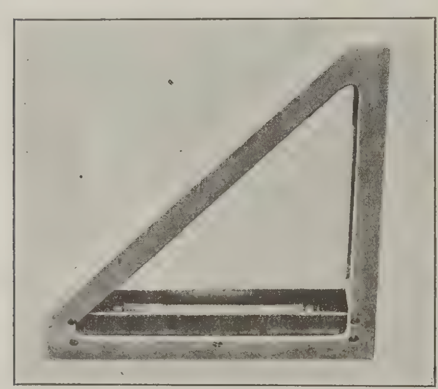

Fig. 6. Special Square used to Determine Vertical Alignment of the Housings

A series of tests should be made along the entire length of the bed to make sure that it is level in both lengthwise and crosswise directions. Such a series of tests should also be repeated at frequent intervals for some time after the planer has been set up, as there is a probability that the foundation will settle, thus disturbing the alignment. Where such settling is detected, the machine is easily brought back into position by means of the screws in the leveling blocks.

It is not necessary to level, in the lengthwise direction, a planer bed which only has legs at the ends, because the distance between the legs is never great enough to cause a deflection in the bed. Consequently, if the bed is a little high at either end, it will still plane straight, because the table will travel in a straight line and there is no tendency for its bearings in the bed to get out of alignment.

Special care, however, ought always to be taken in testing the lengthwise level in all other cases, as all planer beds do not have their ways scraped to a straightedge. Where the bed is merely scraped to fit the table, it insures a bearing, but does not show that the ways are straight, and in such cases, the provision of an absolutely level foundation is required to enable the bed to straighten itself out into proper alignment. When the bed has been brought to a satisfactory level, the Vs of both the bed and the table are thoroughly cleaned to remove grit and dirt, and the oil pockets in the bed are filled with a supply of good machine oil. The table is then replaced upon the bed and the next step is to see that the cross-rail is in proper alignment with the table. For this purpose, a distance rod or some form of surface gage is clamped in the planer tool-post to measure the distance between the rail and opposite sides of the table.

Fig. 4 shows the method of making these measurements with a dial test indicator, which has the advantage of showing the exact amount of any error that may be found in the alignment of the cross-rail. The same general method of procedure is followed with a distance rod; in this case, a piece of hard paper would be used as a feeler. The distance between the table and the cross-rail is measured first at one side of the table and then at the other, as indicated in the illustration. If this test shows the cross-rail to be out of alignment, the error is removed by adjusting the nuts on the elevating screws. These screws are a sliding fit in the bevel gears and carry fine threaded adjusting nuts which rest on the top of the bevel gears. By means of these nuts, the elevating screw at either side of the table can be raised sufficiently to bring the cross-rail parallel with the table. This adjustment should always be made by raising the low side of the rail. If the adjustment was made by lowering the high side of the rail, there would be a little backlash in the adjusting screws. This backlash would allow the rail to work out of the desired alignment with the table.

It was formerly considered necessary for a planer to plane off its own table after having been set up on the floor where it was to be used. Modern practice has discarded this method of procedure. The planers built by leading manufacturers plane their own tables before they leave the shops. Consequently, they require no further finishing, providing the bed has been set up as it ought to be. In fact, the practice of planing off a table is wrong, because if it is necessary to remove any error in the table by planing, it shows that the foundation is not properly leveled, and the trouble should be eliminated by adjusting the leveling blocks.

Additional Operations on Large Planers

Small and moderate-sized planers are usually shipped to the purchaser's plant fully assembled. In such cases the method of setting up which has been outlined puts the planer into condition to be belted to the countershaft; but in assembling large planers which have been taken down to facilitate shipment, or to make repairs on machines that have been damaged in transit, great care must be observed to bring the housings into proper alignment. After the bearings, shafts, and gearing are put into place in the bed, the housings are brought into position and tested to see that their

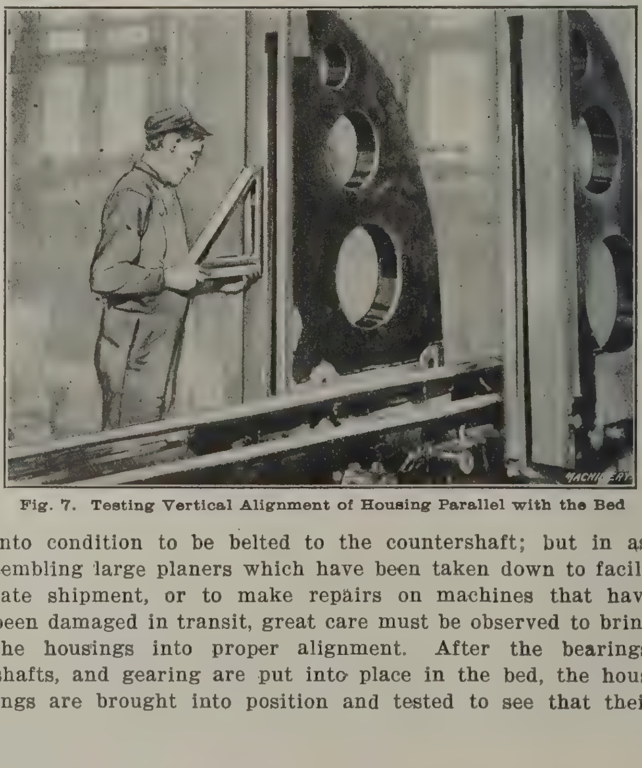

Fig. 7. Testing Vertical Alignment of Housing Parallel with the Bed

faces are square with the ways and that they are in the proper vertical alignment in both the lengthwise and crosswise directions.

The method of bringing the housings square with the ways is shown in Fig. 5. The fixture used for this purpose fits into the Vs and a straightedge is held by a shoulder as shown; the housings are then lined up with the straightedge. A special square shown in Fig. 6 is used to determine the vertical alignment of the housings. This square is fitted with a special spirit level which has been graduated to make each ⅛-inch space correspond to an error of 0.001 inch in 4 feet in the alignment of the housings. The method of using this square is illustrated in Figs. 7 and 8, where the alignment of the housings is being tested in two directions. The square is held against the face of one housing and the position where the bubble stops is noted. The square is then shifted to the corresponding face of the other housing and the position of the bubble is again noted. The same tests are made for the other pair of faces on the housings. If the position of the bubble is found to differ for either set of tests, the square shows the amount of error and the direction in which the adjustment must be made to bring the housings into proper alignment. When necessary adjustment has been made, so that any error which exists is within 0.001 inch in 4 feet, which corresponds to one graduation on the spirit level, the holes in the housings are reamed and they are then doweled into place on the bed. The cross-rail is next mounted in position on the housings and brought exactly parallel with the planer table, by the method previously described. The remaining parts of the planer are now assembled and the machine is then ready to be belted to the countershaft.

Fig. 8. Testing Vertical Alignment of Housing at Right Angles with the Bed

Erecting the Countershaft

In setting up the countershaft, care must be taken to have it perfectly level and parallel with the lineshaft; it must also be accurately located according to the requirements of the foundation plan, as shown in Fig. 1. This plan also gives instructions regarding which is the open and which the crossed belt. The importance of having the countershaft correctly located in relation to the planer lies in the fact that the belts will not shift properly if it is too far in front of or behind the proper position. After the countershaft is placed in position, the loose pulleys and hanger boxes must be given a copious supply of machine oil, and care should be taken to see that the pulleys and shaft turn freely. The collars on the shaft must be set to permit a little end play in the boxes, but not too much.

Some shops are in the habit of overlooking the superior driving and wearing powers of double belting in order to keep the first installation cost as low as possible. Economy in this direction is ill-advised, and double belting of the width specified in the foundation plan ought always to be used. The "cutting" belt, which is the crossed belt in most cases, should be crossed so that the side running back to the countershaft is on the inside next to the housing of the planer. The importance of this arrangement lies in the fact that the side of the belt operated on by the shifter forces the other side with it and enables the reversal to be made in less time than would otherwise be possible.

After all of the belting is in place, all of the pulleys and gearing in the planer should be rotated by hand, to make sure that everything runs freely, before the power is turned on. The gears should be given a good coat of heavy oil, and all of the bearings, loose pulleys, and oil holes must have a liberal supply of the best machine oil two or three times a day for the first week after the planer is placed in service. This precaution will often prevent serious wear while the machine is running itself into smooth running order. In the case of large machines, the further precaution of running them idle for a day or two before starting on heavy work should always be observed.

The time spent in putting new planers into proper operating condition is of little value unless care is taken to protect them from injury while in use. Consequently, some advice concerning the methods of protecting planers from damage will not be out of place in this article. In order to produce accurate work, the ways of a planer must be true, and, owing to their exposed position, special care must be taken to protect them from injury. Several methods are in common use. In planing short work, the ends of the ways may be covered with boards or canvass to keep chips and dirt out of them. A more elaborate method of securing protection for the Vs has been designed and patented by Mr. W. A. Thelin, foreman of the planer department of the Bullard Machine Tool Co., Bridgeport, Conn., where this method has been used for keeping the planers in good operating condition for a number of years.

Fig. 9 shows this device. The two spools at the end of the planer bed have strips of canvass wound on them which are slightly wider than the Vs. These strips are attached to the table, as illustrated, and as the table moves forward, the strips of canvass are unwound from the spools and keep the Vs covered. On the return stroke, the spools rewind the canvass strips through the action of a spring-actuated shaft on which the spools are mounted. Two rollers, carried on counterweighted arms, hold the canvass clear of the ends of the bed, and when the table comes forward to the end of the ways, the arms are swung down by means of blocks on the under side of the guards. An advantage in the use of these guards lies in the fact that they are equally available for all lengths of work and act automatically in protecting the ways from scoring or cutting without hindering the operator in any way.

WATCH MOVEMENT MANUFACTURE*—3

METHODS, MACHINES AND SPECIAL TOOLS USED BY THE SOUTH BEND WATCH CO.

BY DOUGLAS T. HAMILTON†

To produce the small parts of a watch such as staffs, pinions, screws and jewel settings, requires the use of specially designed machinery. It is the methods employed in the producing of these parts, and the care taken in their manufacture, that raises or lowers the value of a watch. Automatic machinery has been a great boon to watch manufacture, but if all parts thus made are not carefully inspected and assembled, there is very little gained by producing them automatically. All parts that enter into a South Bend watch, whether made on automatic machines or otherwise, pass through careful inspections, and all are assembled by expert watchmakers. In the following a few of the special machines used will be described.

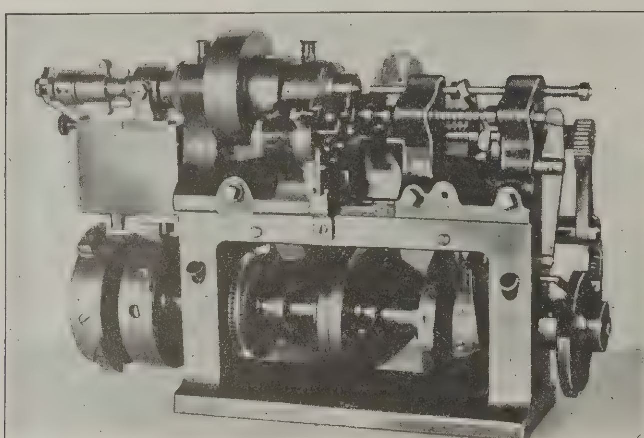

Fig. 26. Automatic Pinning Machine for Bridges

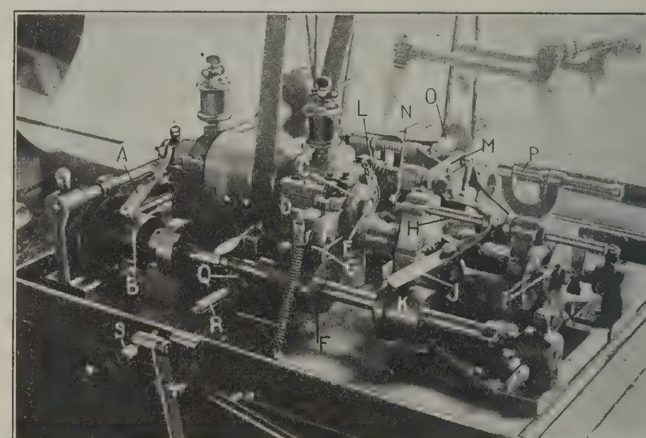

Fig. 27. Automatic Machine for Producing Small Watch Screws

Pinning or Doweling Bridges

The most expensive watches consist of one front plate and several bridges, these forming the bulwarks for the movement. The bridges are pinned and screwed to the front plate and retain the jewels which act as bearings for one end of the staffs. The more important operations on the bridges are: Blanking and shaving in the punch press, facing, stoning, drilling in a jig, counterboring, recessing and pinning or doweling.

The pinning is accomplished in the automatic machine shown in Fig. 26, which is similar, in appearance, to a small automatic screw machine. The construction of this machine is more clearly shown in Fig. 28. The wire from which the pins are made is fed by a feeding tube A by means of a finger which is operated by cam blocks on wheel B. The chuck C is closed by fingers D, operated by a sleeve E and cam blocks on wheel F.

The wire is gaged to the desired length by a spring actuated stop G which is forced forward against the tension of the coil spring H by means of yoked lever I and cam J. The circular cut-off tool K, working at an angle of 45 degrees with the axis of the spindle, is then brought in through the medium of a rack and gear, by lever L and cam M. Before the pin is cut off, stop G drops back, and carrier N held on shaft O is operated or rotated into position by cam P, rack-lever Q, and pinion R. When in line with the work, the carrier is forced forward by cam S and lever T, thus gripping the pin and then dropping back.

The bridge in which the dowel or pin is to be inserted is held in a cage into which it is placed by the operator. Now as the carrier drops back, cam P, rack-lever Q and pinion R rotate the carrier into a position where the pin is in line with the hole in the bridge; then carrier N which is provided with a spring plunger V ejects the pin, inserting it in the work when acted upon by plunger A_1, lever B_1 and cam C_1. The main drive shaft, carrying the various operating cams, is driven by a pulley D_1 through a worm E_1 and worm-wheel F_1. The various cams are so timed that while the pin is being inserted in the work, another pin is being fed out and cut off, these operations being performed automatically.

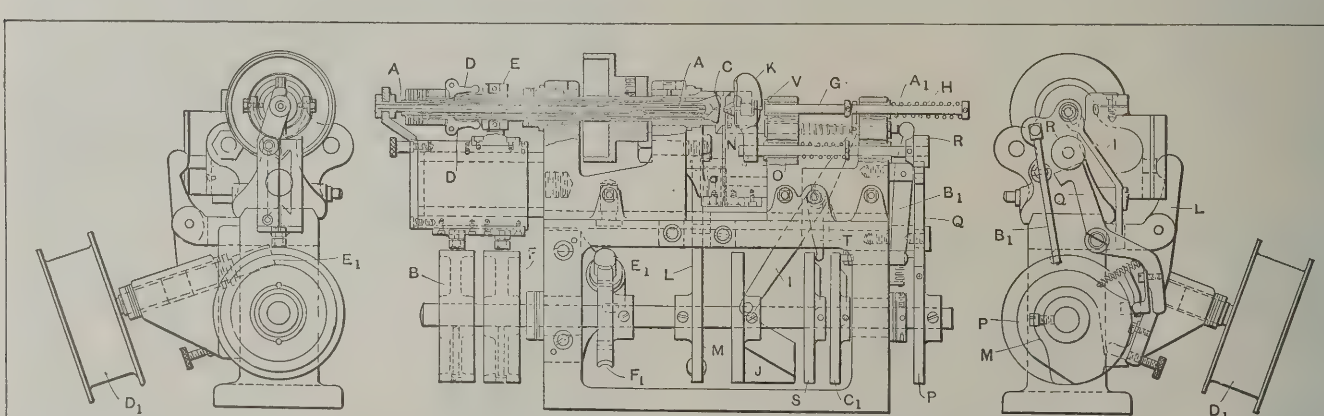

Fig. 28. Construction of the Pinning Machine shown in Fig. 26

Small Automatic Screw Machine

A large number of the cylindrical parts which are used in a watch are produced on the Brown & Sharpe automatic screw machine, but most of the small screws are made on special screw machines, one of which is shown in Fig. 27. The stock—the exact size of the head of the screw—is fed through the spindle by a feed finger operated by lever A and cam B.

The body of the screw, or portion to be threaded, is reduced by a circular form tool C held to a block D, as shown. This block is fulcrumed at E, and is operated by a cam F pressing against the hardened shoe G. It will thus be seen that the cutting edge of the tool, when in operation on the work, passes through an arc. This method of presenting the tool to the work has been found to give better results on

* The second installment of this article was published in the June number of MACHINERY. The fourth and last installment will occur in an early issue.

† Associate Editor of MACHINERY.

small work than feeding the tool in a horizontal plane, as is the usual practice.

The thread is cut by a small mill- or spring-die held in the forward end of spindle H. This spindle is rotated from the rear driving shaft through the change gears I, and is advanced by yoked lever J and cam K. The cams F and K

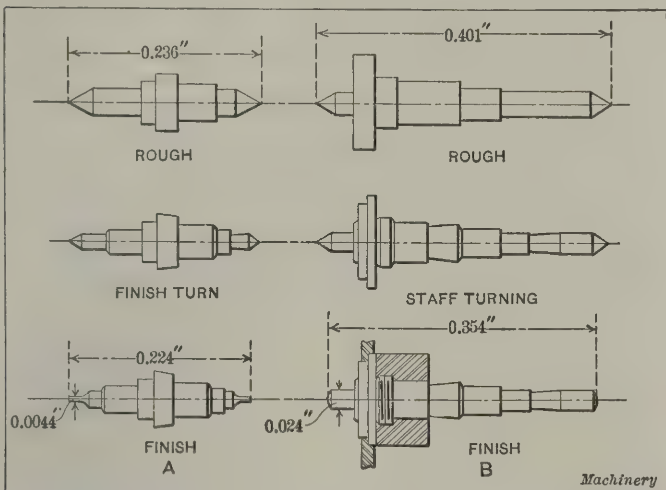

Fig. 29. Various Turning Operations on the Center and Balance Staffs

are so timed that the form tool is raised out of the way to let the die reach the work, the shoe G dropping down onto the cut-away portion of F at the proper moment. The die in traveling onto the work rotates in the same direction as the spindle, the latter reversing to run the die off when the desired length of thread has been cut.

After the thread is completed, the cut-off blade L operated by a cam on the rear shaft comes into action, and severs the screw from the bar. Just as the screw is breaking off, a bushing held in arm M is rotated into position to grip the screw, by

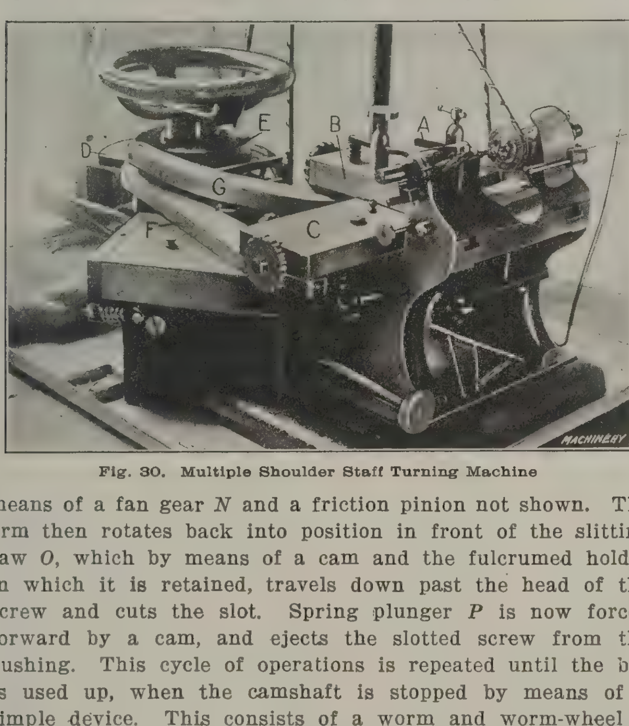

Fig. 30. Multiple Shoulder Staff Turning Machine

means of a fan gear N and a friction pinion not shown. The arm then rotates back into position in front of the slitting saw O, which by means of a cam and the fulcrumed holder in which it is retained, travels down past the head of the screw and cuts the slot. Spring plunger P is now forced forward by a cam, and ejects the slotted screw from the bushing. This cycle of operations is repeated until the bar is used up, when the camshaft is stopped by means of a simple device. This consists of a worm and worm-wheel Q which feed out a shaft R until it comes in contact with an adjustable stopscrew S, thus operating a lever which disconnects the driving clutch.

Staff Turning

The wheels composing the watch train are held on staffs, the ends of the latter running in jewels retained in the lower plate and bridges. Most of these staffs are provided with a number of shoulders of different diameters, as shown in Fig. 29, where A represents the various operations on the balance staff, and B the operations on the center staff. The last operation on the center staff shows the center wheel and pinion assembled.

One of the machines used for multiple shoulder staff turning is shown in Fig. 30. The staff to be turned is held on female centers, and is driven by a small dog. The turning is accomplished by a single turning tool A, held to the tool-slide B, which, in turn, is connected to a longitudinal slide C. Only one-half of the staff is finished at each setting, it being reversed to finish the other end. The movements of the turning tool A are controlled automatically by plate cams D and E. The lower cam D traverses the slide C, and hence moves the turning tool across the work by means of lever F, the ratio of the arms of which is 4 to 1. The top cam E, operating lever G, controls the in-and-out movements of the turning tool, and thus governs the diameter of the staff. The arms on lever G have a ratio of 8 to 1, thus enabling greater accuracy to be obtained on the diameter of the staff. The heights of the lobes on the cams, of course, are made equal to the movements required, multiplied by the ratios of the arms of the levers.

The lobes on cams D and E are so laid out and timed that all shoulders on the staff are faced as well as turned to a given diameter. One girl operates two machines, re-

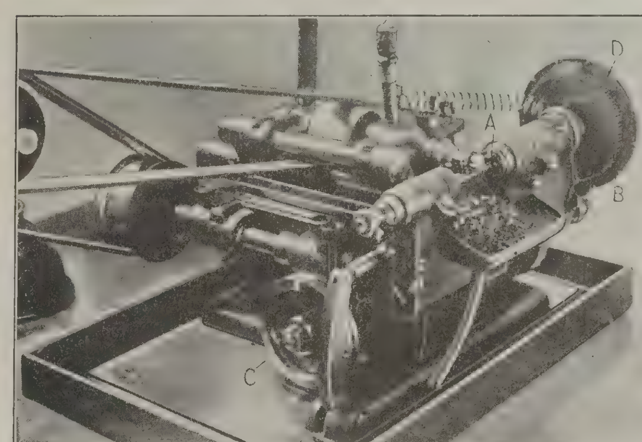

Fig. 31. Automatic Three-cutter Pinion-cutting Machine

moving a staff when finished and inserting a rough one. The machine is stopped automatically by a tripping device, not shown. The operator sits on a chair which is provided with wheels running on a track. This enables her to get from one machine to the other quickly and with very little effort.

Cutting Pinions

Watch pinions, as a rule, are made of steel and are formed-turned and cut off in special automatic staff machines. Then they are placed one at a time on an arbor, the latter being placed between the centers of the machine shown in Fig. 31. The driving center is corrugated, while the dead center is of the female type and is held in a spring-actuated

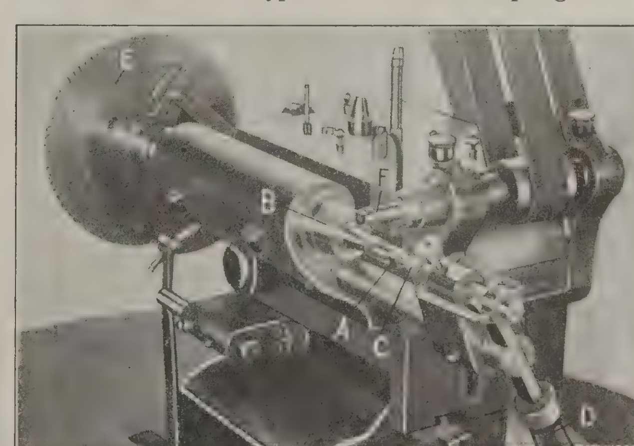

Fig. 32. Machine for cutting the Teeth in the Brass Wheels

spindle or tailstock. As a rule, three cutters are used: The first is a thin saw; the second a roughing cutter; and the third a finishing cutter.

The spindle A carrying the corrugated center is indexed by means of an indexing disk B and a ratchet. After the work has made one complete revolution, a cam held on cam-

shaft C shifts the table, bringing the next cutter into operation. The spindle again makes one complete revolution, when the cam shifts the table, bringing the last or finishing cutter into line. This makes one cut around the pinion, after which the table drops back to the starting position, and the machine is stopped by an automatic tripping device. The index plate D is provided with the same number of notches as there are teeth on the pinion.

Cutting Brass Wheels

The brass wheels, which in connection with the pinions compose the watch train, are blanked out and shaved by sub-

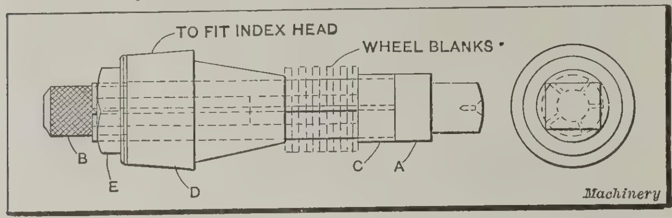

Fig. 33. Arbor used on the Machine shown in Fig. 32 for Holding Brass Wheels

press dies in the punch press. The arms of these wheels are all equally spaced and made of an equal width. The automatic machine used in cutting these wheels is shown in Fig. 32. Eleven of the wheels are held on the arbor A which has a tapered shank fitting in the indexing spindle B. The forward end of the arbor is supported by a spring center C, which is withdrawn from the arbor by pressing on the handle D. The indexing disk E has the same number of teeth as that required in the wheel and is indexed automatically by a ratchet device.

The cutter F is held on an arbor placed in the spindle of the machine. The head carrying the cutter spindle is raised on the return stroke of the cutter by a cam located beneath the head. The table carrying the work is advanced at a uniform speed by a constant-rise cam held on a cam-shaft at the rear, and an automatic arrangement stops the machine when one stack of wheels has been completed.

The arbor on which these wheels are held while the teeth are being cut is shown in Fig. 33. It consists of a central arbor

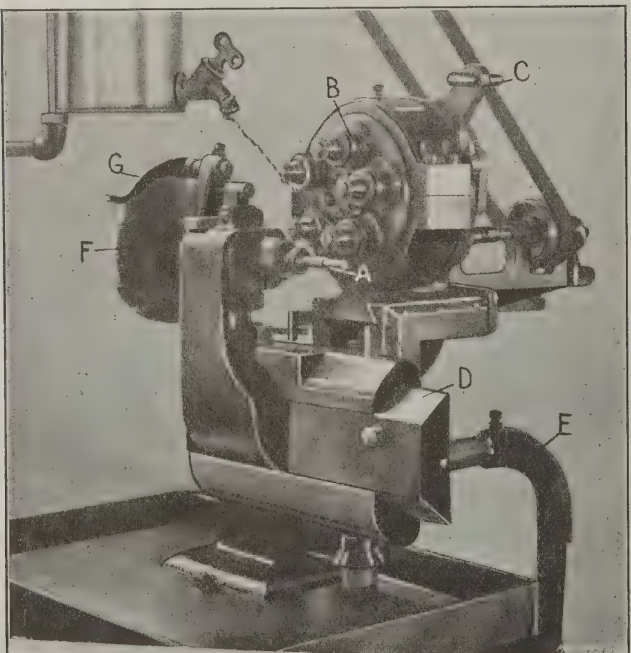

Fig. 34. Machine for Cutting Brass Escape Wheel Teeth

A which has five slots cut in it of the same width as the arms of the wheel. A hole is bored part way through this arbor, and a plug B is inserted to prevent it from collapsing. A washer C of the same diameter as the shoulder on the arbor is put on it as shown; then the wheels are put in place and the tapered sleeve D, which fits the index head, is next slipped over the arbor. Collar-nut E is then screwed onto the threaded end of the arbor, thus clamping washer, wheels and sleeve together.

As these wheels are blanked out and shaved in the punch press, it is evident that the inside of the rim is practically the only place to work from, if a wheel having a rim of an equal width throughout its circumference is desired. By working from this point, and using a milling cutter which will finish the tops of the teeth, it is an easy matter to produce a wheel which will be perfectly balanced.

Cutting Brass Escape Wheels

The escape wheel, so called because of the function it performs in a watch, is made from either steel or brass. The brass wheels are cut by sapphires, seven of which are used as fly-cutters, while the teeth in the steel wheels are produced by hardened steel cutters. Each of these cutters forms one part of the tooth, which differs considerably in shape from an ordinary gear tooth, as can be seen by referring to Fig. 8 in the May number.

The machine used for cutting the teeth in brass escape wheels is shown in Fig. 34. A stack of these wheels is held on arbor A, the latter being retained in the indexing spindle. The teeth are completely formed by five cutters held in the revolving head B, each cutter shaping some part of the tooth. The cutter spindles are driven by gears enclosed in the head. The cutter head itself is indexed by hand to bring the de-

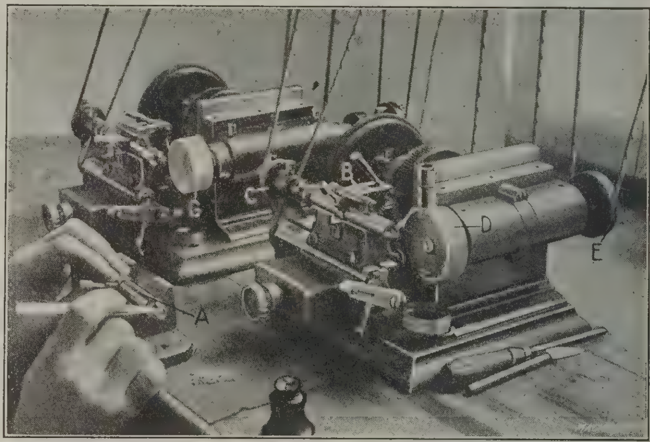

Fig. 35. McGinty Staff Cone Grinding and Polishing Machine

sired cutter into operation, this indexing being effected by means of the handle C. The table or slide D is traversed by hand by means of the lever E. The work is also indexed by hand with the ratchet wheel F, the latter being held in the desired position by pawl G. The teeth in these escape wheels are so delicate that it would be practically impossible to produce them by means of an automatic machine, great care being required on the part of the operator to turn out a perfect wheel.

As it is impossible here to give even a short description of the making of all the parts of a watch movement, only those methods which involve the use of some interesting mechanical device or appliance have been selected. After the steel parts such as pinions, staffs, balance staffs, etc., have been made, they are hardened and tempered. This leaves them in such a state that it is necessary to lap and polish them to the desired size, at the same time improving their appearance.

Grinding and Polishing Machine for Staff Cones

The staffs on which the wheels are held have a coned bearing, which must be of exact size to fit the hole in the balance wheel jewels inserted in the wheel. The staff to be ground is placed in a quill A, the operator using a pair of tweezers for this purpose, as shown in Fig. 35. The quill is then placed, and held by clamp B, in that part of the machine shown to the right in the illustration, which is used for the first operation—grinding. The spindle of the quill A is driven by a grooved pulley C and a small dog, the latter coming against a lug on the quill spindle. The staff is held between pump centers and a faceplate, and the grinding is accomplished by a diamond charged lap D, which is rotated by pulley E.

The spindle carrying the lap is moved back and forth by a cam which, in turn, is operated by a worm and worm-

wheel. This cam is provided with a gradual rise for feeding the lap against the work. When the desired diameter is reached the machine is stopped by means of a trip-stop.

The machine shown to the left is used for polishing the cone on the staff, and is identical in construction with that just described, with the one exception that the lap is given an oscillating movement by means of a crank *F*, shown in Fig. 37. This latter illustration also shows more clearly the construction of this machine. The lap is made of celluloid and

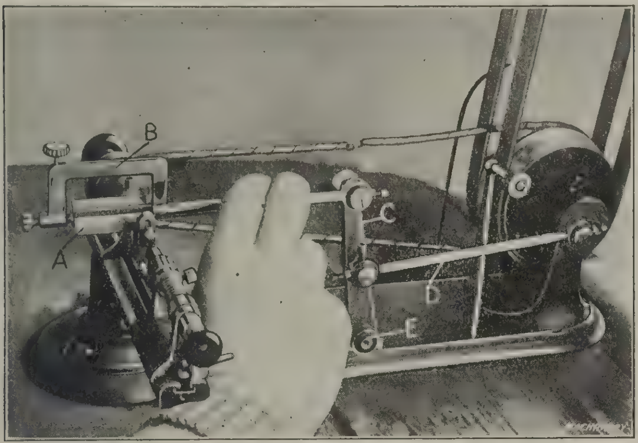

Fig. 36. "Wig-wag" Polishing Machine for Pinions and Staffs

is coated with Vienna lime, obtained in Austria. It is kept in contact with the work by means of a cam that has a cut-away portion, allowing the lap to drop back when the cone has been lapped to the correct diameter.

Before this machine—nicknamed the McGinty cone polishing and grinding machine and known by this name wherever watches are made—was perfected, the grinding of these cones was done by hand by skilled staff makers, who made this a special business. Naturally, when this machine was invented, it was jeered at by these expert cone polishers. About this time the old song "Down went McGinty" was at the height of its popularity, and each time this machine returned to the tool-room for improvements, the polishers would strike up the old refrain. However, after much experimenting the machine was perfected, and at the same time was nicknamed "The McGinty cone and polishing machine." It is now operated by girls who do better work and more of it than was formerly accomplished by expert polishers.

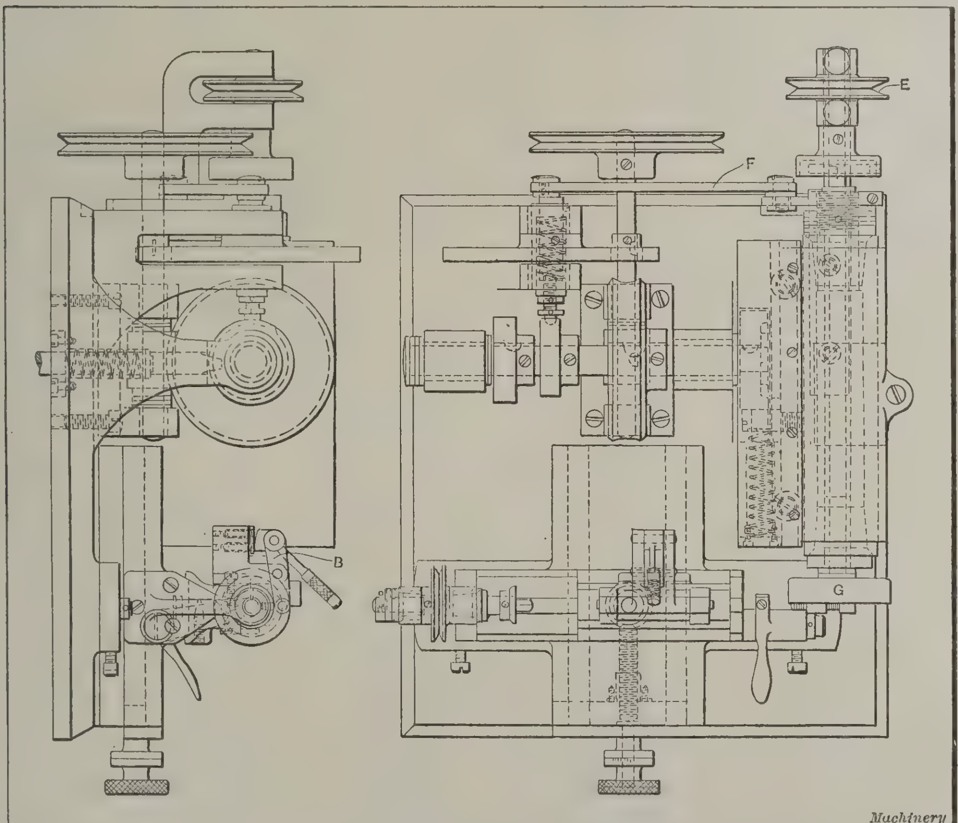

Fig. 37. Construction of the McGinty Staff Cone Grinding and Polishing Machine shown in Fig. 35

Polishing Pinions and Staffs

The pivot ends of pinions and staffs are polished by means of "wig-wag" polishers, one of which is shown in Fig. 36. The pinion is held in a "balloon" chuck provided with a pump center, and the polishing is done with a wing polisher *A* made of machine steel. The wings are ground on a special fixture, to an included angle of 45 degrees, and these lapping

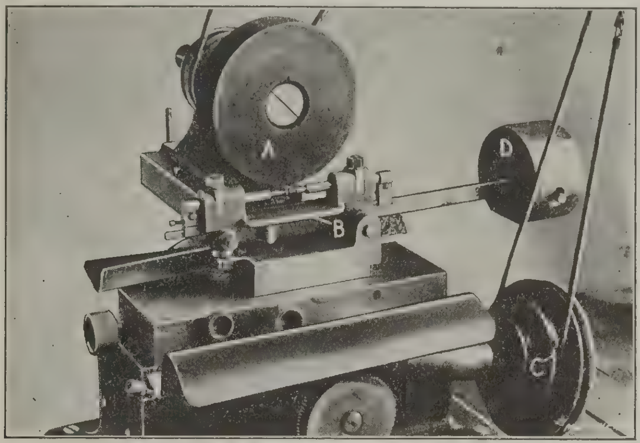

Fig. 38. Pinion Leaf Polishing Machine

edges are charged with rouge mixed with pure lard oil. The wing polisher is held in a bracket *B* which is fastened to a bell-crank *C*, the latter being operated by a connecting-rod fastened on the end of the driving shaft.

In operation, after the part to be polished is placed in the chuck, the frame holding the wing polisher is brought down and the latter kept in contact with the work, as shown in the illustration. As bell-crank *C* is fulcrumed at *E*, the action of the eccentric transmits an oscillating movement to the wing polisher. The machine is furnished with an idler pulley, so that it can be stopped by operating a foot lever, when inserting the work in the chuck.

Polishing and Grinding Pinion Leaves

As previously stated, all steel parts are hardened and tempered, and the pinions are no exception to this rule. After hardening, the leaves or teeth of the pinions are lapped in the machine shown in Fig. 38. The pinion is held between centers, which are retained in a stationary slide *B*. A circular lap *A* made of fiber, and provided with annular grooves, is charged with emery and driven at a high rate of speed. This lap is fed across the work by a cam in one direction and is returned by a coil spring. The cam is operated by a worm and worm-wheel driven from the grooved pulleys *C*.

Traversing the lap across the work rotates the latter on the center, so that all of the leaves are lapped. Weight *D* keeps the adjustable center in contact with the work.

* * *

An article in the *Zeitschrift des Vereines Deutscher Ingenieure* records a number of tests made with belting. These tests indicate that the tension when the flesh side of the belt runs onto the pulley can be 12.5 pounds per inch of width greater than the tension when the belt is run with the hair side in contact. The limiting speed with the hair side of the belt towards the pulley, is about 60 per cent of that with the flesh side towards the pulley.

THE MAKING OF BUSHINGS FOR DRILL JIGS*

PROPORTIONS OF BUSHINGS, MATERIALS USED, TURNING, HARDENING, GRINDING AND LAPPING OPERATIONS

BY F. B. JACOBS†

The making of a set of ten or twenty jig bushings is often looked upon as a long and tiresome operation with something of a degree of uncertainty as to results. This is especially true in some of the smaller shops as very few manufacturing concerns outside of the larger ones have anything like an effective system as applied to this class of work. It is not the intention of the writer to describe anything new but simply to outline the method employed in many of the medium sized shops in the Eastern states for getting out accurate jig bushings with a minimum amount of expense and trouble.

After the jig is bored the holes should be stamped 1, 2, 3, etc., and a chart drawn up as shown in Fig. 1. This need not be an elaborate affair as an ordinary pencil sketch will answer all practical purposes. The value of this chart is apparent, as the toolmaker can at a glance find any dimension for a bushing, thus saving much time that is generally spent in taking repeated measurements. For convenience the bushings are divided into three classes: Liners, shoulder bushings and slip bushings. If there are any solid bushings without shoulders that are used without slip bushings they can be listed with the liners. The letters A, B, C, etc. correpond to the dimensions of the bushings which are filled out in the chart in the spaces reserved for them. Two spaces are reserved under the column C for drill and reamer bushings that are to fit the same liner. The numbers 1, 2, 3, etc. correspond to the figures stamped on the jig to designate the different holes.

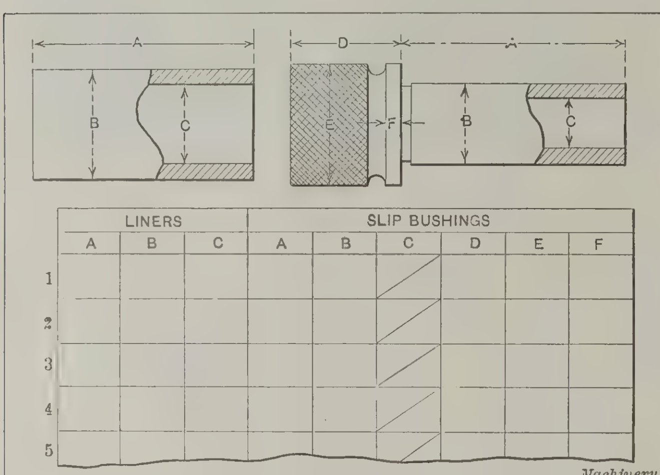

Fig. 1. Arrangement of Table of Jig Bushing Dimensions

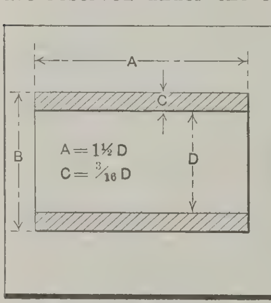

Fig. 2. Proportions of Lining Bushings

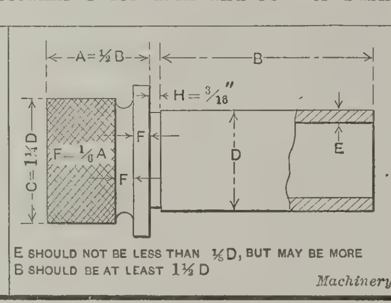

Fig. 3. General Proportions of Slip Bushings

Very few manufacturers agree on a standard for the proportions of jig bushings, each preferring to follow their own ideas. In many cases they are left to the discretion of the toolmaker himself. The proportions shown in Figs. 2 and 3 will generally answer in the majority of cases. When it is necessary to make bushings of unusual length they are often relieved as shown in Fig. 4. Solid bushings should have a shoulder as shown in Fig. 5, when it is intended to have stop collars run against them.

In Fig. 7 are shown three methods of holding bushings to prevent their turning: *A* shows a bushing having a pin inserted which slips in a slot cut in the lining bushing; *B* shows a bushing having a slot milled through the collar, a pin being located in the jig to engage this slot; and *C* illustrates a more elaborate device that is sometimes used. The stop button which is fastened to the jig prevents the bushing from being drawn out of the liner while withdrawing drills or reamers, as well as preventing its turning.

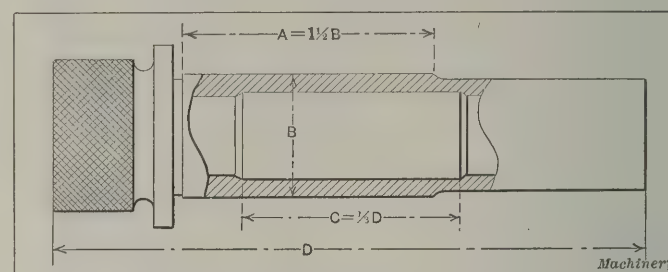

Fig. 4. Proportions of Bushings of Special Length

Bushings are generally made of a good grade of tool steel which insures hardening at a fairly low heat thus avoiding to a great extent the danger of fire cracking. They can be made in much less time from ordinary machinery steel which will answer all practical purposes, provided they are properly casehardened to a depth of 1/16 inch. Where many bushings are to be made a large percentage of the cost of stock can be saved by using machinery steel.

There are several methods followed in turning jig bushings. Some toolmakers prefer to "chuck out" the hole to the desired size and then finish the outside of the bushing by placing it on an arbor; others prefer to turn up the bushings two at a time, end to end, cut them apart and then bore as the final operation. This is an excellent method to follow when making large bushings. The most rapid method, however, is to chuck out the hole and finish up the outside at one setting using bar stock held in the chuck of a rigid engine lathe. This method is not always practicable on large bushings.

ALLOWANCES FOR GRINDING AND LAPPING BUSHINGS

Operation	Diameter of Bushings in Inches					
	½	1	1½	2	2½	3
A	0.008	0.010	0.013	0.016	0.020	0.025
B	0.0005	0.0005	0.0007	0.0008	0.0009	0.001
C	0.008	0.010	0.013	0.016	0.020	0.025
D	0.0003	0.0005	0.0007	0.0008	0.0009	0.001

A—Grind outside; B—Lap outside after grinding; C—Grind inside; D—Lap inside after grinding.

In making allowances for grinding and lapping, many toolmakers neglect to leave enough, which is the cause of many bushings having to be made over again on account of not finishing out. On the other hand many toolmakers leave too liberal an allowance for finishing thereby causing themselves a lot of unnecessary trouble and labor. The allowances given in the accompanying table can be safely used when the bushings are made somewhere near the proportions shown in Figs. 2 and 3, but for extra long bushings more liberal allowances should, of course, be made.

Before hardening the bushings should be plainly stamped with the size and purpose for which they are intended, "15/32 drill," "1/2 ream," etc. They should not be stamped with dull, worn out figures that are used by Tom, Dick and Harry on everything, but with a set of plain sharp figures reserved solely for this purpose. It is poor practice to try to stamp the words "drill," "ream," etc in a straight line,

* For additional matter on jig making and jig design see: "Locating Jig Buttons," June, 1912; "A New System for Locating Holes to be Bored on the Milling Machine," April, 1912; "Some Jig and Fixture Designs," January, 1911, and the articles there referred to. See also MACHINERY'S Reference Books Nos. 41 42 and 43, "Jigs and Fixtures."

† Address: 826 Arch St., Philadelphia, Pa.

as not one man out of a hundred can do this and turn out a respectable looking job. If, however, the words are laid out on a slight curve the results are more satisfactory as slight irregularities of alignment are not then so noticeable. Anyone can prove this to his own satisfaction by a little experiment with a steel alphabet and a block of cast iron. Sharp clean figures and letters neatly laid out not only improve the appearance of the toolmaker's work, but also save the drilling operator a lot of time as sharp clean-cut figures can be read at a glance.

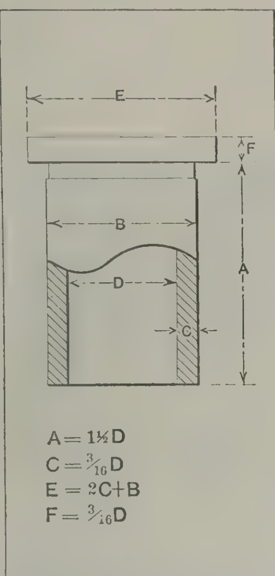

Fig. 5. Proportions of Shoulder Bushings

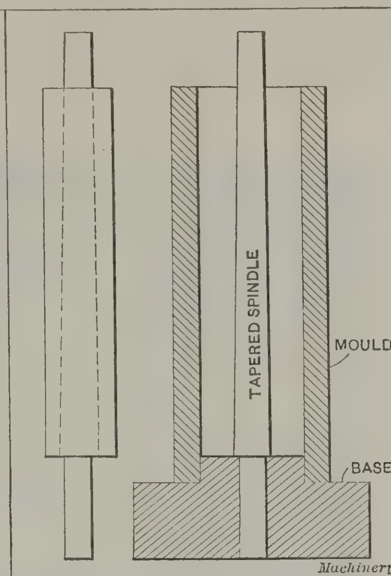

Fig. 6. Lead Lap and Mold used for Casting it

In hardening bushings made of tool steel they should be brought up to an even red heat in a clean fire, and the heating should never be hurried. If heated quickly the bushing is very likely to heat unevenly which invariably results in a warped piece that will not finish out. Gas furnaces are excellent for heating bushings preparatory to hardening. If, however, a gas furnace is not available a good clean charcoal fire in the forge will answer the purpose.

As soon as the bushing has been brought up to an even red heat it should be dipped in water warmed just enough to take off the chill. The bushing should then be brought up to a "sizzling heat" and left to cool in the air. Some toolmakers draw bushings to a medium straw color. This is a mistake as it only tends to shorten their life.

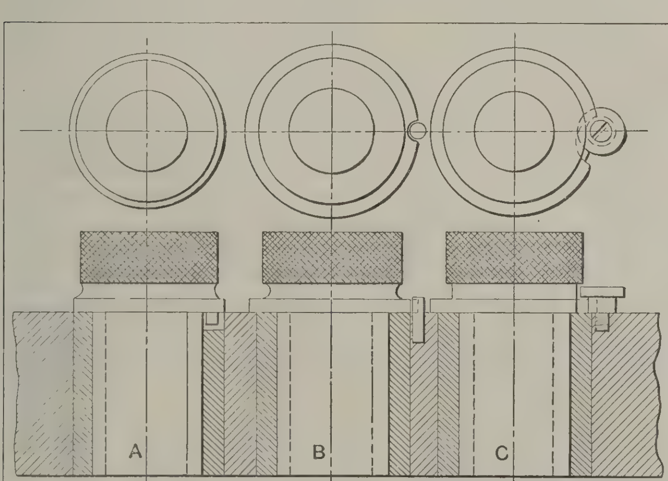

Fig. 7. Methods used for Preventing Jig Bushings from Turning

Grinding and Lapping

There are four methods in common use for finishing holes in jig bushings, *viz:* Lapping with a lead lap, lapping with a lead lap followed by a cast-iron or copper lap, internal grinding, internal grinding followed by a cast-iron or copper lap for removing the last 0.0005 inch. The first method is dead wrong as it invariably results in bell-mouthed holes, especially when the toolmaker charges the lap while in use, which is very poor but at the same time very common practice. The second method is correct for holes too small to be ground conveniently. The third method is wrong as the grinding wheel, no matter how fine, leaves innumerable very fine scores and high spots. These high spots soon wear away leaving the hole oversize. The last method is correct and should be used whenever possible.

In Fig. 6 is shown a lead lap with a steel tapered spindle, and a convenient mold for casting the laps. This mold is provided with a base having a hole to receive the spindle that the lap is cast on. A number of laps can be cast in this mold at one heating of the metal and afterward turned to the size required. Fig. 8 represents a familiar form of cast-iron lap. This lap is split in three places, and provided with a taper-end screw for expanding it to compensate for wear.

Laps should always be charged before—not while they are in use. A good way to charge a lap is to lay it on a cast-iron plate on which some of the abrasive material has been sprinkled. A cast-iron plate small enough to be conveniently handled is then held on the lap and moved back and forth with a regular motion. The lap being rolled between two surfaces picks up a certain amount of the abrasive material. A lead lap can be charged in this manner very rapidly, as the grains of abrasive material readily imbed themselves in the soft metal. A cast-iron lap, being of a harder material, requires more time to properly charge.

Until the last few years emery was the abrasive generally used for lapping. At the present time, however, aloxite, a product of the electric furnace, is displacing emery as it cuts faster, producing excellent results in a comparatively short time as compared to emery. Nos. 90 to 150 are used in connection with lead laps for roughing operations. For the final finishing with cast-iron laps flour aloxite is used. When not in use any abrasive used for lapping should be kept in a covered box to protect it from dirt and other foreign substances. A small chip or piece of grit will often cut a deep score in a piece of work—which neither improves its finish or workmanlike appearance.

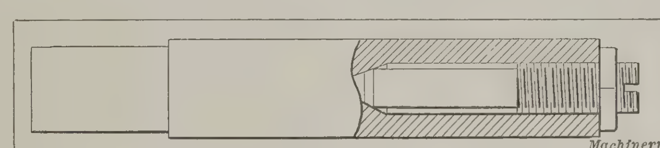

Fig. 8. Usual Form of Cast-iron Lap

Laps should always be run at a fairly low speed. Fifteen to twenty feet surface speed for a lead lap used for roughing, and twenty to twenty-five feet surface speed for a cast-iron lap used for finishing are about right. A high surface speed causes the lap to wear out without cutting as rapidly as it should. Many toolmakers make the mistake of running laps too fast, often causing unsatisfactory work.

For light lapping the work can be held by hand but with a heavy roughing cut it is best to hold the work with an ordinary lathe dog, care being taken to see that the dog is not clamped so tightly as to spring the work out of shape. Lead laps should be split to compensate for wear, and the spindles should have a groove cut along their entire length to prevent the lap from turning.

Before testing with a size plug the work should be washed out with benzine or gasoline to remove all traces of the abrasive material, a few grains of which will wear the size plug below standard size in a surprisingly short time. Washing in benzine or gasoline also brings the work to the same temperature as the size plug, which is important where extreme accuracy is required.

Many toolmakers look on the finishing of jig bushings by internal grinding as a rather uncertain method, whereas it is a comparatively simple process when the following important factors are carefully considered. First, proper selection of grinding wheels; second, correct wheel speeds or at least as near as the design of the machine will permit; third, correct alignment of the headstock in regard to the

travel of the platen; and fourth, proper truing of wheels.

Wheels for internal grinding should be of a medium grit, soft grade and open bond. As a rule the grit should never be finer than 60 grit; in fact a coarser grit can often be used to advantage. Wheels with fine grit cut slowly, fill up readily, glazing and invariably heating the work and causing chattering and other troubles too numerous to mention. In fact the only argument in favor of a fine grit wheel is that it leaves a smooth surface. However, no matter how smooth the surface appears to be, even under a powerful glass, it will have to be lapped to remove the wheel marks for the reason previously stated. When we stop a moment to con-

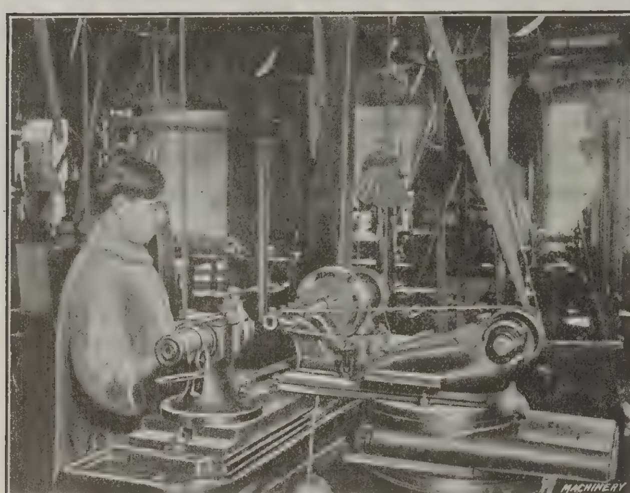

Fig. 9. Grinding the Holes in the Bushings

sider that 0.0005 inch will perfectly lap out the marks left by a 60 grit wheel, there is not much room for an argument in favor of 70, 80, and finer grit wheels.

For the internal grinding of jig bushings on a Brown & Sharpe No. 2 universal grinder, as shown in Fig. 9, the writer has used aloxite wheels, 1½ inch diameter, ⅜ inch face, 60 grit P grade, D-495 bond, with excellent results, the wheel speed being 12,000 R. P. M. The bushings aver-

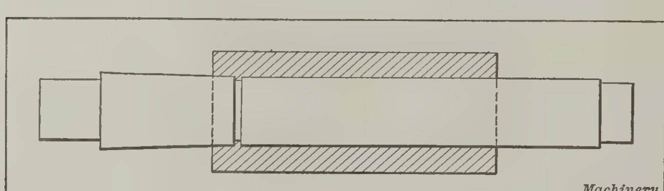

Fig. 11. Arbor for Holding Bushings

aged 2½ inches long, 1¾ inch hole. The holes were rough bored 0.015 inch being left for grinding. The grinding time per bushing, including chucking and truing up, was twelve minutes each and the finish left was good, 0.0005 inch being sufficient to lap out the wheel marks. Reference is made above to the holes being rough bored; this is good practice as the rather rough surface tends to wear the wheel just a little while removing the fire scale thus preventing the wheel from glazing. Once the scale is removed from the hole, the wheel should not glaze readily provided it is of the proper grit and grade.

Wheels for internal grinding should in theory be run at a surface speed of 5000 feet per minute. This, however, is a general rule open to exceptions. A safe practical rule to follow is to speed up the wheel if it wears away too readily, and to reduce the speed where the wheel shows a tendency to glaze. A little attention to this rule will often save much trouble. The toolmaker should bear in mind the fact that it is much easier to adjust the speed to suit the wheel, than it is to try to keep on hand a large variety of wheels to suit all speed conditions.

Assuming that the work in question is to be done on an ordinary universal grinder, the headstock must be set parallel with the travel of the platen to produce straight holes. A practical way to determine parallelism is to clamp a piece of round stock in the headstock chuck, letting it project from the jaws a little farther than the length of the holes to be ground. This piece should have a groove turned in it for the wheel to dwell in during reversal. This test piece is then ground in the regular way with the wheel used for cylindrical work, the headstock being adjusted by means of its swivel base until the test piece is ground parallel. Before calipering, the wheel should be allowed to grind until very few sparks are visible. When once this test piece has been ground straight the setting can be depended on to produce straight holes, provided, of course, that the swivel adjustment of the headstock and the angular adjustment of the platen are not disturbed. To try to straighten up the headstock by calipering the work while the internal grinding is in

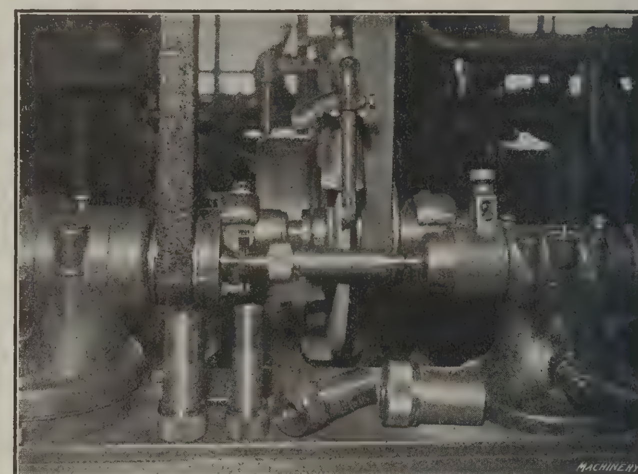

Fig. 10. Grinding the Outside of Slip Bushings

process is at best a difficult job, and the operator is never quite sure of accurate results.

It is common practice to true wheels for internal grinding with a diamond fed by hand, using the eye as a guide. This is poor practice as the wheel is seldom turned parallel, one edge being left to do all the cutting, which, of course, glazes it readily. A more practical way to true these comparatively soft wheels is to feed them past the end of a carborundum rub, in 20 grit H grade. The rub can be held in a suitable holder strapped to the platen of the grinder, or held firmly by hand against the end of the work. As a carborundum rub shows high efficiency when used for this purpose and costs practically nothing as compared to a diamond it is worth considering.

In holding work in the chuck for internal grinding, it is well to exercise due care to see that the work is not clamped hard enough to spring it out of shape. As a rule it does not require much pressure to hold work of this nature as the grinding cut is comparatively light. Attention is again called to Fig. 9 where it is seen that the chuck used in this case is of the variety commonly used on tool lathes. It is my opinion, based on practical experience, that this chuck is an improvement over the chucks commonly supplied with universal grinders, as it is more substantial and has reversible jaws which can be used independently or universally.

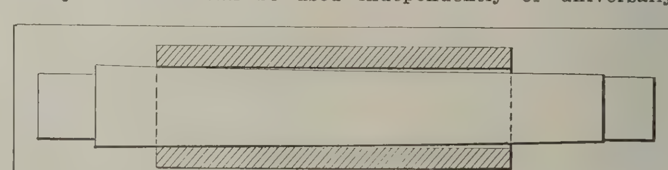

Fig. 12. Improper Fit of Bushing on Ordinary Arbor

As it is general practice to grind internal work dry a certain amount of expansion from frictional heat is always present. For this reason considerable care has to be used in calipering the work with the sizing plug. As the plug is many degrees cooler than the work it is liable, on being inserted, to contract the bushing suddenly, causing bushing and plug to "freeze" together firmly. This can be avoided by cooling the work with a plug that is known to be undersize before calipering with a plug of the desired size. The final calipering should also be done with a plug that is undersize to allow for the final finishing by lapping.

When a wheel of 60 grit is used, a hole one inch or under in diameter should be left approximately 0.0005 inch under size. This amount is sufficient to lap out the wheel marks and leave a dead smooth mirror finish to the hole. This is a general rule based on the fact that a certain amount (in this case 0.00025 inch) is enough allowance to lap out the marks left on a surface by a grinding wheel, and that should suffice for all holes regardless of size. With comparatively large holes, one and one-half inch diameter or over, it is better, however, to make allowance for finishing, owing to the fact that the area of contact of wheel and work is generally not so great and the ground surface is not quite so smooth.

In regard to the external grinding of bushings, there are two important points that should be given consideration,

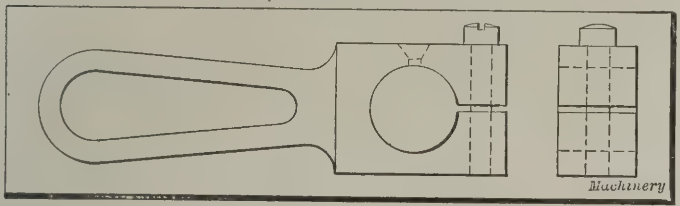

Fig. 13. Lap for Finishing Outside of Slip Bushings

viz: the selection of wheels and method of holding the work. The wheel should be fast cutting and at the same time it should hold its shape and leave a good finish—not the painfully fine finish that delighted grandfather while experimenting with the toolpost grinder, but a good dead finish from which the wheel marks can be readily lapped.

For this work in connection with a Brown & Sharpe No. 2 universal grinder I have obtained excellent results with an aloxite wheel 12 inches diameter, ½ inch face, 5 inch hole, 405 grit, N grade, D-497 bond, the wheel being run at a speed of 1800 R. P. M. In grinding some slip bushings as shown in Fig. 10, the finished surfaces averaging 1½ inch diameter, and 2½ inches long, a work speed of 75 feet per minute was used. The traverse feed of the work was the fastest that this machine was capable of giving in connection with the above work speed, and was approximately an advance of one-fourth the width of the wheel for each revolution of the work.

The finish was excellent and the grinding time for each bushing, removing 0.012 inch, was five minutes. This was accurate work, 0.0004 to 0.0005 inch being left for the final finish by lapping. The above wheel is known as a combination grit, in a medium soft grade and an open bond, and I consider it a great improvement over the hard bonded straight grit wheels used in many toolrooms.

The above work was not done with the idea of establishing a record for this class of grinding, but the object was to show a grinding machine operator what could be done in the line of cutting down production costs by the use of a modern grinding wheel. His time for grinding the same bushings, using a wheel in straight 60 grit, M grade, made by a reliable manufacturer, was fifteen minutes each. He had to use a fine traverse feed, the finest that the machine was capable of giving with a 65 feet per minute work speed to get the desired finish, and to avoid chattering and undue heating of the work.

When a number of bushings are to be ground one after another it is best to mount them on arbors of the same length when practicable to do so, thus saving considerable time generally spent in re-setting the platen, which has to be done whenever the tailstock is moved to accommodate arbors of different lengths. An arbor for holding bushings should be made as shown in Fig. 11. The straight part should be a good fit in the bushing, a slight taper on the remainder of the arbor being sufficient to prevent the bushing from turning on the arbor. When bushings are held on an ordinary arbor or mandrel the operator is never quite sure that the hole and the outside of the bushing are concentric, as one end of the arbor owing to its taper does not quite fill the hole. This is illustrated in Fig. 12. Both Figs. 11 and 12 are somewhat exaggerated to illustrate the principle.

In grinding lining and solid bushings due allowance must be made for a driving fit in the body of the jig. There are three methods in common use for making driving fits on this class of work: First, grinding the bushing until the lower end just enters the hole, the bushing being slightly tapered to bring it to a snug fit when pressed into place; second, grinding the bushing straight for its entire length, leaving it just enough oversize to make a good driving fit; and third, grinding the bushing for nearly its entire length just enough oversize to make a good driving fit, and grinding about one-eighth its length just enough undersize to enter the hole.

The first method is not considered strictly first class practice as the bushing contracts more at the top than elsewhere owing to the taper which leaves the hole in the bushing tapered. The second method is very poor practice as the bushing is very liable to cramp while being forced in place which results in an unsatisfactory job as the hole in the jig is generally sheared by the sharp end of the bushing. The third method is correct as the part that is ground to fit the hole acts as a pilot, thus insuring the proper starting of the bushing, and the body being straight insures even contraction.

In making allowances for driving fits 0.001 inch for each inch diameter of the bushing is considered practical where the holes are one inch or over, and where the holes in the jig are bored smooth. If the holes are rough bored a more liberal allowance is required. After the lining bushings are driven in place they require re-lapping as they always contract a little.

The outside of the slip bushings should be finished by lapping to a dead smooth finish as otherwise they will soon wear loose. This should never under any circumstances be done with emery cloth, but with a cast iron lap as illustrated in Fig. 13. The abrasive used in this case should be of flour grit with lard oil as a lubricant, the abrasive and oil being applied through a hole in the top of the lap. The work should be lapped with a regular even motion to insure its being straight, and should be brought to the temperature of the room by being cooled in benzine or gasoline before testing for a fit. The lapping should be carried to a point where the bushing is a wringing fit in its liner, but not tight enough to stick when left alone for a moment.

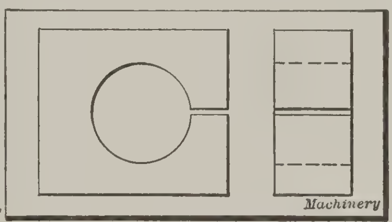

Fig. 14. A Cast-iron Lap which may be used in Emergency Cases

The lap shown in Fig. 14 is often used in an emergency; it is readily made from cast iron and held with an ordinary machinist's clamp. It is practical but not as handy as the lap illustrated in Fig. 13.

After the grinding and lapping of the slip bushings is complete, their tops can be finished by lapping on a carborundum stone, in medium grit, wet with gasoline. A regular motion should be used across the face of the stone without turning or altering the relative position of the bushing. This lapping gives the bushings a workmanlike appearance, and as the dimensions stamped are left black from the action of the fire in hardening, they can be read at a glance.

* * *

In a brief article in *Canadian Machinery*, Mr. Charles T. Main emphasizes a point on which there is a great deal of narrow misunderstanding. Many men possessing technical knowledge seem to believe that they serve their own best interest by keeping it to themselves, whereas, as Mr. Main says, an engineer possessing information, not of a private nature, of benefit to the profession in general, should be broad enough in his outlook to publish it for the benefit of his brother craftsmen. He will find on looking at the matter even from a selfish point of view, that he will not be the loser, for it will bring him into greater prominence and call attention to the fact that he is the man to be employed or consulted in work involving this particular experience. Such men should always be glad to impart to others any information available.

FINE SCREW THREAD STANDARDS

The Navy, U. S. or Sellers standard screw threads have been widely adopted in America, and are satisfactory for the general run of machine work. They have been used for years in the construction of locomotives, cars, steam and gas engines, mining machinery, farm machinery, etc. But satisfactory as the U. S. standard has been, time has shown that it has limitations of use. The automobile is the most prominent example of a highly developed machine in which the need of finer screw threads was manifested. The jar and vibration incident to high speed and rough roads loosened screws and nuts threaded to the comparatively coarse U. S. system, and finer screw threads were required to prevent loss of parts and rapid deterioration. The French car manufacturers recognized this fact early in the development of the automobile.

In April, 1906, the Association of Licensed Automobile Manufacturers adopted a fine pitch screw standard ranging from ¼ to 1 inch diameters inclusive, and varying by sixteenths to ¾ inch and by eighths to 1 inch. This standard was extended to 1½ inch diameter June, 1911, by the Society of Automobile Engineers, the successor of the A. L. A. M.

The need of a fine pitch screw thread system to supplement the U. S. system is also being felt in the machine trade generally. In order to provide for this need it is proposed to adopt the S. A. E. standard and extend it upward to say 4 inches diameter in harmony with the pitches from ¼ to 1½ inch now existing. Replies to a circular letter sent by MACHINERY to the machine building trade indicate that many concerns have adopted the S. A. E. standard screw threads where fine pitches are required, and would gladly use them for most purposes in larger sizes if they were provided.

The extension and general adoption of the S. A. E. standard would undoubtedly simplify the special thread tool problem for the tap and die makers and relieve them of making many special fine thread taps and dies now demanded. The general adaptability of the two standards is set forth in an extract from a letter from a well-known builder of special machinery:

"The A. S. M. E. and S. A. E. standards for diameters and pitches of screws adequately supply our wants for screws of fine pitches. We rarely find the necessity for any finer pitches in the diversified types of machinery and devices that we are called upon to design or construct, and this occurs only when some peculiar condition of design demands it. From our observation and experience in the design and construction of typewriters, sewing machines, adding machines, tabulating machines, type casting machines, ticket vending machines, auto capsule machinery, knitting machinery, Lanston pneumatic keyboards, etc., we can see no reason why another standard of finer pitches than those obtainable in the A. S. M. E. and S. A. E. standards should be established."

THE INFLUENCE OF SHOP CONDITIONS

In a comment on the value of well-equipped shops and pleasant working conditions, the *Engineer* (London) remarks that good machine tools mean good workmen to run them. A manufacturer of machinery who had recently reconstructed his machine shop, converting an old-time, dingy shop into one containing the best equipment, arranged and lighted so as to provide for the highest efficiency, stated that he found it much easier to obtain high-class workmen as soon as it became known that they were to operate high-class machine tools.

It is a mistake to believe that all machine operators work for wages only. Many men operating machines in obscure corners of a shop take considerable pride in the work they do, and they enjoy an opportunity to use the best and most accurate machines. Another of the erroneous, old-time ideas which are apparently giving way to a sounder appreciation of the workman's feelings, is that the average machinist, having to perform work in which he cannot possibly keep clean, does not care whether his surroundings are clean and comfortable or not, but is satisfied to work under conditions of any sort. The new plants being erected all over the country show that employers are realizing the value of light, airy and comfortable workshops, and that the additional investment required is money well spent, as it increases the efficiency of the men and lessens discontent, which is the most subtle cause of inefficiency the manager has to deal with. Other conditions being equal, the firm with a clean, light and well-equipped plant will have much less difficulty in getting along with its workmen than one with a dark and dirty shop. It is not without reason that the industries where labor troubles are most frequently encountered are those where the workmen are employed under unsanitary or uncomfortable conditions.

* * *

INVESTMENTS IN UNDEVELOPED INVENTIONS

If the history of "frenzied finance" and dishonest promotion is ever accurately written it will include many cases of patent exploitation wherein inventors and investors were fleeced by smooth-tongued sharpers who promised to develop and market valuable inventions. Some of the most ingenious discoveries and mechanical designs of the times are hopelessly tied up in litigation resulting from the organization of companies and sale of stock before the inventions were developed.

Capital is necessary to place most inventions on the market, and no matter how meritorious a device may be, considerable argument and persuasive ability on the part of some one having faith in it are generally required to obtain the necessary funds from capitalists. The reluctance of capitalists to invest in unknown possibilities is not shared by clerks, bookkeepers, laborers, servant girls and others eager for large returns on small investments, and this fact is shrewdly turned to advantage by promoters who paint in bright colors the probable returns, quoting perhaps the experience of the original investors in telephone stocks as an example of enormous profits yielded by an invention. Inexperienced people who turn over their money for investment in stocks whose value is problematical are too often bitterly disappointed.

A safe rule to follow is to invest nothing in an undeveloped invention unless you have first-hand knowledge of its scope, its novelty, the probable market, and the character of the men who are promoting it. Even when you possess this knowledge the chances for failure are many, and the investment should be made with full appreciation of the possiblity of loss. Widows, orphans and others whose capital is their only resource should steer clear of mechanical promotion schemes generally. Although not usually conceived with the dishonest intent characteristic of mining schemes, they are nevertheless hazardous investments, quite likely to result in loss.

STANDARDIZATION OF MACHINE TOOL PARTS

It is a proper function of the engineer to conserve as well as to produce. Production with waste is abhorrent to the engineer who fully appreciates his economic relation to the manufacturing world. In fact, engineering is the science of producing efficiently, which means the elimination of false movements and waste effort, the utilization of waste products and the substitution of mechanical power for human muscular effort. The elimination of waste carried to the logical end in engineering work would put an end to competition, but that is a condition of society too far removed from present possibilities for serious consideration now. What we can do is to work for those results which in a competitive world may be agreed on as being for the common good.

In the manufacture of machine tools there is little in common as regards sizes and shapes of those parts in the design of engine lathes, planers, shapers, drilling machines and other so-called machine tools made by the various builders for which interchangeability is highly desirable. It is plain to any unprejudiced person acquainted with the conditions of use that certain standards might be adopted by machine tool builders with advantage to themselves and their customers.

For example, take the floor plan of a dozen different makes of sixteen-inch lathes, and it will be found that, although the variation may be little, practically twelve different layouts of foundations will be required. This is a wasteful and undesirable condition, and it would seem that two foundation plans, one for light and the other for heavy designs, should suffice. Surely this is a difference on which it should be comparatively easy to reach common ground for agreement. A similar understanding might be applied to the spacing of bolt holes in countershaft hangers, and any other features affecting the installation.

The more vital matters on which agreement is desirable are standards for lathe spindle noses, dimensions of tee-slots, direction of feed for a given direction of rotation of a feed handle, general position of handles, dimensions and taper of taper shanks and sockets, number of threads per inch of lead-screws, etc.

The matter of agreement of lathe spindle noses is so important that some manufacturers adopted private standards years ago, and specify them when ordering new equipment. One system that has proved satisfactory is the common U. S. standard bolt screw thread sizes. With this system, chuck and faceplates can be sized with standard taps thus simplifying the home making of special lathe attachments.

The Society of Automobile Engineers has worked out several important improvements in manufacturing conditions by which useless duplication of sizes of stock parts have been eliminated. The work of this society is most commendable and constitutes a worthy example for other societies and associations of manufacturers, to imitate.

THE VALUE OF COST SYSTEMS

In speaking before the American Society of Swedish Engineers recently, Mr. H. L. Gantt, of scientific management fame, pointed out that there are two distinct objects to be accomplished by cost systems and records of factory performances. One purpose of a cost system should be to enable those occupying responsible positions connected with the production to obtain such information as may enable them to devise new and better methods and improve old ones, and to have definite information at hand showing to what extent the new methods actually are more economical than those of former practice. In some shops, however, Mr. Gantt found that the cost system was not kept with this object in view. Very few people connected with the production end of the factory were permitted to make use of the data recorded, and the cost system merely afforded those in charge an opportunity for criticism and fault-finding. No effort was made to devise more economical methods, or to locate the trouble in a systematic way when one month's performance did not come up to that of a preceding month. The executive used the record merely to hold up before his superintendent and foremen, telling them that they did not run their departments as they should.

A cost system run in this way is almost worse than useless; it creates discord and does not serve to increase production. The real purpose of such a system should be to show at any moment if production is falling behind; and a systematic effort should then be made to find the cause, not merely by blaming an individual, but by locating with accuracy the exact conditions which are the cause of the decrease. These conditions may be beyond the control of any of the persons ordinarily blamed. In a machine shop they may be due to hard castings or other defects in the material supplied to the department. They may be due to improper heating and ventilation of the plant. They may be due to unavoidable changes in the personnel. Whatever the cause, it should be ascertained; and unless the cost system accomplishes this, it is of little value because merely blaming a man does not enable him to remedy a defect. He must first find the cause, and the cost system should help him to do that.

Of equal importance is the function of the system which enables foremen, superintendents, designers and others vitally interested in production to determine the value of new ideas; and in order that the cost system may fulfill its purpose in every respect, men in responsible positions within the factory must be given access to the cost data compiled.

THE PATENT THAT GEORGE DIDN'T TAKE OUT

BY A. P. PRESS

George was a good toolmaker, and when he was not making tools he was playing whist, and although he was an expert at both, I think his abilities in the whist playing line rather lapped over his toolmaking capacity.

Now we have all played whist, and when you have a good sized party in the dining room and parlor, the next morning the floor is covered with the scrap punchings where the score is punched out of the cards.

So as they sat at the breakfast table one morning, with the floor covered with chips, Mrs. George said:

"George, why couldn't you put a pocket on the punch, so as to catch all these little pieces? They are awful hard to sweep out of the carpet."

"Sure thing," said George, and that morning after he got a long chip started, and the boss had gone out for an hour, he turned up a pretty little brass sleeve, and soldered it on to the under side of the punch. He put a threaded cap on the end, so he could unscrew it and empty out the punchings.

He took it home that night, and his wife was enraptured. They used it the next whist night, and his friends all complimented him on the success of his invention.

"Why don't you have it patented? There is a fortune in it if you get hold of somebody to push it for you."

When you get the patent microbe started in a man's brain, it is a pretty hard thing to exterminate it, and George went down to see a patent lawyer the next afternoon.

"Yes," said the lawyer, "that is a pretty good thing, but you ought to have a better looking sample than that. You should get a nicer looking punch, and put it on that."

That night after supper, George got busy. First he sent the oldest boy down to the hardware store and told him to get the nicest ticket punch he could find. The kid came back, and George undid the package, took it out, and there was the cutest little punch you ever saw, with a pocket on it to catch the chips and patented some ten years before!

The microbe was exterminated from George's brain.

* * *

A German contemporary publishes an article in which the writer discusses the theoretical principles of the Tesla steam turbine described in MACHINERY, November, 1911, and also referred to in a note in the July number. The German author points out that the efficiency cannot exceed 50 per cent with the construction employed, and on larger sizes the efficiency would be proportionately less.

INDUSTRIAL ADMINISTRATION AND SCIENTIFIC MANAGEMENT—3

CONSIDERATION OF THE MOST IMPORTANT OBJECTIONS TO SCIENTIFIC MANAGEMENT

BY FORREST E. CARDULLO*

Enough has been said to show that laws and economic conditions have a very great effect upon our industries and the efficiency with which they are conducted. Changes in the law which decrease efficiency are usually objectionable and changes are usually more far-reaching and important than most men believe to be possible. While the engineer usually considers such matters to lie entirely outside his work, yet they affect it so vitally that he will before long be compelled to give them his attention, and to apply to them the same hard-headed and rigorous analysis that he now gives to the design or construction of a piece of machinery. When he does, the lawmaker will regard his efforts skeptically, the financier will regard him as a meddlesome bungler, and most men will regard him as a gross materialist without proper regard for the higher things of life.

In the same way that we have previously classified and examined the sources of industrial inefficiency, let us classify and examine the objections which may be raised against scientific management. These objections come from three sources, the employer, the employe and the public.

Objections of Employers to Scientific Management

Taking first the objections raised by the employer, they usually arise either from a misunderstanding of what scientific management is or from a misconception of the fundamental principles of industrial administration. The objection most often raised is that scientific management very greatly increases what some men term the "expense burden" and what others term the "overhead charges." This is true and yet it is not an objection to scientific management if it can be shown that the total cost of manufacturing a given product is reduced by thus increasing the overhead charges. The introduction of a drafting-room or of a pattern-shop into an establishment which has previously purchased such work outside, will increase the overhead charges, but most plants find it cheaper to maintain drafting-rooms and pattern-shops in spite of this fact. If four men are employed, it is just as well to have one of them constantly engaged in planning the work of the other three, and keeping them supplied with tools and material, as it is to have each one plan his own work and run his own errands.

The question of whether scientific management unduly increases the expense burden is one which can only be answered by experience and in the terms of dollars and cents. If the cost of doing a given piece of work is reduced by scientific management, the question of the ratio of the overhead to the direct charges is of no consequence. If, on the other hand, the cost is increased by scientific management no other argument is necessary in order to condemn the system, and the ratio of the direct and indirect expenses is a matter of purely academic interest.

While some employers are willing to admit that the cost of manufacture is reduced when scientific management is employed, they advance the argument that while direct labor may be discharged when it is not employed, the men in the planning department cannot be discharged without destroying the efficiency of their organization, and so must be retained at considerable expense during periods of industrial depression. Similarly, while the wage cost is cut off entirely when men are discharged, the extra fixed charges upon the larger plant usually called for by scientific management, do not cease when times are slack, and that, therefore, in those industries which are particularly subject to periods of depression, scientific management will be a failure, although during periods of prosperity, it may show a reasonable saving in costs of manufacture. To this objection two answers may be made. First, when scientific management shows a gain after taking account of the periods of depression, it ought to be adopted. Second, if scientific management enables a firm to manufacture more cheaply than competitors, that firm will be able to accumulate a surplus so that it can continue to manufacture and store its product when it would otherwise have to be sold at a loss. Furthermore, it will be able to undersell its competitors, will do a fairly large business in dull times, and will therefore be able to operate its business with less attention to industrial conditions than is given by other firms. If scientific management is able to show a saving at any time, the chances are that it will be able to show a saving all of the time.

A third objection often raised to scientific management is that when a shop is run as systematically as this method of management requires, a sudden change in plans is impossible without seriously disarranging the work, so that the rush order or the special job does not receive the attention which it should. The answer to this objection is that scientific management should contemplate all of the conditions likely to arise in the plant and should provide special means for expediting certain work when that is necessary. If such special means are not provided, the system is imperfect and is not scientific management since it is not adapted to the needs of the particular plant.

A great many objections raised against scientific management come from men who have seen shops in which scientific management has been attempted by managers, superintendents or others, who did not understand what it was. Such men have often attempted to combine scientific management with conventional systems, and while they have sometimes developed improvements, they have often fallen into ludicrous blunders. Such blunders cannot be charged to scientific management, and when it is claimed that scientific management has failed in specific instances, it is well to investigate the case, and see whether the failure is one of scientific management or of unscientific management.

Objections of Workmen to Scientific Management—Wearing Out Men

On the part of workmen there is considerable objection to scientific management. I believe that it usually arises from an idea that efficiency lowers wages and throws men out of employment. This objection, however, is rarely if ever alleged, but others are sought to take its place. The first one, and the one worthy of most serious consideration, is the objection that under scientific management men are urged and compelled to work at such a pace that their health and vitality suffers. Now it is doubtless true that men can be overworked in certain industries, but it is equally true that it is very difficult to overwork men in most industries unless the hours are unusually long. What is termed overwork is usually a matter of unsanitary laboring or housing conditions or insufficient nourishment. For instance, a man may be compelled to work in a cramped position or exposed to great heat or poisonous vapors, he may be compelled to eat and sleep in a hot and dirty tenement, or his wages may be too small to buy nourishing food. If the adoption of scientific management lengthens the time during which he is exposed to unsanitary conditions, his health will suffer, but this is not a matter of overwork but a matter of industrial sanitation. Scientific management recognizes the fact that workmen are often exposed to unsanitary conditions, but the scientific method is to change the conditions and not to reduce the amount of work required.

When we come to discuss the trades usually carried out under sanitary conditions, and requiring a considerable expenditure of muscular effort, we will find that the amount of effort required to accomplish a given task may be reasonable for some men but unreasonable for others. Whether a task is too severe or not, depends on the strength and endurance of the individual workman. Tasks possible for a vigorous man are impossible to one who is ill or weak. Men lacking in strength or vigor are not fitted to engage in certain occupations and they should be transferred to other occupations for

* Address: Department of Mechanical Engineering, New Hampshire College of Agriculture and the Mechanic Arts, Durham, N. H.

which their physical defects do not unfit them. For instance, a man whose strength is unequal to the tasks demanded of a hod carrier or blacksmith helper may be very well fitted to become storekeeper's assistant or to operate a punch press.

In this connection it must be noted that a man is not like a machine, but that the wear and tear of the body are repaired by periods of rest. So long as the degree of exertion required of a man is not such as to produce discomfort when continued for several minutes, and so long as proper rest periods occur at suitable intervals throughout the day, the man will not be overworked, but after becoming accustomed to his task will be able to continue his work week after week without any diminution of vigor. If he is properly nourished and works and lives under sanitary conditions, such a man will be just as vigorous and long-lived as though he were engaged in some less laborious occupation.

As a matter of fact it does not pay to wear men out. If men are caused to work at such a rate that their vigor diminishes, they will in their lifetime do less work than they would had they worked at a slower and less exhausting pace, and both the industry which employs them and the community in which they live will suffer accordingly. On that account we need have no fear that scientific management intends to overwork men, although in isolated instances men may be overworked under scientific management either because they are not fitted to the task to which they are assigned or because the one assigning the task was not experienced enough or careful enough to assign a proper task.

One of Mr. Taylor's early successes was to increase the amount of pig iron carried by laborers by properly training them for the task. The amount of pig iron carried after proper training and selection was about forty tons against a previous record of ten tons per day. The first laborer trained for this task was a man named Schmidt, and one of Mr. Taylor's critics thinking the task excessive and severe, very justly inquires, "What became of Schmidt?" Mr. Taylor informs me that Schmidt is at the present time well and hearty and still capable of strenuous tasks and financially much better off than he would be had he not been helped by scientific management.

Harder Work without Corresponding Pay

The second objection raised by workmen against scientific management is that the men are expected to "work very much harder" without receiving a corresponding increase in pay. Often by the introduction of scientific management, a man's output will be increased three or four fold while his wages will be increased not more than from thirty to sixty per cent. The average workman feels that under such circumstances his wages should be increased in the same proportion as his output. When, however, we come to analyze the matter, we find that the workman's contention is not true and that he ought not to expect his wages to be increased in that proportion.

When a man receives his wages, he is paid for several things. In the first place he is paid for his time. In order to get a grown man of potential value as a workman to come and sit in an office and do nothing for eight hours a day, or even to amuse himself in some manner, it would be necessary to pay him something, and probably it would be hard to find men willing to undertake such work, if it may be called work, for a dollar a day. In the second place he is paid for his physical effort. Work requiring no knowledge or experience and which merely requires physical effort does not usually command very good pay. Of course it commands more pay than does the mere expenditure of time, but certainly the effort which an ordinary laborer puts forth, cannot be estimated to command more than 75 cents to $1 a day, and I doubt if the average laborer who receives $2 per day would be willing to take a job at $1.50 per day which did not require any expenditure of effort. A third element for which a man is paid is the ability to receive and understand instructions. A fourth element is skill or dexterity, which enables him to perform a task quickly and well. A fifth element is a knowledge of the details of a trade, which is usually attained by experience and observation.

Let us suppose that a man is engaged in the turning of heavy pieces of steel and that by means of scientific management (*i.e.* by furnishing him proper tools, by standardizing the material, and by informing him of the proper speeds and feeds to use) his output is increased three fold. The time required is the same as before. That portion of his wages which he receives for time expended should therefore be the same as before. The effort required is three times as great as it was before. Since, however, the most of his time is expended in watching his machine and only a small portion of it in changing tools and work, the pay which he receives for the effort expended is very small, and the increase in pay due to the increased effort is proportionately small, certainly not more than 25 to 30 cents per day. The dexterity which he has, and the knowledge of the details of his trade, are no greater than before, and these elements do not call for any inccrease in his wages. A larger measure of ability to follow instructions is required, and this element of his pay should be increased. Of the five elements of his pay two require an increase, and three should remain unchanged. Altogether the increase in pay required by the extra effort and by the increased ability to follow instructions is quite modest, and if the man receives thirty or forty per cent increase in wages, he has received all that he can in fairness ask for. The only way in which we can fix a fair rate of pay is by reference to the rates received by other men engaged in substantially similar occupations. The application of scientific management in different industries will result in different increases in efficiency. In some lines a workman's efficiency will be increased only 20 or 30 per cent, while in other lines it may be increased five hundred or even one thousand per cent. If the work done in the two lines is similar, the pay of the workmen is probably nearly equal before the introduction of scientific management, and ought to be equal when they have attained their best efficiency.

Let us take as an example a foundry in which two different molders are engaged, one on light brass molding and the other on heavy iron molding. Let us suppose that each is paid at the rate of forty cents per hour, that the brass molder puts up twenty flasks a day, and that the iron molder puts up two. Let us suppose that as a result of a careful time study it is found that the brass molder can, without tiring himself unduly, put up thirty flasks a day, while the iron molder can put up six. Each man is then working at his best rate, and while it might be possible for him to do a trifle more work, it can only be done at the expense of his physical welfare. If now, the pay of each is increased in proportion to this increased output, it will be seen that the brass molder will get a fifty per cent increase and the iron molder a 200 per cent increase, the brass molder receiving 60 cents per hour, while the iron molder receives twice as much, or $1.20 per hour.

Now, when you come to think over the results of the application of time study in these two cases, it will be plain that if the work of the brass molder was formerly worth 40 cents an hour, that of the iron molder was worth only 20 cents an hour, and it would be highly unjust after the change in conditions had taken place, to pay the iron molder twice as much as the brass molder. In other words, for work requiring substantially the same intelligence, the same effort, and the same training, workmen should receive substantially similar pay, and this pay should be based upon what constitutes a fair wage under the best conditions, and when they have reached their best efficiency.

The same thing which applies in the case of two molders will apply in the case of two different trades in the same industry, or for that matter, in different industries. If the efficiencies of the workmen engaged in two different trades were unequal before the introduction of scientific management, it follows that injustice will be committed if the increase in wages in each trade is made proportional to the increase in output after, in each case, the workmen have attained their best efficiency.

Another way to look at the matter is to treat it as though the workman were selling his labor under the same conditions as any other commodity. Whenever there is a great reduction in the cost of manufacturing a given product, we expect that there will be a corresponding drop in the price, and usually this is true. The cost to the workmen of doing a given piece

of work is the cost of living. The fact that he does a much larger amount of work than he did before does not increase his cost of living, and consequently the cost to him of doing a given amount of the work is materially reduced, being in the case we have chosen, only one-third of what it was before. Under such conditions the employer may reasonably expect that there will be a decrease in the labor cost, and while the workmen should expect to get higher wages, the employer expects with reason, to pay a lower price per piece. When the workman has an opportunity to do a larger amount of work without any increase in the cost of living, and to receive for his work a larger wage, he is in exactly the same position as the merchant, who by reducing his price is enabled to sell a larger quantity of goods in a given time, to turn over his capital oftener, and to make a larger profit in the course of a year, although he makes a much smaller profit on each article sold.

Finally, we must consider that when a man's efficiency is increased as a result of the application of scientific management, only a small part of this increase in efficiency is due to his own effort and that the most of it is due to the study and effort of the employer. Accordingly any gain which is realized must be divided between the employer and the employe, and usually with the public in the form of lower prices, in order that the public may absorb the larger output resulting. If the employe is to receive all the benefit resulting from scientific management, which would be the case if wages were increased in proportion to output, then it would be no object for the employer to utilize scientific management and its adoption would be of no advantage to the community. If the employe realizes a third of the gain due to scientific management, he has had his share, and must recognize that the other two-thirds belong respectively to the employer and to the community.

On being not required to think, but to carry out Instructions

A third objection often urged by workmen against scientific management is that they are not required to think, but merely to carry out instructions. They feel that when they receive complete instructions as to the method of performing work, it places their work upon a lower plane, transforming them from intelligent workmen into automatons. As one man has expressed it, "I like to think I think, even if I don't think." The answer to this is that Americans have in the past laid undue stress on originality and not enough on ability to follow instructions. If ten men are given explicit instructions as to exactly what to do and how to do it, very seldom will it be that one out of the ten will do exactly as he is told. On the other hand, if ten men are given a puzzle to solve, most of them will succeed within a reasonable time in solving the puzzle. The solution of a puzzle or the origination of a method of work really does not require any higher order of intellect than the exact following of a described method, and is, in the majority of cases, a gift of considerably lower social value.

I have had considerable experience in writing out exact directions informing men in the junior and senior classes of an engineering school, how to perform certain experiments—for instance, how to calibrate a gage. Three men out of five when given the directions for calibrating a gage will read them over and then go to work to calibrate the gage by a method of their own, which is usually incorrect. In the same way, it will be found that when a workman is given a piece of work to do, he will perform the work by a method of his own which is usually incorrect, in that it is not the most efficient method. This brings up the question of whether, for his own amusement, a workman ought to be permitted to adopt inefficient methods of work. When it is put in this blunt manner, every workman will admit that he ought to adopt the most efficient methods of work, and when he realizes that his wages are reduced and his employment endangered if he follows inefficient methods, he will usually be perfectly willing to follow instructions.

The use of instruction cards does not, however, take away from a workman the power of initiative. When a workman succeeds in devising a better method of doing a piece of work than that devised by the planning department, his method will be adopted, and he will receive a reward for devising it. If a workman shows himself capable of devising good methods of work, a place will soon be found for him in the planning department in which he can use his superior ingenuity to his heart's content. Because he has been accustomed to the use of the best methods, he will have a very much better fund of experience to draw upon than a man who has always worked in shops in which the workmen devise their own methods, and on that account his work will be of a superior character.

The use of instruction cards does not prevent a workman from thinking about his work, or from striving to originate new methods, in case he has any originality. Instead, when working from instruction cards, he has constantly before him examples of the best methods of doing work, and his experience is very much superior to that of a man who works in a shop where the workmen devise their own methods.

A man who is minded to do so can advance very much faster in a shop under scientific management, provided he is willing to study and learn. To the intelligent workman such a shop is a trade school, which will help him to a better understanding of his trade, and a chance for larger usefulness.

The argument that scientific management destroys the workman's power of thinking is a fallacy, because it assumes that the only thinking which the workman does is in regard to his work. The higher wages which scientific management involves will bring to the workman opportunities outside of his work which he cannot get otherwise. It will give him money for the purchase of books, for the building of his home, for the education of his children and for increasing the refinements of life. Even if it were true that scientific management curtailed the workman's opportunity to exercise real originality in his work, his intellectual life would still be the gainer from its introduction.

The workman's principal objection to scientific management is that he likes to do things his own way, to work as he pleases and when he pleases. Scientific management is objectionable to him because it compels him to change his habits, which is an uncomfortable process. If a workman were trained under scientific management from the beginning of his apprenticeship, and after several years were put to work in an ordinary shop, the change in habit would be just as disagreeable to him. He would object strenuously to being saddled with additional responsibilities while at the same time his pay was substantially reduced. The slipshod methods of his fellow workmen and the general inefficiency of the shop would grate on his nerves, and be ten times more disagreeable to him than the change in habits which scientific management usually introduces.

We must recognize that men are prone to complain and that anything new, especially if it involves a change in habit, will be the butt of the complaint. If they could not complain about scientific management, they would complain about the length of hours or the temper of the boss or the tools furnished for their work.

Scientific Management involves a Change of Habit

The fact that scientific management involves a change in habit which is disagreeable to many men is not a serious argument against it. People who become accustomed to living in disorderly and dirty surroundings find themselves uncomfortable when obliged to clean up and put things in order. Habits of labor which are inefficient are just as objectionable from the standpoint of the social welfare as habits of life which are unsanitary. Coming generations will look scornfully upon those who are inefficient, just as the present generation looks scornfully upon those who are dirty.

The change of habits involved in the adoption of scientific management is, from the practical standpoint, the strongest objection that there is. The minute you can show a workman that it is to his financial advantage to adopt the methods of scientific management, that minute all objections but this will disappear, but this one is ingrained in his temperament and nervous system, and cannot be reached by logic. Habit is one of the easiest things to form and one of the hardest things to eradicate, but even habits and prejudices must disappear at the demand of social welfare.

A great many misguided souls will urge against scientific

management the same arguments which are urged against all other advances of civilization, namely that it impoverishes the imagination, takes the poetry out of life, puts men to work at machine-like tasks, etc. The same arguments are leveled against all improvements. The sanitary dwelling is less picturesque than the thatched cottage; the mowing machine is not so poetical as the scythe; the division of labor which enables ten little minds in combination to accomplish ten times the task that was formerly done by the ten master craftsmen is said to deaden men's souls and to limit their horizon. It is the eternal battle of common sense and the good of the community against selfish sentiment which regards only its own mental pleasure and takes no account of the good of the swarming many that are benefited by industrial advancement.

No Provision for Unions or "Collective Bargaining"

Another and very valid objection which workmen urge against scientific management is that it makes no provision for unions or "collective bargaining" as our friends the sociologists prefer to term it. It is undeniable that unions are necessary for the welfare of workmen and that without organized effort it would be difficult for them to maintain satisfactory wages and conditions of employment in the face of the tendency of capital to combine into trusts and associations. If scientific management is incompatible with labor unions, workmen cannot afford to accept it, because when scientific management has been adopted and unions have been destroyed, the whole of the benefits will be appropriated by capital, and labor will receive nothing for its increased efficiency.

Notwithstanding that many of the leading exponents of scientific management are opposed to labor unions, and believe that individual bargaining is one of the essentials of scientific management, this is not true. We can still have agreements in regard to minimum wages, hours of labor, conditions of employment, and many other things which affect the welfare of the workmen. The unions, however, must stop short of making any requirements in regard to methods of work or quantity of output or maximum wages paid or premiums given, because such things are not proper subjects of discussion between the unions and the employer, and because any effort on the part of the unions to interfere in such matters will harm workmen even more than employers.

I believe that the reasons that the advocates of scientific management feel their work to be incompatible with unionism is that many of the unions have in times past interfered in matters which were not properly their concern, and by doing so have harmed the cause of labor. Whether scientific management is largely adopted or not, unions will some day cease to interfere in these matters, because it is contrary to their own interests to do so. Since proper demands on the part of unions do not interfere with the operation of scientific management, and since those demands which would interfere with its operation are contrary to the interests of labor, I cannot see that there is anything incompatible in having scientific management in a union shop, and I believe that any effort to destroy unions when introducing scientific management can only serve to delay the date of its introduction.

Even the most serious objections to scientific management on the part of workmen, however, fall to the ground in the face of the fact that when scientific management is adopted workmen receive from thirty to sixty per cent in increase in wages. Not only will there be an immediate increase in wages as a result of scientific management, but with the extensive introduction of scientific management, there will be a substantial decrease in the prices of all those commodities in the manufacture of which it is generally applied. It is usually found that it is impossible to combat the self-interest of a community for a considerable period of time, and as soon as it becomes apparent that the working class, in common with all members of society, receives substantial benefit from scientific management, the objections to it will disappear and those things which at first were regarded as serious drawbacks, will eventually be deemed to be mere trifles and in some cases be regarded as positive benefits.

Objections of the Public to Scientific Management

From the standpoint of the general public, objection can be made to scientific management if it can be shown that it is inefficient, that it injures the health of the workmen, that it lowers the quality of the product, or that it brings about undesirable social or economic changes. The public does not, however, need to worry about the question of efficiency, because if scientific management is not efficient, it will not be used by manufacturers. Scientific management will for a long time be under very severe scrutiny by workmen themselves and it is unlikely that any harm will come to the physical welfare of the workmen unless in very exceptional cases.

Scientific management does not usually lower the quality of the product. In certain cases quality may suffer, but in most cases quality will improve as a result of scientific management. Sometimes a decrease in the quality of the product is not a serious matter, while at other times it is. If it is, scientific management is prepared by proper inspection to insist on such quality as may be commercially desirable. Whenever the public is disposed to require a certain standard of quality, and is willing to pay for that quality, there need be no fear that the quality of output will suffer from the introduction of scientific management.

The principal objection to scientific management is that it will bring about very important social and economic changes with which our present laws are not capable of dealing. One of the effects of scientific management will undoubtedly be the destruction of the small manufacturer. Scientific management achieves its greatest success in comparatively large plants. Those firms which adopt scientific management and are able to secure successful administrators, will crowd their competitors to the wall, eventually absorbing their business and becoming monopolies. Since our present laws are obviously inadequate to deal with such a situation, it follows that we must have a little scientific management in the lawmaking department of our government if we are to avoid social and political evils from the growth of scientific management.

It may be pointed out in this connection however, that men of the "public-be-damned" class do not take kindly to scientific management. Men who are successful in introducing scientific management are those who recognize their duties, and are prepared to act for the welfare of the community as well as of their workmen and themselves. And aside from this fact those monopolies which will be the outgrowth of scientific management will be less oppressive and objectionable than those which are the outgrowth of high finance, legislative favors, or the cornering of natural resources.

Another economic evil which may result from the adoption of scientific management is the mis-direction of effort which will mark the transitory period while conditions are becoming settled. The cause of this is that by the use of scientific management the output of an industry will be very greatly increased. Sometimes the increase will be so great that the community cannot absorb the entire output at the cost of manufacture. The result will be that certain lines of work will be overdone and we will be some time in finding a rational and proper outlet for the extra productive capacity made possible by improved management.

Social and Economic Effects of Scientific Management

Upon surveying the social effects of scientific management, one is impressed with the idea that scientific management will improve social conditions very greatly and that there are only two economic evils prevalent at the present time that will not be materially diminished by the direct or indirect effect of scientific management. The first of these is the misdirected application of capital which results in potential overproduction in certain lines of industry. The second is the diversion of capital from industry for private pleasure. As an example of the first evil, I may cite the textile industry where capital is invested to such an extent that the mills are capable of filling all demands for textile goods when working at only a fraction of their capacity. Examples of the

second evil are unnecessary since they will suggest themselves to most of my readers.

Scientific management must, in the long run, depend for its success upon the habit of mind of those who administer it. We think of the scientist as being a man who is, above all things, intelligently honest, who is without passion or prejudice; who is open-minded and determined to arrive at the truth. The scientific habit of mind is the only one compatible with the administration of scientific management. The man in authority must divorce himself from prejudice, from preconceived notions and snap judgments, and from everything which will turn him aside from the truth. In adopting scientific management, he must recognize certain great principles; some of which are economic, some of which are psychological, some of which are ethical, and some of which are merely physical.

An industrial establishment is merely a part of a great economic system. Recognizing this, the employer will see that if the establishment does not minister to the needs of the community, it is useless. Not only must its product be valuable, but is work must be carried on in such a way as not to harm the community. Work which is carried on at the expense of a part of the community, in order to benefit the remainder, cannot be justified. By such work I mean work carried out under dangerous or unsanitary conditions, or where the wages paid are insufficient to maintain the community standard of living. It may be cheaper to carry on work in that manner, but the moral sense of the community will not in the long run permit of it, and scientific management recognizes the fact.

The interests of all men engaged in a given industry are identical. A certain school of thought is accustomed to regard the labor situation as a war, in which employer and employe are striving to obtain an advantage over each other, each striving to secure from the other the largest possible proportion of the total returns of the industry. Scientific management recognizes this to be an error, and knows that cooperation between employer and employe is essential. It recognizes not only that the employer must purchase the cooperation of the employe by high wages and fair treatment, but also that he must cooperate with the employe by assising him in every way to become as efficient and valuable as possible. Each must cooperate with and assist the other, and must purchase by fair dealing and generous attitude the cooperation of the other.

The greater the productivity of a community, the more prosperous the community will be. High wages and restricted production are incompatible, and only by achieving the highest efficiency can the greatest prosperity be reached. There may be, however, overproduction in certain lines of work, because too much capital or too many men may be engaged in that line. This does not mean that too many men are employed or too much capital is available. It merely means that men are employed in the wrong industries and that capital is invested in the wrong lines. Consequently, the application of scientific management to all establishments engaged in one particular industry, may result in throwing the industrial system out of balance by producing more of one kind of goods than is necessary.

Conclusion

Work well done under proper conditions is interesting and healthful when the worker is healthy and well nourished. Work under unsanitary conditions is unhealthful. A poorly-nourished workman is always overtaxed by relatively small tasks. Unsatisfactory surroundings and slovenly work results in nervous strain which breaks down the workman's health. Men differ mentally and physically in innumerable ways, and each workman must be studied in order to discover the most useful place in which to put him. He must be put in that place where his abilities will be utilized to the utmost.

A careful study of a piece of work by a man of scientific habit of mind, having at his command the knowledge of a large number of expert workmen, will result in the development of methods of doing work which are far superior to the methods usually employed. Workmen naturally perform their tasks in improper ways as a result of habit. In order to have them perform the tasks in a proper way they must have supervisors to see that they form correct habits of work, and they must be encouraged by extra pay to continue in these habits.

The cooperation of workmen must be secured by persuading them that the employer has abandoned the attitude of war and that he is willing to divide the results of his improvements with the men whose cooperation makes these improvements possible.

Finally, the benefits of scientific management are so many and so varied that not only employers and workmen but the community generally will participate in them. It is therefore proper not to object to scientific management but rather to study the ways in which we can eliminate the evils which may possibly come from its use, and take advantage of the benefits just as we take advantage of the benefits of railroads, printing presses and steam power, in spite of the manifold evils which some men thought they foresaw as a result of their introduction.

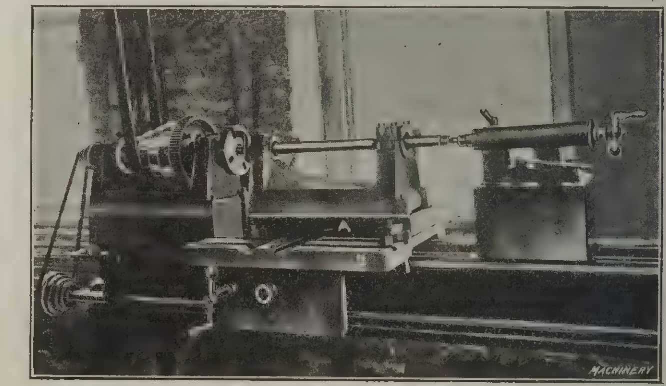
BORING AND FACING THE SPINDLE BEARINGS OF LATHE HEADSTOCKS

There are various methods used for boring and facing the spindle bearings of lathe headstocks. Some lathe manufacturers use boring machines, while others equip lathes with special fixtures for this purpose. The accompanying illustration shows the method used by the Rahn-Larmon Co., Cincinnati, Ohio, in boring and facing the bronze spindle bearings for a 20-inch engine lathe.

After the V-guides have been planed, the caps fitted, and the bearing boxes faced on the planer, the headstock is bolted



Fixture used by the Rahn-Larmon Co., for boring and facing the Spindle Bearings of Lathe Headstocks

to a special table *A* provided with ways to fit the V-guides in the headstock. This table, in turn, is clamped to a special carriage *B*, fitting the lathe shears and provided with a slot in its top face, which by means of a tongue on table *A* locates the bearings in the headstock in perfect alignment with the lathe centers.

The boring is accomplished with a boring bar held on the centers, and driven by a dog. Both front and rear bearings are bored at one setting, two cutters being used. The front bearing is 3¼, and the rear, 2½ inches in diameter. The bronze bearings are next faced with a broad-faced fly-cutter, after which operation the bosses of the bearing caps are reduced to the same diameter as the bronze bearings with an L-shaped fly-cutter. All the operations enumerated, as well as clamping, etc., take about 40 minutes for each headstock.

Statistics relating to the automobile industry in the United States indicate that, at the present time, this industry is the third in importance of the various industries of the country. There were in April, 1912, 652,500 automobiles registered in the United States. The daily production of pleasure cars alone, during 1911, reached 700 a day. There are more than 25,000 commercial cars and trucks in use and it is estimated that 30,000 of these cars will be manufactured during 1912.

THE MOTOR TRUCK IN MANUFACTURING

ITS UTILITY, ADAPTABILITY, CAPACITY AND ECONOMY UNDER SUITABLE CONDITIONS

BY HAROLD WHITING SLAUSON*

There is probably no place where the motor truck is surrounded by more favorable conditions for efficient operation than in the average manufacturing business. Machines are used throughout for the production of the goods; why should not mechanical power be employed for the transportation of the raw and finished material? No matter how large or how small the plant may be, and regardless of the size, nature, or quantity of the product, a motor truck transportation, delivery, and hauling service *must* show a marked saving in time and money over the horse type, if the former is properly installed and operated under efficient conditions. As power-driven machines have reduced the cost of manufacturing goods, so will motor-propelled trucks lessen the hauling charges for those goods.

These may seem like sweeping statements, but they are attested to by thousands of successful truck installations in hundreds of different kinds of manufacturing businesses. The success of these proves the adaptability of the motor vehicle, for each of these manufacturing lines may require its trucks to operate under conditions absolutely different from any of the others. By means of special bodies and a wide selection of types and sizes of power plant, a variety of combinations can be obtained, the proper selection of which will allow almost any operating condition to be fulfilled. A few years ago the motor truck cost more to install and to operate than the horses and wagons required to perform the same amount of work, and this excess expenditure was charged to advertising; but the modern motor truck has been brought to the point where it can show an actual dollar-and-cents saving, and even on this one merit alone can the mechanical means of transportation compete with the horse. Figuring interest on the investment at 6 per cent, depreciation at 10 per cent, chauffeurs' wages higher than those paid to horse drivers, and insurance premiums and repairs at a larger amount than would ordinarily be required in practice, the properly-organized truck installation will show a saving of from ten to thirty per cent over the maintenance expenditure required by a horse system.

From an investigation of many installations made by one company, it was found that interest, insurance, garage expenses, and driver's wages constituted a daily fixed charge of $5.32 for a 5-ton truck. This charge, of course, continues whether the truck is in use or not, and remains constant regardless of the mileage covered. Operating expenses, such as those for tires, gasoline, lubricating oil, and allowance for repairs, overhauling, and depreciation amounted to 15½ cents a mile. For a 50-mile day, the total expense would amount to the fixed charge of $5.32, plus 50 times the 15½ cent per mile operating cost, or $13.07 per day.

This strikes the keynote of the secret of a successful truck installation. Inasmuch as the $5.32 represents a fixed charge that is not affected by the distance that the truck travels, it is evident that the cost per ton-mile will be reduced as the daily mileage is increased. A 5-ton truck traveling 50 miles a day has a ton-mile capacity of 250. Inasmuch as there is but little difference between the operating cost of a loaded truck and one running empty, it will be seen that the hauling expense per ton mile may be reduced to slightly over $0.05. This is on the assumption, however, that the truck will be run at full load at all times—a condition which, obviously, cannot be attained in the average installation. If the truck is run loaded in one direction and returns empty, the hauling cost per ton-mile will be doubled.

There are, consequently, four broad, general conditions to be met in order to secure the most efficient installation. The truck must be selected with due regard to its capacity; its work must be so laid out and routes so arranged that but a minimum amount of time will be spent in idleness, and its active hours must be employed in hauling loads approaching as nearly as possible to its rated capacity; its construction must be such that the necessity for repairs will be infrequent; and its design must be so simple that it may be handled and overhauled by the ordinary intelligent driver or machinist, thereby eliminating the expenses of high-priced help. The fulfillment of the first two of these conditions rests with the purchaser, with the co-operation of the manufacturer of the truck, while the last two depend upon the truck builder and designer—but with the necessary co-operation of the purchaser.

The selection of a truck with regard to its capacity is an important consideration, but one too often overlooked. A 5-ton truck should not be purchased to conduct a 2-ton hauling business, unless expansion in the near future is to be provided for. To haul two tons in this case will cost nearly as much as to haul five, and such an installation would probably show a loss. Of course, it rests with the purchaser as to whether the expansion of this end of his business will, in the future, call for larger trucks, or a greater number of small vehicles, but the installation departments of the truck factories will help him with this problem.

While it is necessary that the trucks should be run fully

Fig. 1. Pierce-Arrow Auto Truck carrying Machinery to the Freight Depot

* Address: Cor. South Broadway and Post St., Yonkers, N. Y.

loaded as much of the time as possible, the fact must not be overlooked that loads in excess of the capacity of the machine will cause the ton-mile hauling cost to increase rapidly. In fact, it is probable that to this tendency on the part of owners and drivers may be attributed the majority of the failures of commercial vehicle installations. By a constant 25 per cent overload, the life of the tires may be reduced by two-thirds.

Inasmuch as a high mileage is essential to efficient motor truck operation there should be as little delay as possible in loading and unloading, and trips and routes should be so arranged that the truck may be given an opportunity to take advantage of its speed and large territory-covering ability. But even though the area to be covered by the truck might, of necessity, be restricted to the factory yard, the use of special loading and unloading devices may easily overcome what would otherwise be serious obstacles to an efficient installation. If the factory is situated some distance from the freight yards, and the truck can be utilized to carry the finished products to the point of shipment and to bring back raw material on the return trip, conditions are nearly ideal, and such an installation should show a marked saving over any other arrangement. In fact, an installation that will allow the truck to travel loaded in both directions is so obviously destined to be successful that the only question to be considered is as to which of the many trucks on the market would be best adapted for the particular requirements of the business. Many manufacturing businesses employ one or more trucks to do "odd jobs" around the yard. As work of this type will consist, probably, in moving heavy machinery or other material, and in traveling under load from one building to another, trucks used for this purpose should show good returns on their investment.

The very multitude of chassis sizes and types and body designs from which the purchaser may choose is striking evidence of the variety of purposes to which the motor truck may be put. Special bodies may be obtained to meet certain requirements, and these may be mounted on any size or type of chassis. It is probable that the average manufacturer will find the conventional stake body the type best suited to his needs. This may be mounted on a chassis of the ordinary length when heavy loads are to be carried, or on a chassis of extra-long wheelbase if its regular load is to be bulky or long.

It is not, however, only because of the unusual opportunity to run loaded a large part of the time that a truck will appear to unusually good advantage when used in a manufacturing business. The fact that a motor truck is a *machine* indicates that it will be well cared for, and that unusual

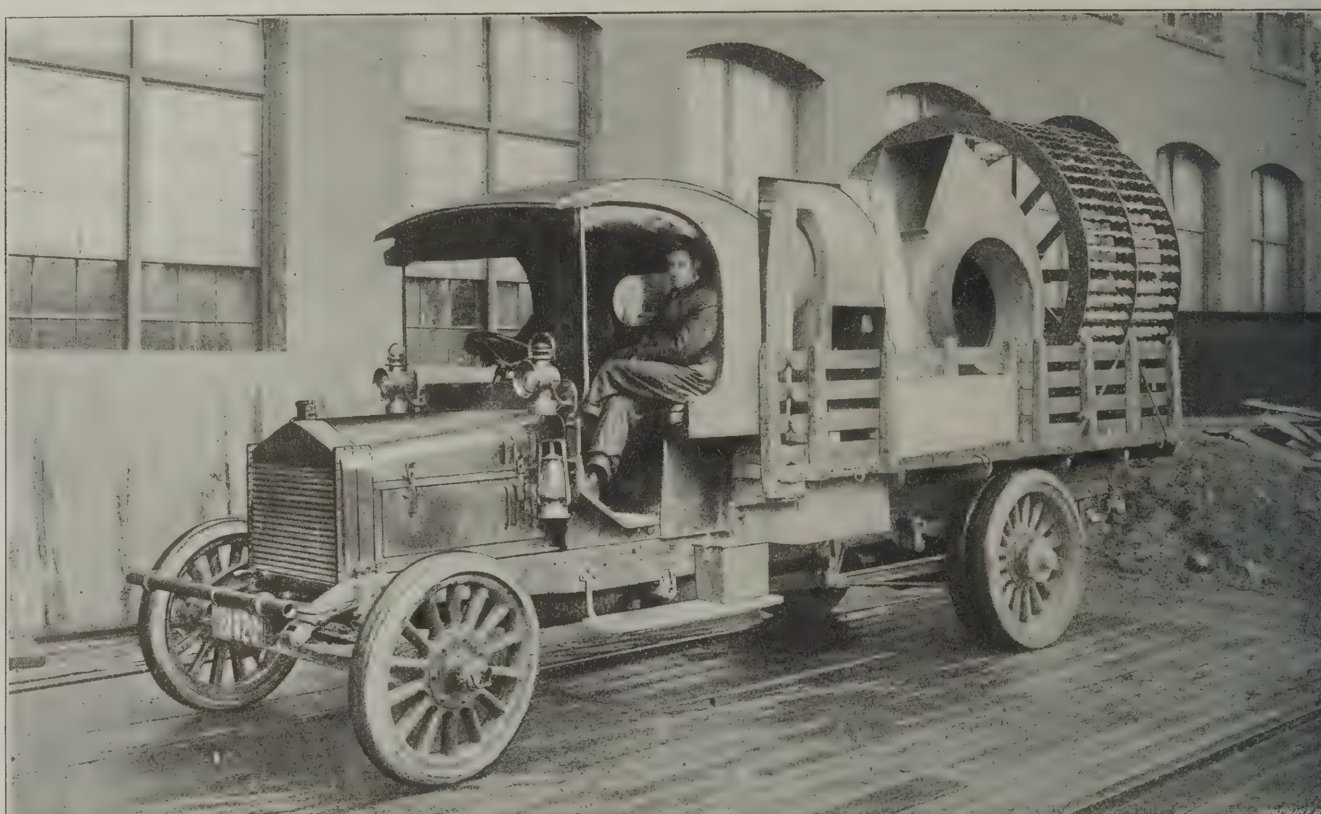

Fig. 2. Pierce-Arrow Five-ton Worm-driven Truck used by a Large Manufacturing Concern for carrying Heavy Castings and Large Parts of Machinery

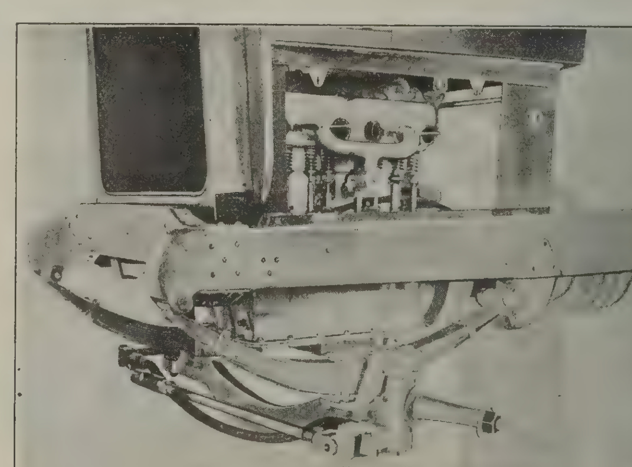

Fig. 4. The Front of a 5-ton Lozier Truck Chassis. All the Vital Parts are properly protected in Case of Collision

facilities will be already at hand for its overhauling and repair. Probably every tool that would be used in a complete garage and repair shop will be found in the average large factory. There will probably be a large force of men familiar with all kinds of machinery, and consequently the motor truck will not be the "strange creature" that would be the case were it replacing the horse transportation system of many another line of business. This enables the factory to retain its old drivers. Thus a complete garage and repair shop may be installed and equipped in the factory yard at but little additional expense, and the attendant saving in storage and overhauling charges will represent a large item. If the truck installation consists of but one vehicle, it may be advisable for a time, at least, to store the machine in a public garage, but even this will not bring the expense above that figured for a 5-ton truck in a preceeding paragraph, as this charge was included in the estimate.

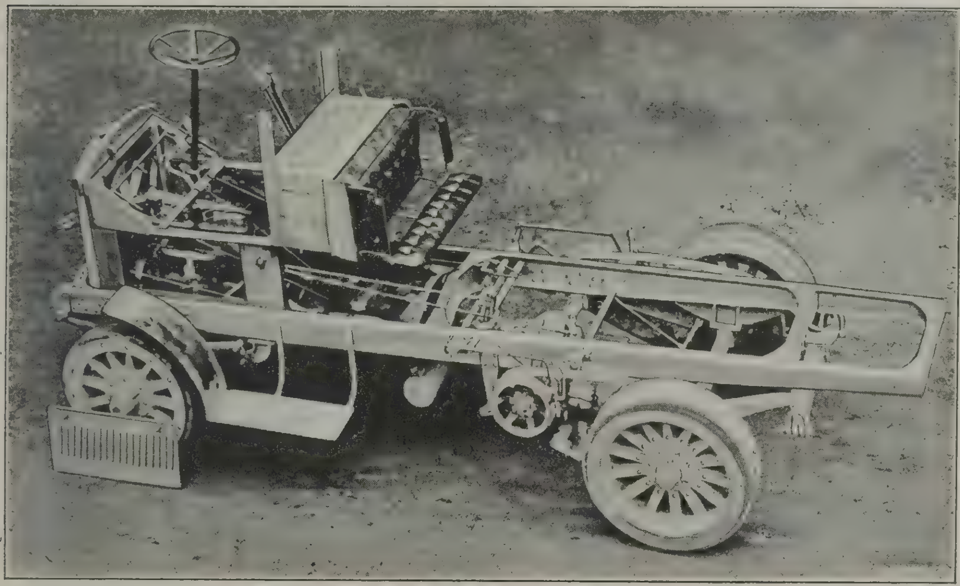

Fig. 5. Chassis of a Five-ton Lozier Truck showing the Accessibility of the Motor located under the Driver's Seat, which can be folded back

If the equipment consists of three or more trucks, it will undoubtedly prove advisable to equip a private garage and employ an expert whose sole duty shall consist in overhauling the vehicles and keeping them in perfect repair. In this case the drivers need only understand the control of the car, and are not required to be experts themselves. Consequently, a considerable saving may be made in chauffeurs' wages, and this forms the third advantage to be found in a motor truck installation in a manufacturing business.

The question of service is naturally an important consideration. No matter how well constructed a motor truck may be, it will require a certain amount of care and attention, and the engine must be overhauled occasionally. If several trucks are used, much of this work may be done at night, and if the power plants are thus kept continually in the top-notch of condition, there need be but little fear of interference with their work during the day. It was not long ago that, in large installations, one truck in every ten was used as a reserve machine. In other words, it was assumed that only 90 per cent of the trucks would be available for service. To-day, through better management of the installation, as well as through improved design, the average percentage of idle trucks has been reduced to about two. Some builders have provided removable power plants that can be used to replace the engine that requires overhauling. These power plants are of the "unit" type and include, besides the motor, the clutch, transmission, and, in some cases, the radiator and all electrical equipment. These parts are all attached to the motor or its base and the entire power plant may be lifted out after the removal of two or three bolts. Thus, by the use of but one extra removable power plant, nine or ten trucks may be kept in practically continuous service, and yet each motor may be thoroughly overhauled as often as necessary.

The unit power plant, which includes the transmission mounted on an extension of the motor base, is not used on the majority of heavy trucks—although some of two, three, and even five-ton capacity will be found so designed. The average five-ton truck is chain-driven from two sprockets mounted at each end of a jack-shaft extending from the transmission case and located about in the middle of the frame. There is at least one notable exception to this design, however, in the form of a shaft-driven five-ton truck that employs a worm and gear for transferring the power from the propeller shaft to the floating rear axle. Practically all of the trucks having a capacity of over three tons use the twin, or dual, solid tires on the rear wheels. Such a wheel is provided with one set of spokes, but possesses two rims, thus giving the effect of an exceedingly wide tire. Instead of using one wide tire on each wheel, however, two narrower tires are mounted on the single felly.

The power plants of the larger trucks are similar to many of those used on the high-power touring cars. The ordinary 5- or 10-ton truck is generally driven by a 30- or 40-horsepower motor located in the forward portion of the chassis, either under a conventional bonnet or under the driver's seat. In the latter design, the seat tips back or to the side in order to render the motor easily accessible. The gear ratios of the truck are much higher than are those of the pleasure car employing a power plant of equal size, for the speed of a 5-ton truck should not exceed 12 miles an hour, while that of one of 10 tons capacity should be restricted to 7 or 8 miles an hour. Some 3-ton trucks are designed to attain a maximum speed of 15 miles an hour—and even higher—but the governors used on the majority of the motors restrict their speed to about 1200 revolutions per minute, and consequently the maximum speed of the truck will depend upon the gear ratios employed. On one truck, the governor is attached to the driving shaft, so that the speed of the car itself, rather than that of the motor, will be restricted.

Fig. 6. Six and One-half ton Saurer Truck hauling Long Steel Girders

It is evident that many designers have kept in mind the desire of truck owners to employ former horse drivers—or other men unskilled in handling a power vehicle—instead of

expert chauffeurs, for the modern motor truck is of exceedingly "foolproof" construction. In fact, continued overloading constitutes about the only means—aside from downright vandalism—by which the average motor truck can be injured. By means of heat-treated and other special steels in the motor, transmission, and other parts of the frame and running gear subject to unusual strain or wear, the present-day truck can successfully withstand a remarkable amount of abuse; but there are right and wrong ways of handling even the most invulnerable truck, and many designers have bent their efforts toward eliminating all possible sources of abuse. In some, the spark control lever has been removed and a fixed point of ignition used in its stead, so that the driver cannot run the motor at slow speeds and with closed throttle when the spark is advanced. On other trucks, an automatic spark advance and retard has been installed by means of which the speed at which the motor is operated regulates the point of ignition. In still another design, a spark lever has been used, but instead of placing this on the steering wheel—as is usually the case—it has been located on the dash where it cannot be reached as easily by the driver as can the throttle. It is assumed that there will be less temptation to "monkey" with the spark if the lever is not so conveniently located.

Fig. 7. Packard Truck with Long Overhanging Body at the Rear, facilitating Loading at a Platform. This Truck does the Work of Four Teams of Horses at an Average Cost of $9.92 per Day, or at a Saving of about $10.00

Fig. 8. A Good Example of the Load that can be put on a 5-ton Truck

Although some of the heavy trucks are provided with planetary transmission, the majority employ the sliding type with either the selective or progressive method of shifting—the latter being in the majority. Modern transmission gears are so accurately cut and are made of special steels of so high a grade that it seems well-nigh impossible to "strip" them. As an added precaution, however, some trucks are provided with special devices which render abuse in this direction impossible. On one such device, the gears are in mesh at all times and each is provided with an individual clutch. The gear control lever is used to engage the various clutches, and thus the different speeds are obtained without any actual sliding or clashing of the gears, and the changes may be made without releasing the main clutch. Other designs employ a notched quadrant which prevents the movement of the gear-shifting lever until the main clutch is disengaged. Still a third system allows the gear-shifting lever to be moved, but the gears themselves are not slid into position until the clutch is released. This action is obtained by means of a bar cam which brings the tension of a spring into play against the gear to be moved. A back-cut on the jaws of the positive clutch with which each gear is provided, however, prevents the movement of any of them while the jack-shaft is revolving, and as this jack-shaft will continue to turn as long as the main driving clutch is engaged, the gears cannot be changed until conditions are proper for the shifting.

Fig. 9. Alco Tank Truck used for Spraying Dust-laying Oil on Roads

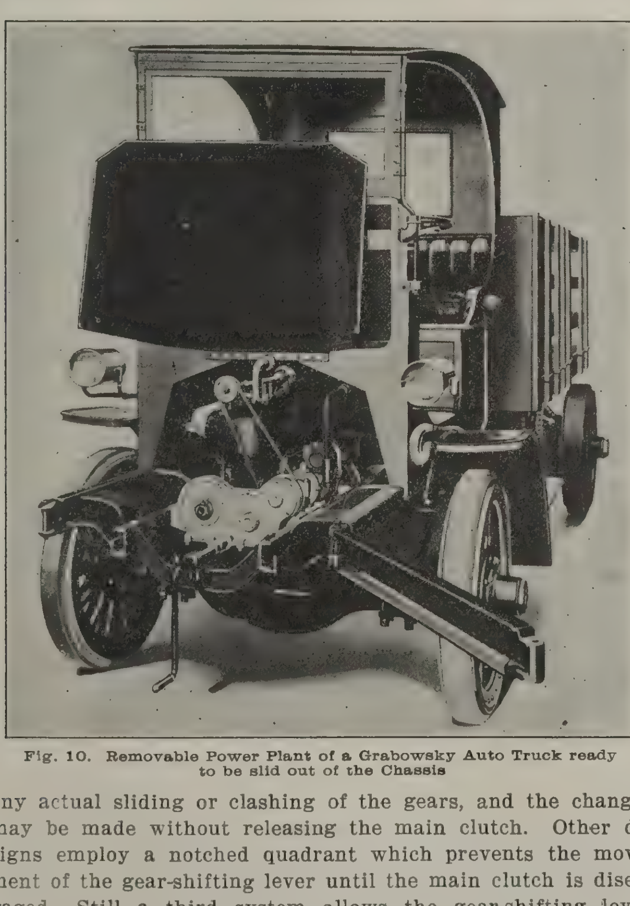

Fig. 10. Removable Power Plant of a Grabowsky Auto Truck ready to be slid out of the Chassis

From 60 to 80 per cent of the load on the modern motor truck is carried over the rear wheels. This insures effective traction and enables the truck to negotiate slippery roads and steep hills with comparative ease. Designers are realizing that, because of its surroundings and the nature of its work, the average motor truck will be subjected to many a hard knock from exterior sources, in addition to those it may receive at the hands of a careless driver. Consequently all vulnerable parts are protected as far as possible from contact with any obstacle which the heavier portions of the truck might strike. For example, a heavy cross-member may be riveted to the forward portion of the frame to serve as a guard for the more delicate radiator, and all of the motor, transmission, and protruding shafts or studs may rest within the confines of the frame proper. On some trucks, the motor sub-frame and radiator are mounted on separate springs to relieve these parts of the shocks and jars of travel that will not be absorbed by the heaviest body springs.

In fact, the modern truck is so well designed and constructed, and there is such a variety of body and chassis types and sizes from which to choose, that the blame for an unsuccessful installation may generally be laid to the purchaser of the truck and his system, rather than to the builder. There are, of course, many problems to be met and changes to consider, but each problem can be solved and all difficulties overcome especially well in a manufacturing business.

* * *

The corrosion of nickel, chromium, and nickel-chromium steels has been investigated by Messrs. J. Newton Friend, J. Lloyd Bentley, and Walter West, of Darlington, England, and the results of the investigation have been placed on record in a paper read before the Iron and Steel Institute of Great Britain. One of the interesting conclusions arrived at is that in certain neutral corroding media, such as salt water, the resistance to corrosion rises with the percentage of chromium. Hence, the employment of chromium steels in the construction of ships seems to be fully justified on this ground alone. Nickel steels appear to be resistant both to acid and neutral corroding media, in proportion to the percentage of nickel.

DESIGN OF A HYDRAULIC INTENSIFIER

A SYSTEMATIC METHOD OF CALCULATING THE DIMENSIONS OF THE DIFFERENT DETAILS

BY J. B. VARELA*

The object of this article is to explain in a simple and direct manner the calculations necessary for designing a hydraulic intensifier that shall fulfill certain specified requirements, and be of correct design, as nearly as possible, from the view-point of the engineer. The specifications that will govern the design may be briefly stated as follows: Required, a hydraulic intensifier to raise the pressure from 1500 pounds per square inch to 4500 pounds per square inch, having a capacity of 10 cubic feet on the low-pressure side. The choice of the materials, as well as of the proper working unit stresses, is left to the judgment of the designer.

In order to ascertain the diameters of the rams and the corresponding lengths of the stroke, it is advisable to tabulate the various possible diameters together with their corresponding lengths of stroke, and then select the most suitable dimensions as dictated by practical considerations.

Large Ram			Small Ram	
Diameter	Area	Stroke	Diameter	Area
21	346.36	49.8	12	113.1
17	226.98	76.1	10	78.54
16	201.06	86.0	9	63.62

The high-pressure cylinder acts as the low-pressure ram, as shown in Fig. 1. This arrangement is the most economical in the use of materials, as well as in the space occupied by the apparatus.

The sizes tabulated indicate fairly good proportions. We will select the third set of possible dimensions and calculate how they balance. The area of the low-pressure ram multiplied by the pressure acting on it must equal the product of the area of the high-pressure ram by the pressure acting upon it plus the excess load required to overcome the friction of the machine. Thus:

$201.06 \times 1500 = 301{,}590$ pounds, the load on the low-pressure ram,
$63.62 \times 4500 = 286{,}290$ pounds, the load on the high-pressure ram.

15,300 pounds, the excess load on the low-pressure ram. This difference is necessary, as noted above, in order to overcome the frictional forces that oppose the motion of the rams.

The volume of the low-pressure cylinder is assumed to be equal to the volume displaced by the low-pressure ram, that is $201.06 \times 86 = 17{,}291$ cubic inches, which is slightly in excess of the required volume. The actual volume of the low-pressure cylinder greatly exceeds this figure, as will be seen from Fig. 1. The length of the stroke is 86 inches, which is not abnormal.

The friction of the packing may be calculated by the following formula:

$$F = \mu P D$$

in which F represents the force of friction; P, the internal pressure in pounds per square inch; D, the diameter of ram in inches; and μ a coefficient, the value of which depends on the kind of packing used. (Although U-leather packing offers the least frictional resistance, we will use hemp packing in our design owing to the fact that it is easy to replace, cheap to maintain, and that leakage can be readily avoided.) The value of μ for hemp packing may be taken as 0.20. Hence the force of friction against the stationary ram is: $F = 0.2 \times 4500 \times 9 = 8100$ pounds; and for the movable ram: $F = 0.2 \times 1500 \times 16 = 4800$ pounds; making a total of about 12,900 pounds.

The inside diameter of the low-pressure cylinder is 18½ inches and the internal pressure 1500 pounds per square inch. Using Lamé's formula, we have:

$$D = d\sqrt{\frac{S+P}{S-P}}$$

* Address: 433 New St., South Bethlehem, Pa.

in which D represents the outside diameter of the cylinder; d, the inside diameter; S, the working unit tensile stress, taken as 8000 pounds per square inch; and P, the internal pressure, also in pounds per square inch. Hence:

$$D = 18.5\sqrt{\frac{8000+1500}{8000-1500}} = 22.37, \text{ say } 22\tfrac{3}{8} \text{ inches.}$$

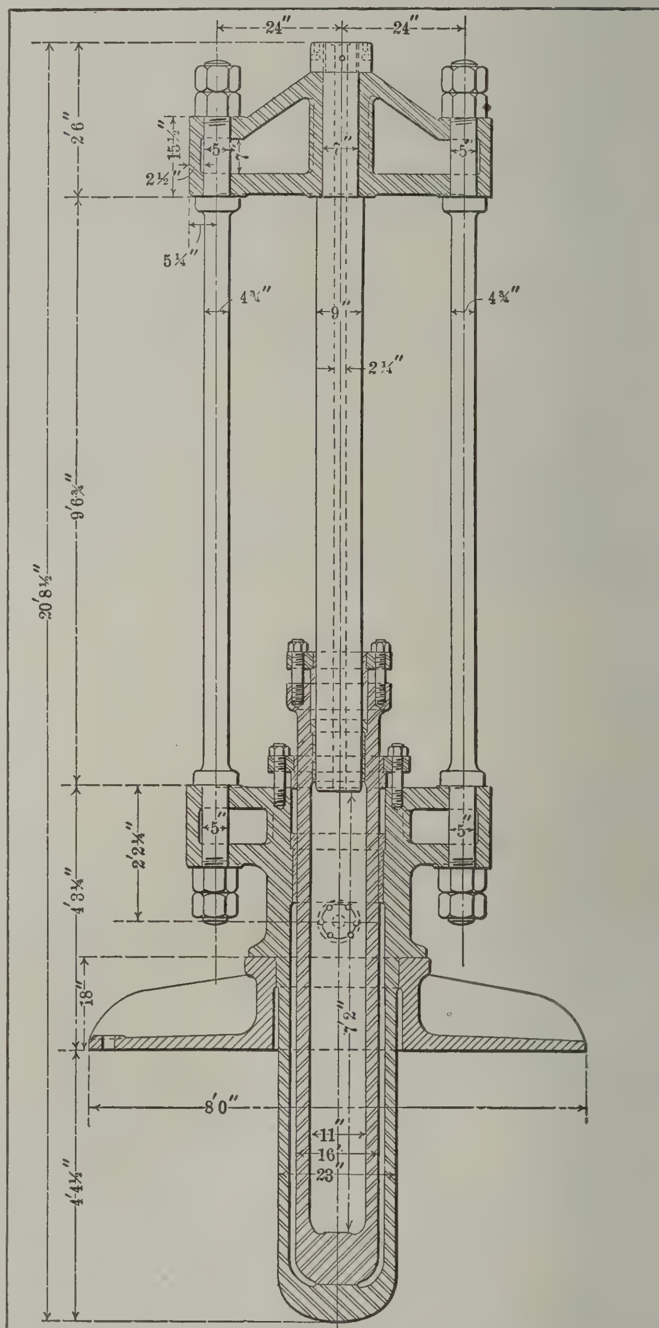

Fig. 1. General Assembly View of Hydraulic Intensifier

Therefore, the thickness of the cylinder wall is:

$$\frac{22.375 - 18.5}{2} = 1\ 15/16 \text{ inch.}$$

Using Peterson's formula as a check on the above calculations, we have:

$$t = \frac{p\,r}{S - 2/3\,p}$$

in which t represents the required thickness; p, the internal pressure in pounds per square inch; r, the internal radius of the cylinder in inches; and S, the working unit tensile stress in pounds per square inch. Therefore:

$$t = \frac{1500 \times 9.25}{8000 - 2/3 \times 1500} = 1.98, \text{ say 2 inches.}$$

These results are in close agreement with each other. Owing to the fact that the water under pressure percolates somewhat into the pores of the casting, thereby reducing the actual effective thickness of the cylinder walls to resist the pressure, and because of the difficulties that may arise when casting the cylinder if its walls are made too thin, it is advisable to make the thickness of the walls slightly in excess of the calculated value. Another reason for increasing the thickness of the walls is on account of the fact that the cylinder will be subjected to a test pressure double the normal working pressure, while the maximum tangential unit stress S should not exceed, under the test, 15,000 pounds per square inch.

Substituting these new values in Peterson's formula:

$$t = \frac{3000 \times 9.25}{15{,}000 - \frac{2 \times 3000}{3}} = 2.135, \text{ say } 2\tfrac{1}{4} \text{ inches,}$$

which makes the outside diameter of the cylinder 23 inches.

The outside diameter of the movable ram is fixed at 16 inches, and from Fig. 1 it can be seen that the inside diameter is made 11 inches. This ram is subjected to an internal pressure of 4500 pounds per square inch, and also to an external pressure of 1500 pounds per square inch. We may, therefore, assume for simplicity that the actual pressure is the difference between the two, and since the thickness is fixed, we can determine the value of the tangential unit stress S acting upon the inner surface of the bore.

From Lamé's formula we have:

$$S = \frac{(D^2 + d^2)\, P}{D^2 - d^2}$$

$$S = \frac{(16^2 + 11^2)\ (4500 - 1500)}{16^2 - 11^2} = 8377, \text{ say 8400 pounds per}$$

square inch, which is a safe stress.

The test pressure will be applied simultaneously to the inner and outer surfaces of the ram. The tangential unit stress S then becomes, according to Lamé's formula, 16,750 pounds per square inch, exceeding the maximum value previously fixed. Strictly speaking, however, these stresses are the apparent tangential unit stresses acting at the inner surface of the bore. If we take into account the longitudinal elongation of the cylinder, the true tangential unit stress T, upon the inner surface of the bore, is found by the following formula:

$$T = \frac{(r_1^2 + 4\, r_2^2)\, p_1 - 6\, r_2^2\, p_2}{3\, (r_2^2 - r_1^2)} \qquad (1)$$

in which r_1 and r_2 are the inner and outer radii of the ram, respectively; and p_1 and p_2, the corresponding inner and outer pressures. Substituting the known values in this formula, we have:

$$T = \frac{(30.25 + 4 \times 64)\, 4500 - 6 \times 64 \times 1500}{3\, (64 - 30.25)} = 7030 \text{ pounds}$$

per square inch.

When the test pressures are applied, the values of p_1 and p_2 become 9000 pounds and 3000 pounds per square inch, respectively, and the corresponding value of T found by Formula (1) is about 14,060 pounds per square inch, which is well within the maximum value assigned for S.

A possible, but not probable, contingency may arise when the movable ram is subjected to the full internal pressure of 4500 pounds per square inch, while the external pressure is zero. In this case the value of S as obtained from Lamé's formula is:

$$S = \frac{(256 + 121)\, 4500}{256 - 121} = 12{,}565 \text{ pounds per square inch, which}$$

is a safe stress.

The total pressure acting on the small or stationary ram is $63.62 \times 4500 = 286{,}300$ pounds, nearly. Let us assume that this load is carried by two tie-rods placed as shown in Fig. 1. Let A represent the area at the root of the thread of one of the tie-rods, and assume the working unit tensile stress to be 10,000 pounds per square inch for mild steel. Then:

$$2\,A \times 10{,}000 = 286{,}300, \text{ whence } A = \frac{286{,}300}{2 \times 10{,}000} = 14.32 \text{ square}$$

inches.

From a table of bolts it is seen that the diameter of bolt having the area at the root of its threads next larger in value to 14.32 square inches is a 5-inch bolt. We, therefore, make the diameter of that portion of the tie-rod that fits in the casting 5 inches. Since the diameter at the root of thread is 4.48 inches, we will make the diameter of the body of the tie-rod $4\tfrac{3}{4}$ inches.

The next step is to design the top casting. This piece is a simple beam carrying a concentrated load at the center. It is a rather difficult matter to calculate the required dimensions directly from the formula, and consequently we will assume the most suitable dimensions and check them for strength. For a simple beam with a concentrated load at the center of the span the maximum bending moment occurs at the point of application of the load, and its value is:

$$M = Pl \div 4$$

in which M represents the bending moment, P the load, and l the length of the span.

The load P equals 286,300 pounds, or 143.15 tons; the length of the span is 48 inches. Consequently

$$M = \frac{143.15 \times 48}{4} = 1718 \text{ ton-inches.}$$

The unit tensile stress acting on the outer fiber at the center of the beam is found by the formula:

$$\frac{M}{S} = \frac{I}{c}$$

in which M represents the bending moment found above; I, the rectangular moment of inertia of this section; and c the distance from the neutral axis to the outer fiber. The cross-section of the top casting at the center is as shown in Fig. 2, which is equivalent, as far as the rectangular moment of inertia is concerned, to that shown in Fig. 3. The moment of inertia about the neutral axis A-A is:

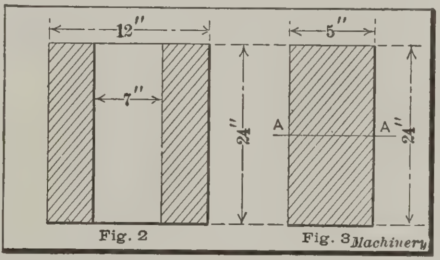

Fig. 2. Section of Top Casting at Center. Fig. 3. Equivalent Section of Top Casting

$$I = \frac{5 \times 24^3}{12} = 5760, \text{ and } c = 12 \text{ inches.}$$

$$\text{Hence, } S = \frac{1718 \times 12}{5760} = 3.58 \text{ tons per square inch,}$$

which for a steel casting is well within the limits of safety. When the test load is applied, this unit stress becomes equal to about 14,200 pounds per square inch, which is also well within the maximum value previously fixed.

The ends of the casting are in shear, the value of which is $286{,}300 \div 2$ pounds. The area resisting this shearing stress is 81.75 square inches. Hence the shearing unit stress is:

$$286{,}300 \div (2 \times 81.75) = 1750 \text{ pounds per square inch, about.}$$

Practical considerations, in addition to the stresses produced by the external forces, were the controlling factors in proportioning this piece.

The next step is to check the studs that compress the glands. We will assume the extreme case of the glands being subjected to the full pressure on their lower surface. For the low-pressure gland, the total pressure acting on its lower surface is about 42,500 pounds. This load is borne by ten 2-inch studs. The area at the root of the thread of a 2-inch bolt having 6 threads per inch is approximately 2.5 square inches, thus giving a working unit stress of about 1700 pounds per square inch. This is a very low value, but it must be borne in mind that the gland may be unevenly

screwed down, due to the comparatively large diameter of the bolt circle, thus inducing greater stresses in some bolts than in others.

The total pressure acting on the lower surface of the high-pressure gland is about 74,200 pounds. This load is carried by eight 2-inch studs having 6 threads per inch, and consequently the working unit stress is about 3700 pounds per square inch. Owing to the fact that the bolt circle is smaller in diameter than in the previous case, the danger of an unevenly screwed down gland is not so great, and for that reason we are stressing these bolts twice as much as those in the low-pressure gland.

* * *

BAR TURNER FOR "LIBBY" TURRET LATHE

A box-type of turning tool having some interesting mechanical features embodied in its construction is shown in Figs. 1 and 2. This turning tool is used on the "Libby" turret lathe, manufactured by the International Machine Tool Co., Indianapolis, Ind., and is used for turning bar stock. It has a capacity for turning bars from 3/4 inch up to and including 3 1/4 inches in diameter. It is clamped by four bolts to the face of the turret, the boss or shoulder *A*, Fig. 2, fitting in the bored hole in the turret, and thus aligning the tool. It carries a single high-speed turning tool *B* of 1 by 5/8 inch section. A cut 1 inch deep—the full width of the tool—can be taken in machine steel without any perceptible chatter.

The main frame or body *C* is a steel casting, cored to clear the largest bar—3 1/4 inches—and provided with openings to allow the chips to drop out. The front face of the frame is machined to receive two blocks *D* which carry the hardened and ground roller supports *E*, the latter being free to rotate on hardened and ground studs held in the blocks. These blocks *D* are provided with T-bases which fit in corresponding grooves in the frame and in the two blocks *F*, the latter being held to the frame by two bolts as shown. The roller supports are adjusted by collar screws *G*, which are screwed

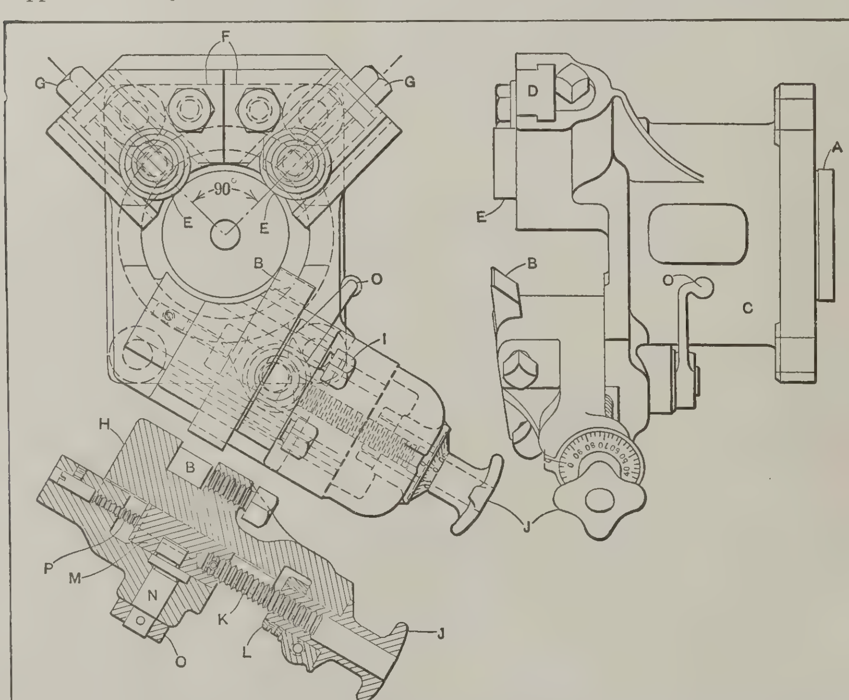

Fig. 2. Construction of the Bar Turner shown in Fig. 1, showing how the Turning Tool is withdrawn from the Work when retreating

into the frame, the collar fitting in a slot cut in the base of the block. The studs on which rollers *E* rotate are provided with oil grooves and proper means for lubrication.

The tool-slide *H* fits over a dovetailed guide machined on the front face of the frame, and is provided with an adjustable gib. A groove is cut in the tool-slide to receive the turning tool *B*, the latter being clamped rigidly in position by two set-screws. The 2 1/2-inch adjustment of the slide *H* for the diameter of the work is effected by means of a knob *J* and screw *K*. The knob is provided with a collar having 100 graduations, and as screw *K* has 10 threads per inch, each graduation equals a movement of the slide *H* of 0.001 inch. The overhanging arm of the slide is bored to receive the reduced end of the knob and is split and provided with an adjusting screw to compensate for wear. A collar *L* screwed onto the end of the knob and locked by a headless screw is used to take up the end play resulting from the frequent adjusting and the thrust of the tool.

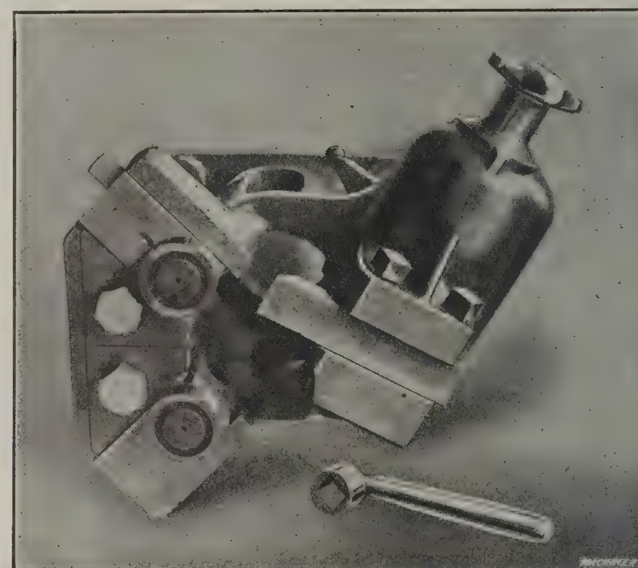

Fig. 1. Box-type of Turning Tool for the "Libby" Turret Lathe

The ordinary box-tool commonly used on turret lathes and screw machines is drawn straight back over the work after taking a cut; consequently, if a heavy cut has been taken—causing the tool to spring away from the work—the tool will make a spiral mark when returning. This objectionable feature is obviated in the particular tool illustrated in an interesting manner. The forward end of screw *K* is pinned to a block *M* which fits in a slot cut in the frame *C*. This block is actuated by an eccentric stud *N*, the latter being operated by a handle *O* held on it by a pin. When the cut has been finished, the operator pulls out handle *O*, rotating the eccentric, which, in turn, withdraws block *M* from stop *P*. Then as screw *K* is fastened to block *M*, thus connecting it with slide *H*, it follows that the slide carrying the turning tool must also recede. When handle *O* is pushed in, block *M* is located in the exact position by stop-screw *P*, which is locked with a headless screw, thus setting the turning tool again to the correct diameter.

Another commendable feature in the construction of this tool is the location of the turning tool relative to the supports and the body of the holder. The turning tool is set tangentially to the work and is also so placed that it can be located in advance of the supports or face of the holder. This construction allows the tool to cut close to a large shoulder—much larger than the width of the frame—without any portion of the holder coming in contact with the work. This feature makes this turret tool especially valuable for turning large work. The wrench shown in the foreground in Fig. 1 is used for tightening the set-screws on the turning tool.

D. T. H.

* * *

On January 1, 1912, there were 70,000 power driven vehicles in use in Germany, about 63,000 of which were passenger cars and about 7000 trucks. Of the passenger cars about 23,000 were private pleasure cars and 30,000 were used for business purposes. There were also 5200 motor cabs and omnibuses in use.

MUSEUMS OF SAFETY AND THEIR ACTIVITIES*

A BRIEF HISTORY OF THE MOVEMENT FOR THE PREVENTION OF INDUSTRIAL ACCIDENTS

BY MANCIUS S. HUTTON†‡

It is not so many years ago that labor was considered one of the cheapest of commodities and the employer of labor simply hired a new man in place of one incapacitated through injury at his work. He did not take the time to study how accidents could be prevented, nor did he spend money in placing safeguards about the works; but he was willing to spend the same or more money in fighting, in the courts, the claims for damages which the injured employe tried to obtain. The old common law liability of employers was very lenient at first towards the firms in whose shops accidents happened, but latterly the juries have been awarding larger sums to the sufferer. Within the last four years, however, the relations between the employer and his workmen have been changing in many places by the former's recognition of his responsibility for his work people, and he has been trying to safeguard the dangerous places around his factory. He has also been forced somewhat to do this by the casualty insurance companies in order to obtain a lower premium from these companies.

Present Activity in Passing Laws to safeguard the Industrial Worker

In nearly all the states, at the present time, laws in regard to safeguards have been made more stringent. In some of the states, commissions have been appointed to investigate and report to the legislature on the whole question of accident and sickness prevention, with the object of enacting laws which would tend to reduce the number of industrial accidents by compelling the introduction and use of safeguards. These laws, however, should not be made so exacting as to bankrupt the small employer.

When enacting workmen's compensation laws in the various states, which in no case were made compulsory, the law makers so changed the common liability law that it became to the advantage of the employer to accept the terms of the compensation law rather than to go to the courts under the liability law. This was done by taking away from the law the two defences under which the employer had the best chance of winning the suit. These defences are known as the "assumption of risk" and the "fellow servant rule." The former of these is that an employe who contracts to work for an employer assumes the hazard of the occupation. The latter one is that an employer cannot be held responsible for an injury to the workman which was caused by another employe engaged in the same work.

The recognition on the part of the employer of his responsibility toward his work people, the passing of more stringent factory laws, and the enacting of compensation laws, all have brought the employer to the realization that the question of safety and sanitation in his factory is a very vital one. He is now, therefore, studying these questions and others which are related to them. It is obvious that it would be to the employer's advantage to find all the material and information on safety devices brought together in one place for study. This is the genesis of the idea of museums of safety.

Foreign Museums of Safety

The first museum of safety was opened to the public at Amsterdam, Holland, in 1893. This museum, at the start, was a very small affair and was entirely supported by private subscriptions, but it soon outgrew its first quarters. In 1910 the city gave a site for a new and larger building, while the parliament appropriated $22,500 for the building. The running expenses will, as hitherto, be borne by private subscriptions. This museum was opened eight years before the country passed a workmen's compensation law.

There are at present sixteen museums of safety, of which fourteen are in Europe, one in the United States, and one in Canada. In the following table is given the location of these, together with the year of their opening and the year in which the compensation law in that country was first enacted.

City	Country	Year of Museum Opening	Year of Enactment of Compensation Law
Amsterdam	Netherlands	1893	1901
Berlin	Germany	1903	1884
Budapest	Hungary	1908	1907
Copenhagen	Denmark	1910	1898
Dresden	Germany	1911	1884
Gratz	Austria	1911	1887
Helsingfors	Finland	1910	1895
Milan	Italy	1906	1898
Montreal	Canada	1909	1909
Moscow	Russia	1908	1903
Munich	Germany	1906	1884
New York	United States	1907	1906
Paris	France	1905	1898
Stockholm	Sweden	1908	1901
Vienna	Austria	1909	1887
Zürich	Switzerland	1902	has none

The year given for the New York museum is that of the first exhibition of safety devices. It was not until three years later that a permanent museum was opened. The year given in the fourth column is that of the first Federal Compensation Law in the United States.

The following countries which have passed compensation laws have no public museum of safety:

Country	Year of Enactment of Compensation Law
Norway	1894
Spain	1900
Belgium	1903
Great Britain	1907

From the table it will be seen that Germany has three museums at the present time and Austria two. It is an interesting commentary on this movement that while Switzerland has never passed a compensation law, yet it was the second country to have a public museum of safety and sanitation located at Zürich; and Germany, which was the first country to have such a law, did not open its first museum at Berlin until nineteen years after the law went into effect. This latter museum is one of the largest and most up-to-date in the world. Its actual location is at Charlottenburg, a suburb of the city. The building occupies one-sixth of an acre and contains, besides the exhibition hall, the administration offices and a lecture hall which can accommodate two hundred people. The exhibition hall covers an area of 64,000 square feet.

In the summer of 1911 there was held in Dresden the first International Exhibition of Hygiene. This exhibition was opened to the public in April and closed in October. From the time of its opening to the first of September it has been estimated that four million people visited it. Nearly every country was represented, even those of South America, by either a pavilion or a section in a building. The United States was the only large country which was not officially represented. It was an educational campaign put in practical form by means of models and charts, so that the lesson could be easily understood and would not easily be forgotten. The preparations for the exhibition required over four years. After it had been closed there was a popular demand on the part of the German people that the models and charts which had taken so long and so much painstaking care to prepare should not be destroyed, but should be kept in a museum. Thus it was that Dresden's name was added to those cities which have a permanent museum.

One reason why the German museums are ahead of others in regard to their buildings and exhibits is the encouragement and financial backing which the government gives them. In the case of all the foreign museums, with the exception of that in Vienna, the government or the city in which they are located have given some financial help. Some of the foreign

† Address: 257 W. 86th St., New York.

‡ Mancius S. Hutton was born in 1881. He was educated at Columbia University, from which he received the degree of mechanical engineer. He served an apprenticeship with the Niles-Bement-Pond Co., and held positions with the American Radiator Co., American Museum of Safety and the Industrial Safety Association, as junior salesman, curator and assistant-secretary respectively. Mr. Hutton is now associated with Frederick A. Hall, engineer, New York.

museums occupy only part of a building, as is the case of the one in Paris, which is located in the Vaucasson Gallery of the National Conservatory of Arts and Trades.

To the average American these foreign museums are of no practical benefit, as few can visit them and the literature which they publish is not within the reach of everyone unless translated. The reason for mentioning them has been to show the large number located in the principal centers of Europe.

The American Museum of Safety

The idea of having a museum of safety devices in America was conceived by the present director of the Museum in 1900, on his return from abroad where he had seen, in Paris, a partial exhibit from the Amsterdam museum. The next seven years were spent in educational work by means of lectures throughout nearly all the states. The next step forward was the holding of an International Exhibition of Safety Devices in New York City which lasted two weeks. This was held at the Museum of Natural History in February, 1907. It exhibited practical safeguards in the way of models, photographs and actual devices manufactured by American firms; it also had actual devices, photographs and charts of methods which were in use abroad. These latter were obtained from the foreign museums. After this exhibit was over it was decided to hold another the next year, which should be open for a longer period. The exhibition of 1908 was held at 231-241 West 39th St., New York City, and extended over a period of two months (April-May); it contained exhibits from eighty different American firms, while the foreign museums were again represented by documents, photographs and charts. There were only a few models of foreign devices shown at this exhibition. The next year was spent in lecture work and in visiting factories in which safety devices were being used. In November, 1910, the first permanent Museum of Safety and Sanitation in America opened its doors and invited the public to come and visit it. It is located on the sixth floor of the United Engineering Building, 29 West 39th St., New York City, and occupies two rooms. It is open every day, except Sundays and holidays, between the hours of 9 A. M. and 5 P. M.

There are four methods in which a museum of this kind can have its work brought to the attention of the public:

1. By the collecting and displaying in a museum of the actual safety devices themselves, or, if too large or cumbersome, of models of them. The devices should be constructed so that they can be operated in the same way as in actual practice. If either the device or model cannot be shown, then the device should be illustrated by photographs, blueprints or charts.
2. By the assembling of a library of all the literature pertaining to the subjects which have to do with the question of improving the workmen's condition. The library should be fully catalogued and contain foreign books and pamphlets as well as American literature.
3. By means of lectures illustrated with lantern slides of the best safety devices. These lectures are delivered at the principal industrial centers and before employers, workmen, societies, associations, state and city officials, and others interested.
4. By the publication of literature on various subjects relating to the workmen's welfare, such as illustrated books, pamphlets and leaflets; besides promoting the movement through articles published in the daily papers and the technical press; and the making of special reports and publishing of same.

The first and second methods are by far the most advantageous as regards the studying of safety devices and industrial hygiene, but they are limited to those persons who live in or near the city in which the museum is located. Those outside this narrow area would not gain any advantage from it. The third method has a larger scope, but is limited by the fact that it is only possible to lecture a limited number of times in any year in any one large industrial center. The publication of illustrated books, pamphlets and leaflets which can be mailed to anyone, places the last method far ahead, as regards the number of persons which it reaches, of all the other methods combined.

It may be of interest to those not familiar with the service which such a museum can render, to make some extended references to the activities of the American Museum of Safety. It applies all four methods given above. In its exhibition hall it now has over two hundred full-sized apparatus and models, besides having at least three thousand mounted photographs from both foreign and American practice. The exhibits, including the photographs, are divided into three sections, each of which is under the jurisdiction of a committee; more sections will be added from time to time, as space and exhibits warrant. The three sections at present are: iron and steel; fire prevention; and industrial hygiene and sanitation. There is also a general section which includes exhibits which do not come properly under the other three. The chairmen of these section committees are men who are authorities on their special subject.

The exhibits are put in the museum by the manufacturer or inventor himself. Among the conditions for exhibiting are the following:

1. No exhibit is allowed to be displayed which has not been approved of by the Board of Approval of Exhibits.
2. There will be no charge for space in the exhibit hall.
3. The installation of an exhibit is at the exhibitor's expense.
4. Exhibits are accepted with the understanding that they are not to be removed within twelve months except with the consent of both the Director and the Chairman of the Board of Approval.
5. Exhibits are not accepted which are not purchasable in any market or commercially available in the industries as a means to prevent accidents.
6. Untried inventions are not accepted.
7. The museum assumes no responsibility for any damage by fire or loss by theft.

These conditions are nearly the same in all the museums.

A few of the more important firms which are exhibiting in this museum at the present time are: The United States Steel Corporation, and several independent steel companies, Brown & Sharpe Mfg. Co., Mergenthaler Linotype Co., National Cash Register Co., Norton Co., Patent Scaffolding Co., Pennsylvania Railroad Co., Prudential Insurance Co., Standard Oil Co., Travelers Insurance Co. and many others.

The American Museum has been visited since its opening by the presidents, general managers and committees of safety of different companies, state factory inspectors, casualty insurance inspectors, engineers, workmen and students. The museum provides a demonstrator who shows and explains all the devices.

The library of the museum contains bulletins, reports, catalogues, books, charts and articles taken from different publications. When this library was started there was very little literature on these subjects in the English language, while the foreign publications were more numerous, especially those in German. Accident prevention is now a very live subject in America, the result of which is that special articles and books are increasing in numbers. Many of the foreign publications are not easily obtainable anywhere else in the United States for reference or study. This library is growing very fast and is an important adjunct to the museum.

In lecturing before associations, workmen, superintendents, foremen, inspectors and others, the museum has had a splendid chance to do educational work. At the present time there are four members of the museum who are doing this lecture work. Each of them has from one to two hundred colored slides of practical safety devices. During the last year the director of the museum has had the opportunity of lecturing before the superintendents, foremen, and workmen of several of the large steel companies, the New Jersey Zinc Co. and the Pennsylvania Railroad Co. The number of people who have been reached by these lectures averaged between three to twenty-one hundred at each lecture. The total number of lectures delivered during the year has been in the neighborhood of fifty.

From the time of the museum's first inception to the present time, there have been published a number of pamphlets and books to promote the work of the museum, as well as to educate the public to the waste of life in the industries. The museum has had the cordial cooperation of the daily papers and the technical press in the work which it is carrying on. The museum, at the present time, is engaged in publishing

"Safety Manuals" and leaflets, of which two manuals and three leaflets have already been published. Other manuals and leaflets are in preparation and will be issued from time to time during the course of the year. The museum has embarked on a new method of valuable help to the employer which is the inspection of plants and the reporting of the kind of safeguards recommended. The museum is always glad to answer any legitimate question in regard to accident prevention.

The museum awards annually three gold medals, the first of which is known as the "Scientific American Medal of the American Museum of Safety," and is given to "such individual or corporation as has produced and exhibited in the American Museum of Safety within a recent period of years any perfected device of utility which in the judgment of the Jury of Award of said museum best conserves human life and limb in the processes of productive industry." This medal has been awarded three times. The second medal is the "Travelers Insurance Company Medal of the American Museum of Safety," which is awarded to the "American employer or other corporation which in the judgment of the Jury of Awards of the museum has done most or achieved greatly, during a recent period of years, in the conservation of the lives and limbs of their workmen by means of safety devices for machines and processes." This medal has been awarded twice. The last medal is the Louis Livingston Seaman Medal of the museum to be given for progress and achievement in the promotion of hygiene and sanitation and the mitigation of the evils of occupational disease. This was awarded for the first time in 1911.

The Legislature of the State of New York passed in May, 1911, a bill incorporating the American Museum of Safety. The museum is a non-commercial enterprise, and it does not take orders for any of the devices it happens to exhibit. It has so far received no financial support from city, state or national government, but is maintained entirely through membership subscriptions. In this respect it differs from the foreign museums, which, as explained before, obtain at least some governmental support. It is to be hoped that the industrial community will realize the public service which the museum is rendering and will seek to cooperate in its work as a public duty.

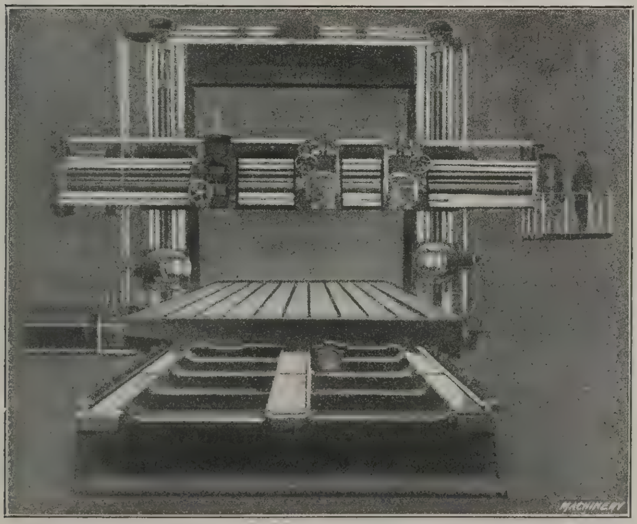
A LARGE GERMAN PLANER

The accompanying illustration shows a planer built by the firm of Wagner & Co., Dortmund, Germany. This machine is intended for work on turbine housings and is built for F. Schichau in Elbing. The extreme length of work that can be



A Large Planer which takes in Work approximately 34 by 16 by 13 feet

done is about 34 feet 5 inches, and the extreme width, 16 feet 5 inches, the limit in height being 13 feet 1 inch. The main drive is from a 60-horsepower motor. The machine is provided with a milling head in addition to the four planer heads. Auxiliary motors are used for the various feeds.

PLANING STEEL RACKS FOR FROG AND SWITCH PLANERS

The rack used on the frog and switch planers manufactured by the Cincinnati Planer Co., Cincinnati, Ohio, is made of a steel forging instead of from cast iron, on account of the heavy duty that this type of planer is called upon to perform. The rack is made in sections, these being fastened securely by bolts and dowels to the under side of the planer table. To cut the rack teeth, the sections of the rack are clamped to the planer table, as shown in Fig. 1, the rack teeth being formed with cutting tools held in the tool-head.

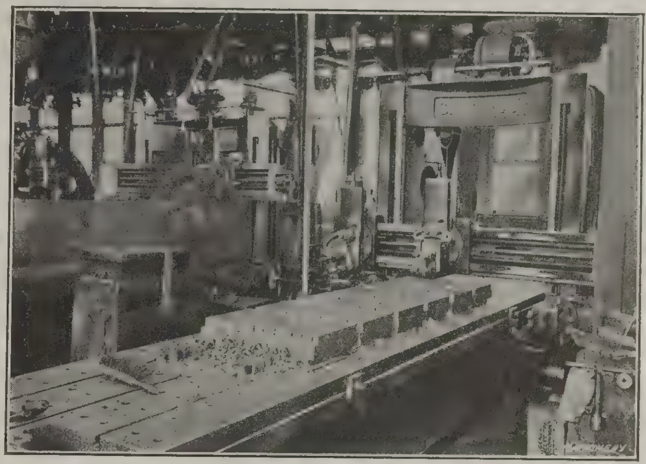


Fig. 1. Planing Teeth in Steel Racks for Frog and Switch Planers

The rack sections shown clamped to the planer table in Fig. 1 are made from 40-point carbon steel forgings, and the teeth, which are 1½ diametral pitch, are cut from the solid block. Naturally, this operation requires considerable time, and calls for a special type of planer tool equipment. The successive tools used are shown in Fig. 2. Here *A* is the first roughing tool—similar in shape to a wide parting tool—with a nose ⅝ inch wide. This tool is used to rough out the teeth, taking a cut 0.040 inch deep per stroke, at a cutting speed of 40 feet per minute. After all of the teeth have been roughed out to within about ⅛ inch of the proper depth, tool *B*, having a stepped face is used to rough out the angular

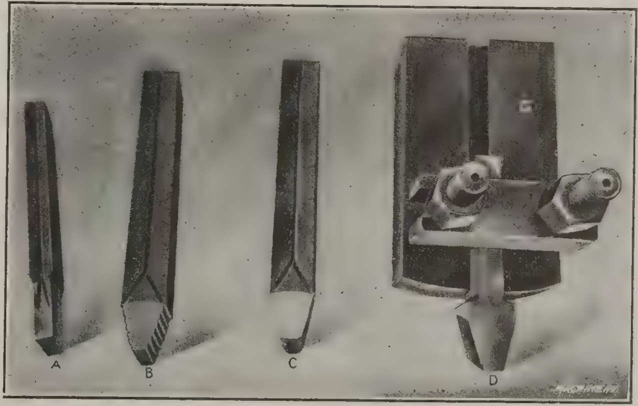

Fig. 2. Successive Tools used in Cutting the Steel Rack Teeth in the Rack for a Cincinnati Frog and Switch Planer

sides of the teeth. Next, tool *C* is put in the tool-holder, and all the teeth are finished to within about 1/64 inch of the proper depth.

The final shape is given to the teeth by the rack-tooth cutter *D*. This is held by a strap, bolts and nuts in a slot in the special block *G*, the latter fitting snugly in the clapper-box. Holding the finishing tool in this manner insures that the teeth will be accurately formed on the sides, and also maintains the proper face angle. The spacing of the teeth, of course, is accomplished by means of the micrometer collar on the rail-screw.

The total steam power used in the United States is about 27,000,000 horsepower. It is estimated that 35,000,000 horsepower could be made available from the waterfalls. Of this about 5,000,000 horsepower has been developed.

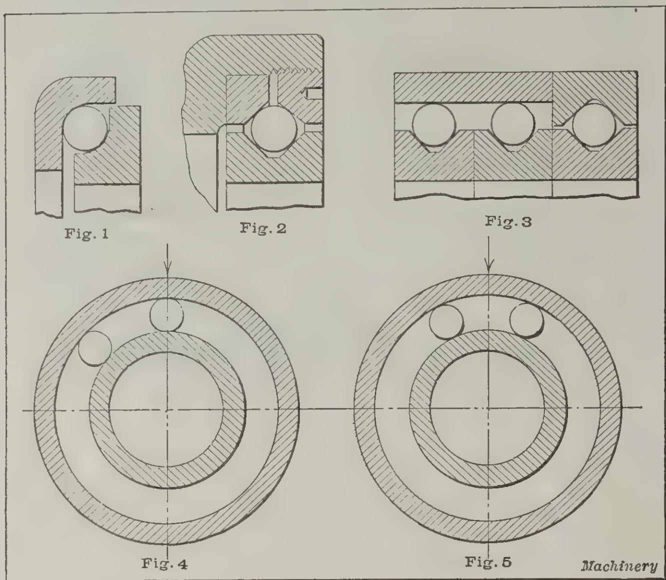
BALL AND ROLLER JOURNAL BEARINGS*

THEIR DEVELOPMENT FROM EARLY TYPES AND CONSIDERATIONS IN THEIR DESIGN

BY ROBERT H. GRANT†

In a previous article, appearing in the August number of MACHINERY, the writer reviewed the history and development of ball and roller thrust bearings. In this article ball and roller journal bearings will be treated.

The first type of ball bearing used was that known as the cup and cone type, a section of which is shown in Fig. 1. The design of these bearings has been varied considerably, some designers having advocated a two-point bearing, and others a three-point bearing; some have believed in the use of large balls, and others in balls of a smaller size, etc. At the present time it is of little importance, however, as later types of bearings have taken its place.



Figs. 1, 2 and 3. Early Types of Ball Thrust Bearings. Figs. 4 and 5. Action of Ball Journal Bearings when Distance between Bearing Points is too Great

The next type of bearing was the grooved ball shaft bearing, a section of which is shown in Fig. 2. This bearing had three hardened steel races, and was fitted to a housing or hub. The plain outer race was driven into place and the threaded race was a good fit in the housing, so that the two would be in alignment with each other. The inner race or cone was a sliding fit on the shaft, so as to allow it to adjust itself to the outer races. This bearing was satisfactory for light loads and high speeds, but had to be very accurately ground and fitted; otherwise there would be a three-point bearing instead of a four-point, which would soon cause wear. On account of the expense of manufacture and mounting, this bearing has been very little used. The adjustable feature also caused a great deal of trouble due to the fact that inexperienced users would adjust the bearings improperly; hence, types were developed in the early years of bicycle manufacture which could not be adjusted.

The next bearing developed was a modification of the grooved ball shaft bearing, as shown in Fig. 3. The first bearing in the series is a regular grooved ball thrust bearing which takes the end thrust, while the other ball bearings take the journal load, thus distributing it over the whole length of the journal bearing. This bearing was applied to a railway car as early as 1888 and is now quite extensively used on electric cars.

While many other bearings have been developed and tried, the regular annular ball bearing has been adopted by nearly all manufacturers as the standard. These bearings are now being made of the same inside and outside diameters and thicknesses by all makers. The various makes differ only in the material, workmanship, size of ball, and design of cage. The material mostly used for the ball races is an alloy steel made in the form of tubing. One steel much used for this purpose, as made by the Becker Steel Co., of New York, is composed of carbon, 1 per cent; chromium, 1.25 per cent; manganese, 0.35 per cent; phosphorus and sulphur, not to exceed 0.025 per cent; and silicon, 0.25 per cent. In German bearings a chromium content between 1.50 to 1.60 per cent is used. It is claimed that this alloy steel gives still better results. Alloy steels of this type will stand a high surface pressure, which is necessary on account of the fact that the ball has practically only a point bearing in the race.

The cage, the design of which varies considerably with different manufacturers, should be made of a light, strong material and should prevent the balls from coming in contact with each other, and at the same time give them perfect freedom of action. The diameter of the balls to be used must, of course, be determined largely by the load that is to be carried; the ball must have sufficient diameter to stand the strain. It is evident that the closer the points of contact are to each other when the load comes onto the balls, the better will the bearing run. If the balls are small there will be a greater number of points of contact, and the bearing will work more freely, but the size of the ball must be kept within safe limits to prevent it from breaking.

The ball cage is of vital importance, as it reduces the friction between the balls, preventing them from rubbing against each other, but it should be so made that the bearings can be almost entirely filled with balls. In Figs. 4 and 5 are shown two diagrammatical sketches to illustrate the importance of having the bearing nearly filled with balls and the bearing points as close to each other as possible. When the load is directly over one ball, as shown in Fig. 4, this ball will carry the greater part of the load. When the load comes between the balls, as in Fig. 5, the ball just coming into action will necessarily take more of the load than the ball which is leaving the line of action. It will carry this increased load until it reaches the center and for some distance beyond. Thus it can be seen that if three or four balls are at the same time near the line of action, the load of the bearing is more evenly distributed over the balls. This condition can only be obtained by making the cage so that the balls practically fill the annular space of the bearing.

Types of Ball Bearing Cages

The first cages used were designed with so great a distance between the balls that the bearing could carry only a very light load. In recent constructions it has been found possible to make ball bearings with a cage where 96 per cent of the space between the races is filled with the balls. The balls are introduced through filling slots, the size of which is a little less than the diameter of the ball, so that the latter are forced in between the two races under pressure. The shallow filling slots are not as deep as the ball races and are inclined at an angle to these. The early cages, such as shown in Fig. 6, were made from brass castings and were very clumsy and heavy. Later sheet-steel cages came into use, but the best cages, at the present time, are pressed up from sheet bronze or brass, in two parts, and are then riveted or fastened together after the bearing has been assembled.

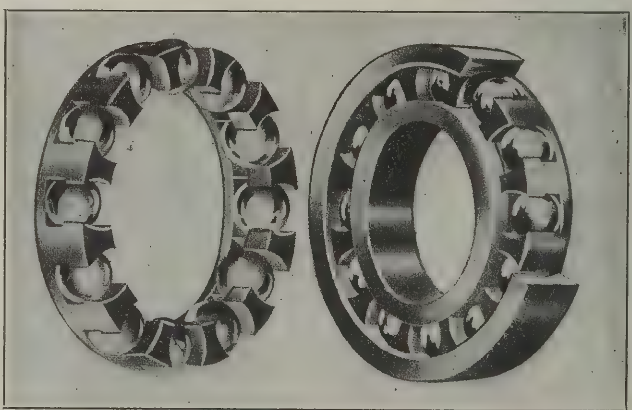


Fig. 6. Early Type of Ball Cage for Journal Bearings

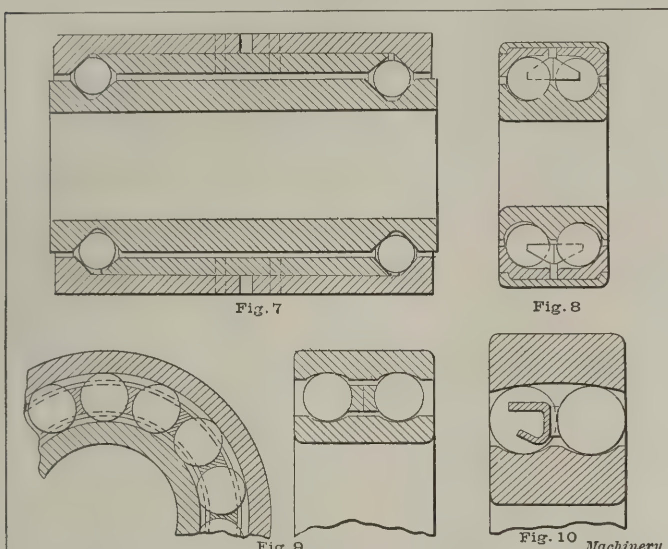
*See "Ball and Roller Thrust Bearings," MACHINERY, August, 1912.
†Address: 912 Oakland Ave., Ann Arbor, Mich.

Double Row Annular Bearings

On account of the thrust to which annular bearings are sometimes subjected, the regular type was found unsatisfactory for certain work, and the double-row annular bearing was introduced. The first double-row annular bearing made in this country was designed and put on the market by the writer in 1890. The first design of this bearing is shown in Fig. 7. This bearing was not ground, but simply polished, and proved very satisfactory in a great many cases. It was, however, somewhat ahead of its time, and did not become as popular as the single-row bearing. The first double-row bearings of this type were made from soft steel and casehardened. Later they were made from regular tool steel and finally from an alloy steel.



Figs. 7 to 10. Various Types of Double Row Ball Journal Bearings

A type of double-row annular bearing made by the New Departure Mfg. Co., Bristol, Conn., is shown in Fig. 8. This bearing is composed of a cone with two grooves, two cups, and a shell. One cup is first forced into the shell, then the bearing is assembled and the second cup forced into place, after which the shell is spun over at the ends. When this bearing was first made, the cage was solid, and, therefore, caused considerable trouble, as it was practically impossible to get both races of exactly the same diameter. This caused the balls on one side to run at a different speed from those on the other, resulting in damage to the cage. This difficulty was overcome by making the separator in two parts, thus allowing each row of balls to run independently of the other.

Another type of double-row annular ball bearing is that brought out by Fichtel & Sachs, as illustrated in Fig. 9; this is practically composed of two single-row annular bearings. The cage used in this case is especially advantageous, as it permits the balls to occupy about 96 per cent of the annular space. The balls are introduced after the cage has been put into the bearing.

The double-row annular ball bearings manufactured by the S. K. F. Ball Bearing Co., Fig. 10, have a distinctive feature of self-alignment. Although this bearing has a retainer made of one piece, it is so constructed that both rows of balls take an equal amount of the load at all times.

Review of Manufacturing Methods

In the manufacture of annular ball bearings the methods have changed very rapidly. The bearings were first made by turning the races from a solid bar, which was a very expensive process, as about 75 per cent of the stock was wasted. In Fig. 11 is shown the method wh ch the writer adopted in the early stages of the ball bearing manufacture, in order to economize on material as well as to cheapen the cost of production. The operations were performed on a Cleveland automatic screw machine and consisted in first drilling and reaming the central hole; then, with a hollow mill having a pilot to guide it, the space between the races was cut out. A grooving tool formed the recesses for the balls, after which the pieces were cut off. As the larger sizes of bearings came into use, forgings were adopted for the races for these sizes. The method first employed for finishing these forgings was to use a hand screw machine; later the semi-automatic machine was adopted for this work.

The latest and best method for making the ball races is to make them from tubing. On account of the processes through which the tubing has passed, the metal is very dense and close grained, so that the bearings made from this material have an excellent bearing surface.

After the races have been machined it is necessary that they should be heat-treated. The treatment consists in heating the bearing very slowly to or near the recalescent point and then allowing it to cool slowly. This treatment is given to the ball races in order to prevent them from warping out of shape in the hardening process. After being hardened they are subjected to an artificial seasoning; without this operation they would not keep their shape.

The simplest method employed for the seasoning is to use a wheel about 6 feet in diameter, mounted on the top of a tank containing boiling water. The wheel is slowly revolved, and to it are attached wire baskets which hold the races. These come into contact with the boiling water for a short time, after which they cool off slowly during the remainder of the revolution of the wheel. The races are subjected to this treatment for about twelve hours, and in this way a result which ordinarily requires two months for its accomplishment is rapidly obtained.

The next operation is to rough-grind the bearing, after which it is allowed to rest for several days before being finish-ground. When finish-grinding the bearing, it is completely finished all over except on the outside diameter, which is left until after the bearing has been assembled, in order to insure perfect concentricity. The machines and methods used in the manufacture of ball bearings will be taken up in detail in a future article.

Roller Journal Bearings

In the making of roller journal bearings, the most difficult problems are to insure the alignment of rollers and to take care of the thrust at the end of the roller. Most of the improvements on these bearings have been to provide rings or collars to hold the rollers in position, as well as to take the thrust. One of the first roller bearings to be manufactured was made by the Ball Bearing Co. of Boston, Mass. This bearing had thin annular disks or washers at the ends, with flat brass stay-rods connecting them. The sides of these stay-rods were concave and held the rollers in place. The rollers were made in short lengths with nothing to prevent them from wearing out through the end of the cage, which they very often

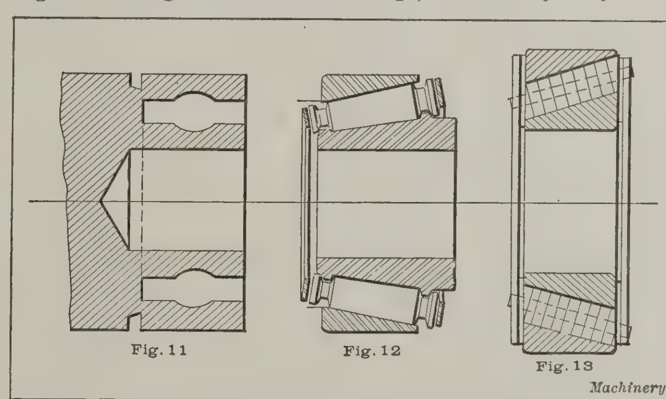


Fig. 11. Method of Turning Ball Races from Bar Stock. Figs. 12 and 13. Taper Roller Journal and Thrust Bearings

did when the sleeve, casing or roller was not ground perfectly straight.

The Standard Roller Bearing Co. of Philadelphia, Pa., then brought out another roller bearing in which the cage was made by drilling holes into the ends of sleeves, the metal in which was thinner than the diameter of the roller to be used. Two such sleeves were used for each bearing (one at each end), the two sleeves being held together by stay-rods. A ball was placed at the bottom of the drilled hole, against the end of the roller, in order to minimize the friction. This construction, of course, overcame the difficulty of having the roller wear through the cage end, but the rollers were not kept in perfect alignment, as the holes in the cages had to have some play in order to have the bearing run smoothly.

Other bearings have been developed which overcome the difficulties mentioned. Among these are the Zahn bearing where the roller is provided with a groove around it which fits either a projecting ring solidly held in the bearing, or shoulders on the races which are supposed to keep the roller in perfect alignment, and, at the same time, take the thrust. Another bearing known as the Johnson bearing, which is shown in Fig. 14, is provided to take the end thrust as well as the annular load and to overcome the difficulties due to lack of alignment in the rollers. In this bearing the stay-rods which hold the cage together are provided with two balls inserted in them which hold the rollers in alignment. The ends of the cage are grooved and a hardened steel washer is inserted. The balls which take the end thrust bear upon this washer. The roller is also provided with a ball at each end to eliminate friction. This bearing has some good features, but it is very intricate and must be made with great care. It is also rather expensive unless used where the end thrust, as well as the radial load, is to be carried.

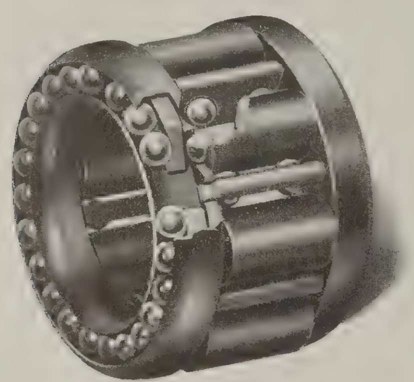

Fig. 14. The Johnson Bearing for taking Both Radial Load and End Thrust

Taper Roller Journal Bearings

Taper roller journal bearings have certain advantages, but they also introduce certain conditions which are difficult to overcome, the same as do taper roller thrust bearings. The first bearings of this kind were made by the Grant Axle & Wheel Co., of Springfield, Ohio. This bearing took the thrust on the cone and had holes in the rollers with stay-rods through them to form the cage. This style of bearing is supposed to take the thrust as well as the radial load. When taking the thrust on the ends of the roller, however, there is a tendency to twist the roller and to get it out of alignment with the axis of the shaft, and if the rollers are not all of exactly the same size, the larger rollers that take the thrust will soon chip off and wear out.

The Timkin Roller Bearing Co., of Canton, Ohio, soon followed the Grant Axle & Wheel Co. in making a bearing in which the thrust was taken exactly as in the Zahn bearing previously mentioned, where the roller is grooved and fits ridges in the race. To still further develop this bearing, two grooves were provided in the roller and two ridges on the inner ball race, as shown in Fig. 12. The latest type of straight roller taper bearing is that shown in Fig. 13. Here the rollers are made up of short straight sections, the same as in a plain roller thrust bearing. The use of straight rollers in this bearing causes slippage of the rollers. On account of the difference between the surface speed at the large and small diameters of the cone, there is a great deal of slippage which, although it increases the friction, at the same time takes the thrust of the bearing.

WORM AND HELICAL GEARS AS APPLIED TO REAR AXLE DRIVES*

European practice extending over a period of fifteen years has given ample evidence of the eminent success of the worm and helical type of gearing, and the author feels confident in saying that in the near future a large percentage of the cars in the United States will be equipped with this drive. The principal reason for the adoption of the helical form of tooth appears to be its peculiar quality of silence, regardless of speed or load. With the best methods of design and assembly, great durability, strength and efficiency are obtained.

It is impracticable in an article of this character to cover all the details satisfactorily. However, the author believes that on all styles of cars in the United States to-day the worm gear could be used successfully for rear axle purposes.

* Abstract of paper by Mr. Frank Burgess, read before the Society of Automobile Engineers at the Detroit meeting, June 27-29, 1912.

The successful worm gear should embody the following qualifications:

1. Cheapness of construction.
2. Strength for resisting shocks.
3. Hardened and smooth surfaces for durability.
4. Material of a suitable composition to reduce friction.
5. Simplicity of construction and mounting.
6. Perfect bearing conditions.
7. Noiselessness at any speed or load.
8. Reversibility.
9. Lightness in weight.
10. High efficiency in power transmission.

Granting that there is some argument against the worm in regard to trucks as to the dead axle proposition, this could be overcome by using a worm gear on each end of the axle, the same as sprocket wheels, having a double worm gear drive in place of the cumbersome chain drive. If at first slightly more expensive than the chain and sprocket drive, less repairs will more than make up the difference. Care should be taken to have accurate bearings, both radial and end-thrust.

RESULTS OF EFFICIENCY TESTS ON ORDINARY TYPE WORM-GEAR FOR AUTOMOBILE REAR AXLE DRIVE FOR ELECTRIC VEHICLES AND LIGHT POWER CARS

Number of Test	Temperature of Worm-gear, Degrees F.	Twist of Shaft in Degrees	R. P. M. of Worm	R. P. M. of Worm-gear	Input, Transmission Dynamometer, Horsepower	Output, Brake Horsepower	Efficiency, Per Cent
1	74	$1\frac{1}{4}$	1393	143	1.64	1.01	61.6
2	82	2	1423	146	2.65	2.11	79.6
3	86	$2\frac{3}{4}$	1416	145	3.41	3.11	91.3
4	86	$3\frac{9}{16}$	1416	145	4.46	4.15	93

6	94	$5\frac{7}{16}$	1389	142.5	6.72	6.12	91.2

Worm-gear: Phosphor-bronze, 39 teeth.
Worm: Casehardened steel worm, solid on shaft, quadruple thread.

Considerable discussion has arisen in regard to the relative merits of the straight and Hindley types of worm gearing. In my opinion both can be used successfully, although each has its own advantages and disadvantages. For most purposes, particularly where considerable power is to be transmitted, the Hindley type has the advantage, but with ordinary machinery it is somewhat more difficult to obtain the same degree of accuracy as can be obtained in the case of the straight type.

From tests made there is no question but that there is a larger bearing surface on the Hindley type of worm than on the straight. Therefore this type of gearing will for the same pitch present a bearing of greater durability, and heat less than the straight type, particularly under heavy load. The straight type may have less trouble with end-thrust bearings. The worm can move in its position longitudinally with the worm axis and therefore does not require as close an adjustment of the end-thrust bearings. With first-class bearings the Hindley type has the advantage, as a smaller and lighter gear can be used, thus reducing the expense.

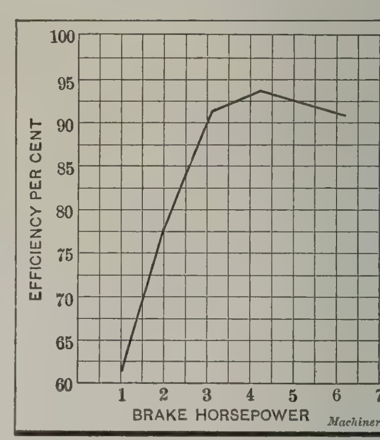

Diagram showing Relation between Brake Horsepower and Efficiency, based on Results of Tests

Some efficiency tests on an ordinary type worm and worm-gear for automobile rear axle drive, for electrical vehicles and light-power cars, were undertaken by the author. A transmission dynamometer, similar in some respects to the apparatus used at the Massachusetts Institute of Technology by Prof. Riley, was constructed. The prony brake was adopted for an absorption dynamometer, and a long shaft of small diameter was arranged to obtain the torsion of the shaft in degrees by an electrical indicator apparatus for a transmission dynamometer. The results of the tests are given in the accompanying table. The diagram shown gives a curve plotted from the results obtained in the tests and recorded in the table.

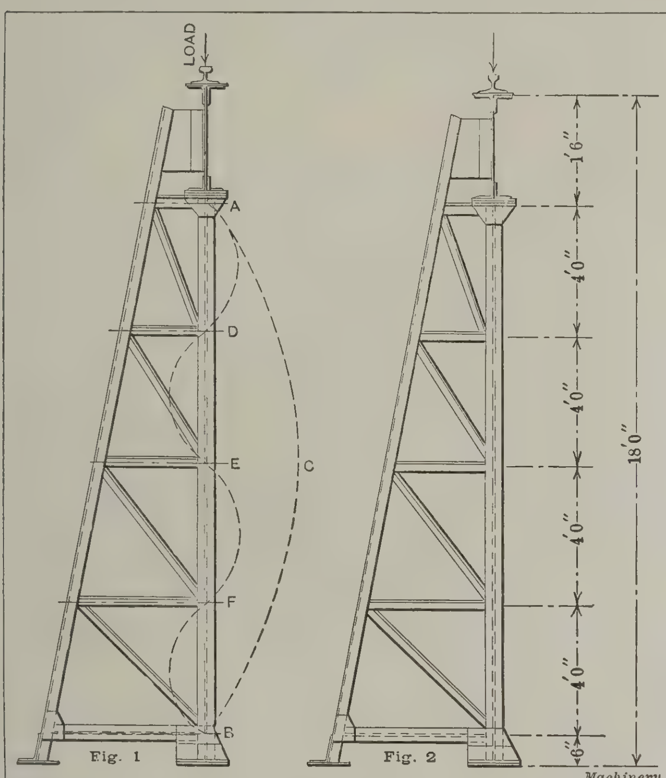
STRESSES IN AN A-FRAME FOR A CRANE RUNWAY

AN ANALYSIS OF THE PRIMARY STRESSES AND A DISCUSSION OF THE STRESSES IN THE LATTICE BARS

BY HARRY GWINNER*

Fig. 1 is an outline of an A-frame or trussed column for a crane runway. The following information has been requested in connection with it: "A discussion of the stresses in the members; a graphical analysis of the stresses; and an investigation into the influence that the other members have upon the perpendicular main member when choosing a section, as in the case of a column."

This frame will be treated as being subjected at different times to a different set of forces, which actually occurs in practice. In Fig. 1 the frame is shown as being subjected to a direct load along the axis of the main member *AB*. Under this load there is no tendency for the frame to rotate about the foot of the column *AB* (provided there is no eccentric stress in the column), and while the trussing does not receive any primary or direct stresses from this load, it does receive secondary stresses when the column begins to deflect under the load, or when the inevitable shortening begins to take place—that is, when the points *A* and *B* approach each other.



Figs. 1 and 2. Analysis of Stresses in A-frame for Crane Runways

The object of the trussing is to prevent buckling in the column at the points of attachment of the trussing, and will compel the member *AB* to assume the compound curve line, threading in and out of the column through the points of attachment *ADEFB* instead of bending along the single curve *ACB*, when deflection begins to take place. Thus the member *AB* may be treated as a column or strut of one-quarter of the length of *AB* (since the trussing as shown in the figure divides the length into four portions), so far as bending in the plane of the trussing is concerned.

To test the column to note the effect of the trussing or bracing, assume in Fig. 2 a direct load of 150,000 pounds, and the dimensions as shown. Assume a 15-inch by 42-pound I-beam for the column, and use the straight line column formula:

$$P = 16{,}000 - 70\frac{l}{r}$$

where

P = permissible unit stress,

l = length of column,

r = radius of gyration.

Then we have for the permissible unit stress per square inch for the four-foot sections:

$$16{,}000 - 70\frac{4 \times 12}{1.08} = 12{,}890 \text{ pounds,}$$

1.08 being the least radius of gyration about the line 1—1, Fig. 3.

The permissible unit stress for the full length portion, taking the radius of gyration about axis 2—2, is:

$$16{,}000 - 70\frac{18 \times 12}{5.95} = 13{,}460 \text{ pounds}$$

Thus it will be seen that the trussing breaks the continuity of the column on the weaker side, and, hence, strengthens it materially.

Stresses in Truss Members

The stresses in the truss members are secondary ones, similar to those induced in the lattice bars of a built-up column. Some years ago the writer took up the matter of stresses in lattice bars with Prof. Mansfield Merriman—the author of the well-known work on "Mechanics of Materials" —who, at that time gave the information that no rational formula had been deduced for accurately computing the stresses. In an article on "Tests of Built-up Steel and Iron Compression Pieces," in the *Transactions of the American Society of Civil Engineers*, Vol. LXV, 1909, the results of the experiments undertaken showed that there is no simple mathematical law governing the distribution of the stresses in a latticed column, and in Bulletin No. 44, issued by the University of Illinois Engineering Experiment Station, on "An Investigation of Built-up Columns Under Load," a portion of the summary of the tests says: "It seems futile to attempt to determine the stresses which may be expected in column lacing for central loading by analysis based on theoretical consideration or on data now available."

Hence, it is theoretically impossible to assign any definite values to the horizontal reactions, or the tendency to buckle at the connections of the trussing to the column. However, the following method is sufficiently accurate to determine the stresses for the purpose of proportioning the trussing. Using the formula $16{,}000 - 70\frac{l}{r}$ to get the permissible unit stress on the column, and with the assumption that the column is very short, 16,000 pounds per square inch will be used. The expression $70\frac{l}{r}$ may, therefore, be taken as the measure of the stress per square inch due to bending in the column under a direct load.

If l is in feet, this expression becomes $70 \times 12\frac{l}{r} = 840\frac{l}{r}$. Designating this stress per square inch as S, we have $S = 840\frac{l}{r}$. Then, by assuming a load put on the side of the column to produce this stress, we can more easily ascertain the stresses. Hence, place the column as shown in Fig. 4, loading it with a uniform load of w pounds per linear foot, and treat it as a beam. Then the beam will tend to deflect as shown by the dotted curve *xzy*. If the column is treated as being pin-connected at *A* and *B* in Fig. 1, it will have a tendency to assume the curve *ACB* shown in Fig. 1, which is very similar to he curve *xzy* in Fig. 4. Under his assumption, we may treat the bending in the column as if it were caused by the uniform load in Fig. 4.

Now, $\frac{wl^2}{8}$ is the bending moment in foot-pounds, or $\frac{12wl^2}{8}$ is the bending moment in inch-pounds. Then,

* Dean of Mechanical Engineering and Superintendent of Shops, Maryland Agricultural College, College Park, Maryland.

$$\frac{\text{Bending moment}}{\text{Section modulus}} = \frac{M}{Z} = S_1$$

Therefore, $\frac{12}{8} \times \frac{wl^2}{Z} = S_1.$

Let I = moment of inertia,
C = distance from center of gravity to extreme fiber,
A = area of section,
r = radius of gyration.

Then,

$Z = \frac{I}{C} = \frac{Ar^2}{C}$, and, from the previous equation,

$$S_1 = \frac{12wl^2}{8} \times \frac{C}{Ar^2} = \frac{3wl^2C}{2Ar^2}$$

Therefore, as S and S_1 are approximately the same, $\frac{840l}{r} = \frac{3wl^2C}{2Ar^2}$ and solving for w, we have:

$$w = \frac{560Ar}{lC}, \text{ or total load} = \frac{560Ar}{C}$$

Therefore, R in Fig. 4 is $= \frac{560Ar}{Cl} \times \frac{l}{2} = \frac{280}{C}Ar.$

Having found R, treat the frame as for finding the stresses in a latticed truss, and as indicated in Fig. 5.

The writer recently requested sme information on trussed columns from two expert detailers and designers on columns employed by a bridge company with whom he was at one time employed. They both agreed that the most suitable way to handle such problems was to assume a deflection of two or three inches at the center of the column (after designing the column to take care of the direct load), and then to ascertain the amount of load which, when the column was treated as a beam, would produce this amount of deflection. The stresses at the different points along the beam (column), are proportional to the ordinates of the curve as shown in Fig. 4.

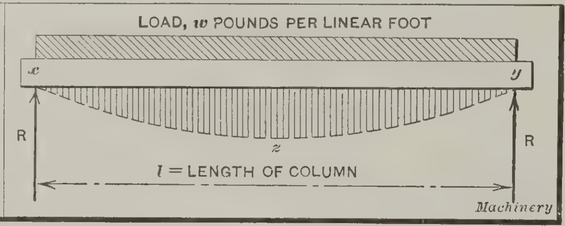


Fig. 3 Fig. 4. Column treated as Beam

Under this assumed deflection, the lengths of these ordinates can be measured on the supposition that this deflection, or elastic line, is a sinusoid, the equation of which is

$$Y = \triangle \sin x \sqrt{\frac{P}{EI}}$$

as given in Johnson's "Modern Framed Structures" under column formulas. This method is rather crude, but it has the advantage of giving something upon which to work.

The New Jersey Steel and Iron Co. has incorporated in its specifications the following clause: "The lattice bars shall be so spaced that each channel between the lattice connections shall be stronger than the column considered as a whole, and their size shall not be less than would be obtained by treating the column as a lattice girder supported at the ends and loaded at the middle with a load equal to 3 per cent of the total compression on the column. Mr. Pritchard, who was the engineer of this firm at one time, says the 3 per cent rule was first published in 1891 in the *Lehigh Quarterly*, and that it was adopted as a result of experience.

It is the opinion of the writer that the secondary stresses due to the direct load, as mentioned in the foregoing paragraphs, are very small, and that the theoretical sections required to take care of them are so small that these sections are impracticable, and that any structural shapes which are large enough for the rivets will be greatly in excess of any theoretical sections required.

In general, the practice is to entirely neglect these secondary stresses in crane frames and to design the trussing of such frames for horizontal loads. These horizontal loads are produced when the brakes are applied to the trolley traveling at right angles to the crane girders. The coefficient of sliding friction of the wheels on the rails is found to be about 0.2, and the maximum horizontal load possible, therefore, will occur when the brakes are so suddenly applied to the moving trolley carrying its maximum load, as to cause it to slide on the rails. Therefore, to proportion the trussing, assume 0.2 of the maximum vertical load plus 0.2 of the weight of the trolley applied horizontally at the rails of the runway girders, and design the A-frame as a cantilever for half this load, as it is assumed that the bridge girders of the crane

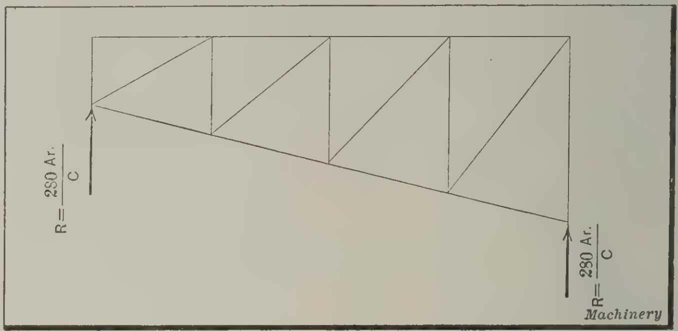

Fig. 5. Frame treated as Latticed Truss

transmit the other half to the opposite A-frame. The column AB (Fig. 1) is therefore designed to take the combined stress due to the direct vertical load and this horizontal load.

The A-frame is often used out-of-doors, and is therefore subjected to wind pressure, and often additional stresses are induced by the swaying of the live load carried by the crane or by an inclined pull caused by the load being out of plumb when the crane starts to lift it. All of these stresses must be considered and the design treated accordingly.

In the request for information that prompted this article, nothing was said relative to the stresses induced by forces in a plane at right angles to the plane of the trussing. If the moment of inertia of the cross-section of the column is not sufficiently strong to take care of these forces, side bracing should be used. The calculation of this bracing is made in a manner similar to that of the portal or intermediate bracing in a bridge.

COURT DECISION ON EMPLOYERS' LIABILITY

A recent unanimous decision of the Illinois Supreme Court in the suit of Milford Streeter of Aurora, Ill., against the Western Wheeled Scraper Works, establishes a new basis for the relation between employers and employes as regards accidents and accident prevention, this new basis being a consequence of the new state employers' liability law of Illinois, which is similar to those enacted in several of the other states. The court, affirming the decisions of two lower courts, holds that the old law, under which an employe could not recover if he knowingly worked on defective or unsafe machinery, is now a dead letter. The wording of the conclusion of the court's decision is as follows:

"The law does not leave to the employer's judgment the reasonableness of inclosing or protecting dangerous machinery, or permit him to expose to increased and unlawful dangers such of his employes as may be driven by force of circumstances to continue in his employ rather than leave it and take chances of obtaining employment elsewhere under lawful conditions. The guarding of the machinery mentioned in the statute is a duty required of the master for the protection of his workmen, and he owes the specific duty to each person in his employ. To omit it is a misdemeanor, subjecting him to a criminal prosecution."

* * *

The oldest metallic objects to which archaeologists have assigned a probable date are those found at Nagada in Egypt. These consist of some pieces of gold, a bead, a button and fine wire of nearly pure copper, which are supposed to be at least 6300 years old. Nearly all the ancient gold that has been examined contains silver enough to give it a light color.

SELECTING THE NUMBER OF TEETH FOR GEARS AND SPROCKETS*

BY G. M. BARTLETT†

The tables in the accompanying Data Sheet Supplement contain the decimal equivalents of all fractions with denominators up to 60. In machine design it is frequently necessary to determine gears and sprockets with low numbers of teeth to give approximately such ratios as can be expressed exactly only with very high numbers of teeth. For example, in a certain machine employing a chain drive, it is required to have the speeds of the driving and driven sprockets as near as possible to 1149 and 473 revolutions per minute. It is stipulated, however, that the number of teeth in the larger sprocket must not exceed 60. Dividing 473 by 1149, we find that the ratio is 0.4117. By referring to the table of fractional equivalents given in the accompanying Data Sheet Supplement, the nearest fractional value to this ratio, with a denominator less than 60, is found to be 7/17. Hence, the number of teeth in the two sprockets can be 14 and 34, or 21 and 51. This will give speeds of 1149 and 473.118 which introduces a comparatively small error. In the absence of such tables, the method of obtaining the approximate fraction 7/17 would be rather cumbersome, as will be seen from the following:

```
473 | 1149 | 2
       946
      ----
       203 | 473 | 2
             406
             ---
              67 | 203 | 3
                   201
                   ---
                     2 | 67 | 33
                         66
                         --
                          1 | 2 | 2
                              2
                              -
```

This is the operation by which the greatest common divisor is sometimes found. Next, place the partial quotients obtained in a row as below. Beneath the first number, write its reciprocal ½. Beneath the second number write a fraction, the numerator of which is the second number itself, and the denominator of which is the product of the first and second numbers plus 1. For the numerator of the next fraction, multiply the partial quotient (3) by the numerator of the second fraction (2), and add the numerator of the preceding fraction (1). The result is 7. For the denominator, multiply the partial quotient (3) by the denominator of the fraction just found (5), and add the denominator of the preceding fraction. The result is 17. Proceed in the same way for the succeeding fractional values, the method used being that of continuous fractions.

2	2	3	33	2
$\frac{1}{2}$	$\frac{2}{5}$	$\frac{7}{17}$	$\frac{233}{566}$	$\frac{473}{1149}$

These fractions approach the value of 473/1149 as we proceed towards the right, but as we cannot use more than 60 teeth in the sprocket, the fraction 233/566 cannot be used. Hence, we must use the fraction 7/17, or, if this fraction does not give a sufficiently close approximation, we must use some fraction between 2/5 and 7/17 that might come closer to the required ratio and which has a denominator less than 60. Between the values of 2/5 and 7/17 there are, then, the following fractions: 23/57, 21/52, 19/47, 17/42, 15/37, 13/32, 24/59, 11/27, 20/49, 9/22, 16/39, and 23/56. Whether or not any of these gives a closer approximation, can only be found by trial. In the present case, of course, the matter would be easily determined, as 7/17 comes so very close to the required ratio.

As another example, suppose it is desired to feed stock to a punch press through rolls of 4-inch diameter, the rolls being turned by a ratchet and pawl at the end of each stroke of the punch. The feed is to be as near as possible to 2¼ inches, and the number of teeth in the ratchet to be as low as possible. To find the answer to this problem with the aid of the tables in the Data Sheet Supplement, we proceed as follows: The feed for one revolution of the rolls is $4\ \pi = 12.5664$. To feed 2¼ inches, the rolls must make $2.25 \div 12.5664 = 0.1790$ of a revolution. Referring to the table, the nearest fraction to this ratio is 5/28; hence we choose a ratchet of 28 teeth, feeding five teeth at a stroke. The feed will be 2.244 inches instead of 2.25 inches, an error of only 0.006 inch. If we should choose the next higher fraction to the ratio 0.1790, which is 7/39, the ratchet will have 39 teeth, and the feed of seven teeth in this ratchet will be equivalent to a feed of 2.256 inches, which also involves an error of 0.006 inch.

If a plate cam is to be cut on a lathe, and it is necessary to feed the tool 0.53 inch for each revolution of the cam, and the lathe is so constructed that it takes 10.35 revolutions of the lead-screw to feed the tool 0.53 inch, the change gears must be so selected that there will be a velocity ratio of 1 to 10.35 between the work-spindle and the lead-screw. Two pairs of gears will be required. Assume the ratio of the intermediate gears arbitrarily as 1 to 3; it remains to find a combination with a ratio as near as possible equal to

$$3 \times \frac{1}{10.35} = 0.2899$$

Referring to the Data Sheet Supplement, the nearest fractions to a ratio of 0.2899 are 11/38 and 9/31. As change gears with multiples of these numbers of teeth are usually not available, we take the nearest available fraction, which is 7/24, giving gears with 28 and 96 teeth, respectively. The ratio 1/3 can be obtained by using gears with 24 and 72 teeth, and the value of the train of four gears, hence, is:

$$\frac{96 \times 72}{28 \times 24} = 10.286$$

which gives a feed of 0.527 inch per revolution instead of 0.530 inch, an error of only 0.003 inch.

Problems in cutting racks for gears of a given diametral pitch, or in cutting screw threads of unusual leads may be considerably simplified by the use of this table.

IMPROVEMENTS IN GAS ENGINE DESIGN

BY GEORGE M. STROMBECK*

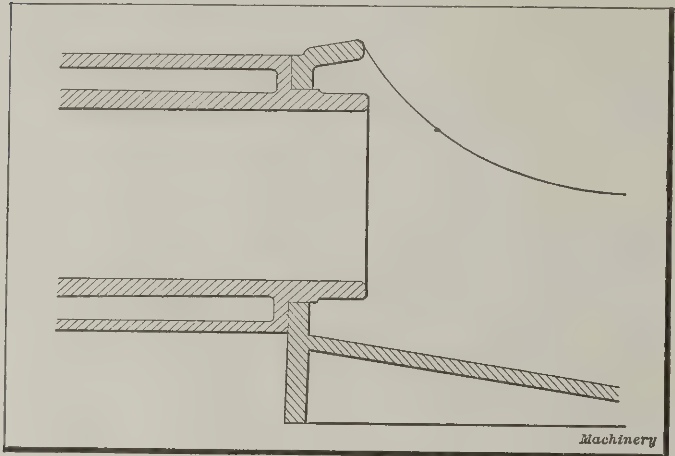
In gas engine design, as well as other matters, experience is the court of last appeal. When any particular practice has stood the test of years, it is not safe, except through knowledge gained by unusually wide practical experience, to condemn it, as there may be reasons for its existence that outweigh the theoretical objections to it. This is especially true in an industry where competition is so keen as in the gas engine business. While much of Prof. Hirshfeld's criticism of gas engine design in the July number of MACHINERY is justified, he attacks a number of things which the writer, after five years' shop experience, believes to be sound practice.

In regard to overhanging cylinders, it is doubtful if anyone would justify the construction in Fig. 1 of the previous article, but the modification hinted at in Fig. 2 and further developed in the accompanying illustration has much to commend it: first, the entire length of the cylinder on all sides is free to expand, and, second, the metal is uniform at all places; these are both the best possible conditions under which a cylinder can retain its shape, thus permitting lighter rings with consequent reduction in engine friction and wear. From a manufacturing point of view the construction is simpler than that shown in Fig. 4 (former article), because all the work can be done at one setting and in a lathe, making it easy to obtain true work. In reference to Fig. 4, every shop man knows that this design involves at least two settings for machining, and this increases the cost. Furthermore, there is a chance of getting the guides out of line with the bore; moreover, some parts of the cylinder section are heavier than others, and as the ribs are bolted to the frame there is a possibility of undue stresses not present with the overhanging cylinder. The makers of a very widely known and successful engine have manufactured over twenty thousand with an overhanging cylinder during the last dozen

* Chief draftsman, Root & Vandervoort Engine Co., Moline, Ill.

years, and have had no trouble whatever from them. In fact, they are so pleased with their performance that they are continuing this feature in a new line now being brought out.

Another point in design which the writer believes has more to justify it than to condemn it is the direct connection between the water jacket in the cylinder and in the head, Fig. 9. That solution of a problem which is direct, and, all things considered, saves most time, must be conceded to be the best engineering practice. Reasonable care in the machining of the ends of the cylinder and head will produce a surface that readily holds a gasket. The only time when trouble would be experienced would be when a part of the circumference is subjected to a much higher temperature than the rest, and when this is the case it would probably be difficult to make a tight joint even though the water jacket were not cut through. If only a part of the extra work necessary to provide other means of cleaning the jacket is applied to making the joint between the head and cylinder right, the trouble with the jackets will not be enough to deserve mention. Any other method would first of all deprive the foundry of a most positive means of holding and venting the jacket core, with a resulting higher loss of castings (with same care and labor). The cleaning out of the core sand and, later,



Method of Attaching and Supporting Gas Engine Cylinder

removing of scale would be much more difficult and far less certain if pockets or hand holes were used. There is a remarkable agreement among manufacturers in this point of design, which would not be the case had their experience proved to them that the present methods were wrong.

A minor point in design is the oil groove around the base. While this, no doubt, serves to collect some oil which would otherwise reach the floor, it is doubtful whether the advantages gained offset the foundry difficulties. To be of service, such a groove must be continuous, which can only be done by bringing it outside of the bosses for the anchor bolts. If this is done, larger flasks and the handling of more sand is necessary; but more objectionable than this is the fact that the sand forming the grooves is poorly supported, requiring careful securing. Even then it may wash away in pouring the casting. These objections have been sufficient to cause the removal of such a drain from such engines as were at first designed with it.

The splash collar on the crankshaft, Fig. 15, is, in theory, a fine thing, but its cost is disproportionate to its advantages. While it looks innocent enough, such a little knife edge would add a very large percentage to the cost of grinding the shafts, which is the present practice. With a straight shaft the operation is simple; with a splash collar more or less complication would be introduced, and much greater care in handling the finished product would be required. The splash collar is a refinement which a very large majority of users of small and medium sized engines would not want to pay for.

The use of malleable iron for connecting-rods is, according to experience, anything but an objectionable practice. The maximum return for minimum effort, that is, the cost, must determine this as well as all other problems in engineering manufacture. In small sizes, steel drop-forgings are the solution. In larger sizes, this is out of the question, and the designer must choose between the turned rod and a cast one. If he wishes the benefit of the economical I-section, the material must either be steel casting or malleable iron. The art of casting steel is not as advanced as that of casting malleable iron; hence, there is more uniformity with the latter.

William Kent, in the latest revised edition of his "Pocketbook," says, on page 430, of malleable iron: "For the repeated stresses of severe service the malleable casting ranks ahead of steel, and only where a high tensile strength is essential must it be replaced by that material." On page 431 he says: "The effect of annealing is to oxidize and remove the carbon from the surface of the casting, to remove it to a greater or less degree below the surface, and to convert the remaining carbon from the combined form into the amorphous form called a 'temper carbon' by Professor Ledebur, the German metallurgist. * * * In the American practice the annealing process is rather a heat-treatment than an oxidizing process." On the following page Mr. Kent says: "It was formerly the general belief that the strength of malleable iron was largely in the white skin always found on this material, but it has been demonstrated that the removal of the skin does not proportionately lessen the strength of the casting."

The above statements agree exactly with the writer's experience with malleable iron connecting-rods. Barring accidents, there has been no trouble with such rods. The effect of inertia on the rod, to be sure, makes it a beam under a continuous load, but this load does not act when the rod is under its greatest stress, nor is it at any time very large in engines of the size that are usually fitted with malleable-iron rods. Hugo Güldner, in his excellent book on gas engine design, gives the maximum bending moment M_b in the plane of the motion of the rod, caused by the inertia, as follows:

$M_b = 0.000002\ n^2 r A g L^2$, where

n = revolutions per minute,

r = radius of crank in inches,

A = area of mean section of rod in square inches,

g = weight of one cubic inch of the material of the rod in pounds,

L = length of rod in inches.

Applying this to an actual case will show the relative unimportance of this bending stress. An engine making 350 revolutions per minute has a connecting-rod 27 inches long. The mean section is I-shaped and has an area of 1.65 square inches, and a moment of inertia of 1.09. The bore is 6½ inches, and the stroke is 11 inches. Substituting in the formula:

$M_b = 0.000002 \times 350 \times 350 \times 5.5 \times 1.65 \times 0.26 \times 27 \times 27 = 421$ inch-pounds.

The rod section is 2¼ inches deep. The fiber stress is then, according to the usual formula:

$$S = \frac{M}{I/C} = \frac{421}{1.09 \div 1.125} = 435 \text{ pounds per square inch.}$$

When it is remembered that this stress does not occur until after the maximum force of the explosion has been exerted, it is plain that it needs but little consideration, and that the use of malleable iron in the connecting-rod is not objectionable.

Concerning the low-tension ignition system, it would seem singular that manufacturers should adhere to it so strongly if there were not much in its favor. Equally singular would it seem that all leading manufacturers of magnetos are now developing low-speed, low-tension magnetos for make-and-break service, if they did not believe in this system. The sooting up and fouling of spark plugs even with automobiles is proverbial. If this is the case in an engine which explodes regularly every cycle, what is to be expected in a hit-and-miss engine on a light load, where the explosions are far apart, giving plenty of time for lubricating oil and soot to foul the plug? With the make-and-break ignition, the motion of the igniter prevents this. The practice of the manufacturers is the result of the experience of numerous experts, continually in the field, who have had full opportunity to compare both systems under all conditions.

MANUFACTURING THE VIXEN FILE*

METHODS USED IN PRODUCING A CIRCULAR CUT FILE

BY CHESTER L. LUCAS†

Since the days when primitive man used the file for sharpening his implements of field and war, the file has been one of the most common tools. As in many other commonplace things, however, no one seemed to see room for improvement until, in 1900, Alexis Vernaz, of Yverdon, Switzerland, was trying to devise a hand tool for cutting a lot of exceptionally hard castings. The Vixen file was the result of his efforts. His whereabouts is not known at present, but there is an Elliott Cresson medal waiting for him that was awarded by the Franklin Institute in 1909 for making the first radical improvement in files for generations. The essential points of the Vixen file are well described by a sentence from the patent specifications: "A file provided with teeth cut in the form of arcs, having their bases located rearwardly with respect to the cutting edge of the teeth."

Fig. 1 illustrates a Vixen file, in which it will be seen that the radical difference between it and the ordinary file lies in the shape of the teeth. The object of curving the teeth is to provide a shearing cut, and by reason of this shearing cut

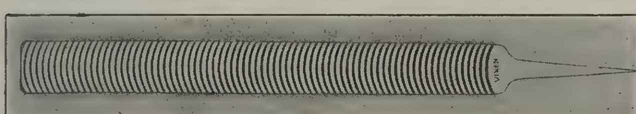


Fig. 1. The Vixen File

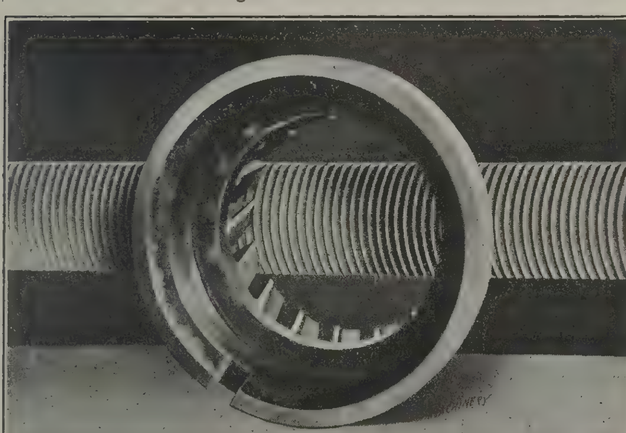

Fig. 2. How the Teeth are cut on Vixen Files

the file is self-clearing. The determination of the radii of the arcs of the cutting teeth of the various sizes of files was the result of experiments which indicate that the best cutting tooth is obtained by using a radius approximately the width of file being made. Teeth cut on smaller radii in proportion to the width of the file make it impossible to guide the file correctly, and teeth of much larger radii do not cut nor clear as easily. The teeth of Vixen files are milled with hollow cylindrical cutters. Several of these cutters are shown in

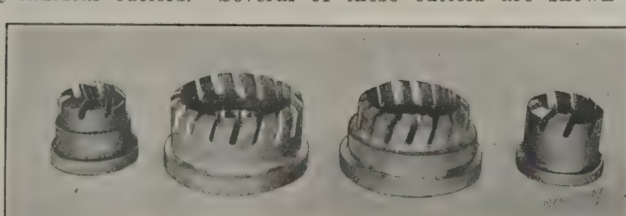

Fig. 3. Four of the Cutters

Fig. 3. Of necessity, the cutter is slightly inclined to the face of the file while cutting the teeth, in order that the side of the cylindrical cutter not being used may clear the parts of the file not being cut. This condition is graphically shown in Fig. 2. The amount of this inclination varies from 2 to 4 degrees, depending on the different depths of cut. By thus inclining the cutter to the work and securing a rake to the teeth, an added quality is given to the tooth, enabling it to cut rapidly. The inclination of the axis of the cutter results in cutting the teeth slightly deeper at the center than at the edges, therefore, the face of the finished file is slightly lower

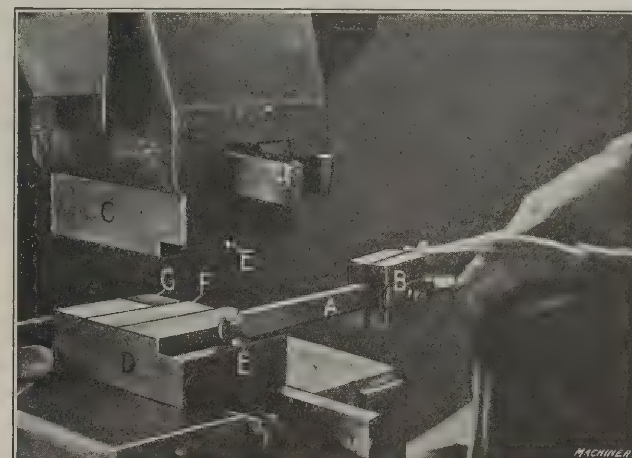

Fig. 4. Forging the Tang

in the center, the amount, however, is so small that it is practically imperceptible.

Steel for Vixen Files

The steel from which Vixen files are made is a Swedish chrome steel and is ordered on specification calling for chemical analysis as follows:

Carbon	1.20 to 1.35 per cent (1.25 per cent desired)
Chromium	0.40 to 0.60 per cent (0.50 per cent desired)
Manganese	not to exceed 0.40 per cent
Silicon	not to exceed 0.30 per cent
Phosphorus	not to exceed 0.03 per cent
Sulphur	not to exceed 0.03 per cent

The hardness, according to the Brinell hardness scale, should be from 130 to 170, a hardness of 150 being desired.

Operations in Making the File

The first operation in the making of the file consists in the shearing of the bar stock to length. This is an

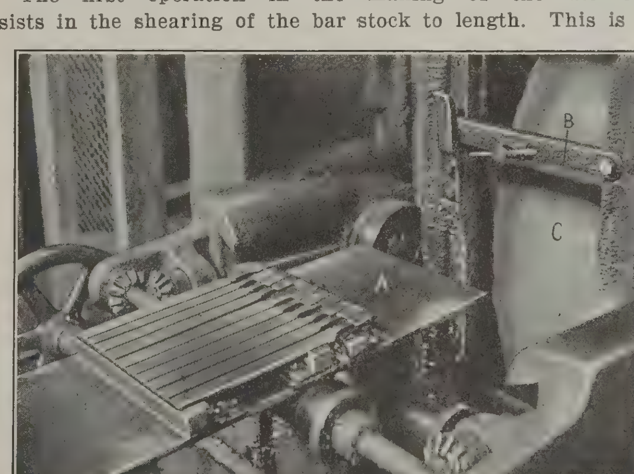

Fig. 5. Grinding the Sides

ordinary operation and is performed upon a shearing press of the usual type. From the shearing press the short lengths of steel go to the tanging hammer where the tangs of the files are forged in the manner illustrated in Fig. 4. The dies, and the beginning of the tanging operation are here illustrated. A helper hands the file blank, one end of which has been heated to a forging heat, to the operator of the hammer in which the tangs are forged. The blank *A* is held in special tongs *B*. The first part of the tanging operation consists in "nicking" the end of the file blank between the two half rounded projections *E* at the front of the dies *C* and *D*, leaving

* For further information on file making, see the following articles in MACHINERY: "File Making at a Sheffield Works," April, 1911, engineering edition; "Toolmakers' Files," January, 1911; "Vernaz Circular Cut File," October, 1909; "Making Swiss Files in America," September and October, 1907. See also MACHINERY's Reference Book No. 48, "Files and Filing."
† Associate Editor of MACHINERY.

the file blank in the condition shown. After this blow the operator shifts the file blank to the middle section F of the dies which have beveled faces corresponding with the taper of the tang. By rapidly turning the blank after each blow, the metal beyond the nicked portion of the blank is drawn out to approximately the shape of the finished tang, after which one or two blows are struck on the finishing faces G of the die to complete the tang. It is an almost incredible fact that the tang of an 8-inch file is forged in from ten to fifteen seconds from the time it is taken from the fire.

Following the tanging operation, the trademark impression is stamped upon the shank of the file, after which the blanks are annealed by being heated in large quantities in iron boxes and allowed to cool very gradually. The annealing operation decarbonizes the exterior surface of the steel, and before cutting the teeth it is important that this inferior surface of the stock be faced off. This operation, called stripping, is common in making files of all kinds, the metal being removed on large broad-faced grindstones, six feet in diameter. The files are held by the tangs on the plate shown at A in the illustration Fig. 5, which is dropped into position against the wheel and clamped by bar B, after which the holding plate and files are reciprocated in a vertical line against the face of the wheel C, at the same time being flooded with water and fed gradually against the wheel. By this means, 1/64 inch is removed from each side of the file-blanks, leaving them perfectly flat and ready for the cutting of the teeth.

Cutting the Teeth

The most interesting operation in connection with the making of the Vixen file is the cutting of the teeth. The machines for cutting the teeth are operated in groups of eight, being driven from lineshafting at the rear of the rows of machines. Two of these groups of machines are shown in Fig. 6. The machine consists essentially of a spindle which carries the cylindrical cutter and a table which supports the file blank in a plane at right angles to that of the cutter spindle. As the cutter revolves, it is fed forward to the file blank, withdrawn, the file holding table moved forward the distance of one tooth and the cutter spindle brought forward again. Thus, the teeth are cut one at a time and the machine is automatically stopped after the last cut. Referring to Fig. 7, the cutter spindle, its method of feeding and the cross feed of the work table, may be seen. The cutter spindle shown at A is driven by bevel gearing from the extreme right-hand end of the machine. By means of gear B in mesh with gear C operating on a worm-shaft, the worm D engages a worm-wheel, not shown, which causes cam E to turn against yoke F. Yoke F is attached to collar G, and thus as the high part of the cam is reached, the cutter is fed forward to its deepest position with respect to the file and, of course, returned when the low part of the cam is reached. The double spring box H constitutes a means for insuring the feeding of the cutter to the proper depth of the tooth in each instance; the springs within the barrels overcoming any tendency for uneven feeding of the spindle caused by chips lodging upon the cam or from other sources.

The cutters themselves are made of Rex high-speed steel. Four of these cutters are shown in Fig. 3, and, as may be seen, they are milled very deep between the teeth, which allows them to clear themselves of chips rapidly and provides for many sharpenings before they are worn out. The cutting faces are ground to an included angle of 60 degrees and the cutter is held to the end of the spindle by a flanged sleeve I, shown in Fig. 7, which is tightened by a spanner wrench holding the cutter securely in place. The illustration Fig. 7 also shows the method in which the files are held for cutting, consisting of the two clamping screws J which operate against jaw K of the vise. For varying the depth of the tooth, handwheel L is used, thereby bringing the work table nearer to or farther from the cutter. The number of teeth cut per inch varies from 6 2/3 to 16, and for spacing the teeth there is a ratchet and pawl upon the end of the feed shaft. This pawl, shown at M in the illustration Fig. 7, is operated by a lever N which, in turn, is reciprocated by the arm O. Another view of this machine is shown in Fig. 8 which more clearly shows the cutter and its relation to the file blank.

The widths of the files vary from ⅞ inch to 1¾ inch.

There are, on each side, from 90 to 250 teeth, varying, of course, with the pitch and length of the file. It takes twenty-five minutes to cut the teeth in one side of an ordinary 12-inch Vixen file, as compared with one minute for cutting the teeth on one side of an ordinary commercial 12-inch file. Hence it is apparent that the manufacturing cost of a Vixen file is comparatively high.

Hardening

Previous to heating the files for hardening, they are treated with a charcoal and oil preparation to prevent the lead used in the heating from clinging to the teeth and thus interfering with the hardening. The files are brushed with this solution and placed against racks of steam pipes as shown in Fig. 9, to bake the coating on before the files are placed in the lead pot.

The molten lead in which the files are heated is kept at a temperature of 1400 degrees, its condition being indicated by a Bristol pyrometer. Several files are kept heating in the lead pot, being immersed to the tangs. A bar across the top of the lead pot holds the files beneath the surface of the

Fig. 10. The Cold-straightening Operation

molten lead so that they may be heated slowly and evenly. A file is taken from the lead pot by the hardener, and before being quenched in the brine solution in which the files are hardened, the red hot file is rapidly straightened across lead blocks with a wooden faced hammer. This operation, which is shown in Fig. 11, is necessary on account of the strains set up in the steel by the milling of the teeth. After straightening, which takes but a few seconds, the file is plunged straight down into the brine and moved rapidly up and down until the "singing" has nearly ceased. The file is then quickly removed, sighted, and again straightened after the manner shown in Fig. 10. For this purpose the file is clasped in an iron holder, *A*, after sighting, and placed with the high side down against the wooden bar *B*, the tip end of the file being caught under bar *C*. Pressure is then applied to straighten the file and cold water splashed upon the upper side to bring the file back to a straight condition. This operation of straightening requires a great deal of judgment, for, if the file is kept in the hardening tank a few seconds too long, it will break when pressure is applied for straightening, and on the other hand if removed too quickly, the temper of the file will be impaired.

Sharpening the Files

From the hardening department the files go directly to the sharpening machines. Unlike the sharpening of most tools, files are sharpened by being passed over jets of steam which is mixed with a cutting paste made with a fine mineral abrasive powder. The sharpening machine shown in Fig. 13 is equipped with three nozzles which are shown being used

Fig. 11. Straightening Hot Files

in the operation of sharpening Vixen files. The base of the machine contains the sharpening paste which is led to the nozzles of the steam pipes and thus is propelled against the sides of the file when it is moved backward and forward over the nozzle. A spool, shown just above the nozzle, is used to keep the file at the proper distance from the nozzle. In

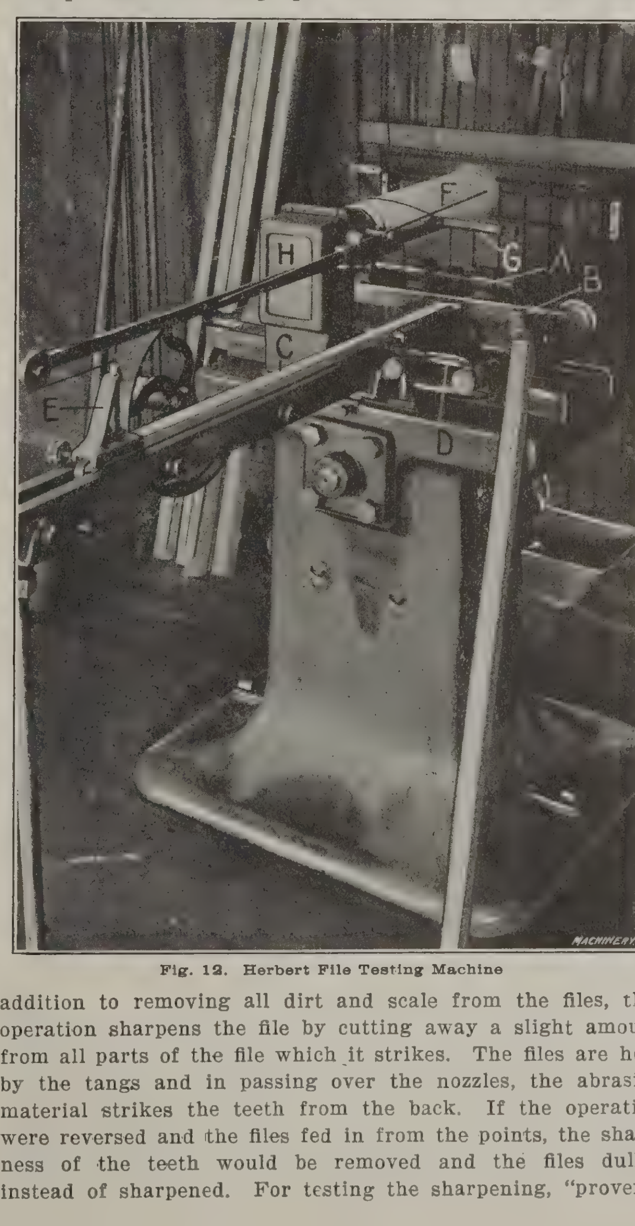

Fig. 12. Herbert File Testing Machine

addition to removing all dirt and scale from the files, this operation sharpens the file by cutting away a slight amount from all parts of the file which it strikes. The files are held by the tangs and in passing over the nozzles, the abrasive material strikes the teeth from the back. If the operation were reversed and the files fed in from the points, the sharpness of the teeth would be removed and the files dulled instead of sharpened. For testing the sharpening, "provers"

are used. These provers consist of short pieces of soft steel which are drawn over the file by hand. Even to those unaccustomed to this work, the prover indicates the fact that the file has been really sharpened, and to the sharpener the prover reveals any sections of the file which are not quite up to standard sharpness. Lime is added to the special sharpening compound to prevent the files from rusting after they leave the sharpening machine. The final operation consists in cleaning out the file under a jet of live steam, and after oiling, the files are ready for use.

Testing Files on the Herbert File Testing Machine

A Herbert file testing machine, shown in Fig. 12, the working parts of which are shown in detail in Fig. 14, forms the

Fig. 13. Sharpening the Files

only practical method of testing the cutting and enduring qualities of the file. This machine was described in detail in MACHINERY, December, 1907, and is also described in MACHINERY'S Reference Book No. 48, "Files and Filing." Briefly stated, the machine consists of a reciprocating file holder *A* in which the file *B* is held, backed up by suitable supports. The file is reciprocated across the end of the square test bar *C* at the rate of 50 strokes per minute. On the return stroke, the bar is withdrawn slightly by means of arm

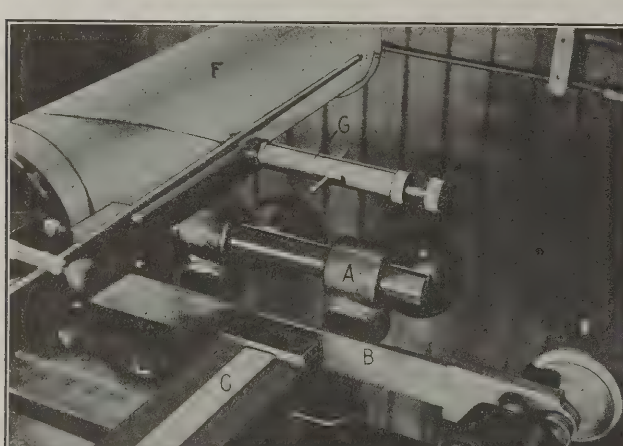

Fig. 14. Details of the File Testing Machine

D. The forward feeding of the bar is accomplished by means of a 30-pound weight which is attached to the bar at the front of the machine by a chain running over a pulley. The rate of forward travel of the bar is recorded on the chart *F*, by the pencil held in the holder *G*. By means of clockwork within the case *H*, the chart cylinder is turned slowly, with the result that a curve is traced upon the chart which indicates the cutting efficiency of the file tested.

Credit is due to Mr. W. D. Craft, manager, and Mr. C. M. Zubler, superintendent of the Vixen Tool Co., Philadelphia, Pa., for courtesies shown the writer in the preparation of this article.

Muzzling the gears may not stop them from biting, but it promises to muffle the bark.

MAKING THE FOSTER SAFETY SET-SCREW

BY CHESTER L. LUCAS*

In the new factory of the New Haven Machine Screw Co., New Haven, Conn., which appears in Fig. 1, a considerable part of the work consists in the making of the Foster safety set-screw. The factory is of reinforced concrete, and in designing the building, special attention was given to the lighting system; as may be seen, almost all of the wall space is taken up by windows. Fig. 2 shows a view of the automatic

Fig. 1. Home of the Foster Safety Set-screw

turret lathe department in which the blanks for the set-screws are made. Low carbon steel is used in making the set-screws. The turret lathes used are of the multi-spindle type, operating on four bars of steel at once, and when the blanks are dropped from these machines they are in the condition shown at *A*, Fig. 3, having the point roughly shaped, the opposite end rounded, and the stock drilled from the central hole.

In the second operation the hole is broached to a hexagonal

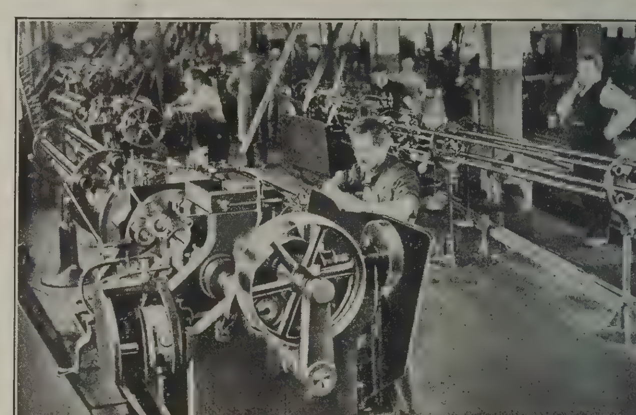

Fig. 2. The Automatic Turret Lathe Department

shape.† This operation is performed in a punch press, using the attachments shown in Fig. 4. Referring to this illustration, *A* is a dial revolving on a stud *B* which is fitted to the bed of the press. Around the edge of this dial, bushed holes are spaced to receive the set-screw blanks being broached. The dial is turned, bringing each of these holes successively under the broaching punch *C* by means of an indexing arrangement at the side of the press. This indexing arrange-

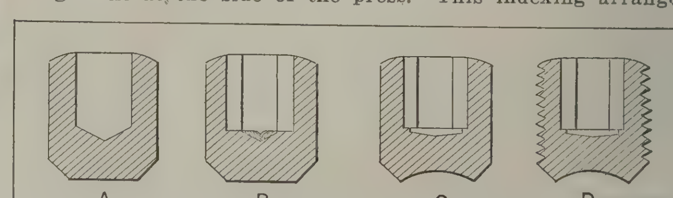

Fig. 3. The Four Steps followed in Making the Set-screws

ment consists of a lever *D* fulcrumed on the stud *E* and operated from the main shaft of the press. At the lower end of the lever, motion is transmitted to an arm *F* which reciprocates the indexing pawl *G* at each return stroke of the press ram. In broaching, the operator places the blanks in the holes in the revolving dial, and as they are indexed to the position under the punch, they are broached. Upon reach-

* Associate Editor of MACHINERY.

† A method of progressively broaching square holes in socket wrenches was described in the March, 1902, number.

ing the position directly under finger *I*, they are ejected from the dial by being pushed out by this finger at the down stroke of the press. By referring to *B*, in Fig. 3, which shows the result of this broaching operation, it will be noticed that the metal removed from the six corners of this hole is pushed into the conical end of the hole. In order to clear out these chips and make a neater looking hole, the set-screws are re-drilled in the machine shown in Fig. 5. This machine works upon the blank from both ends, the blank being held by means of jaws *A* and *B*, of which jaw *A* is movable and

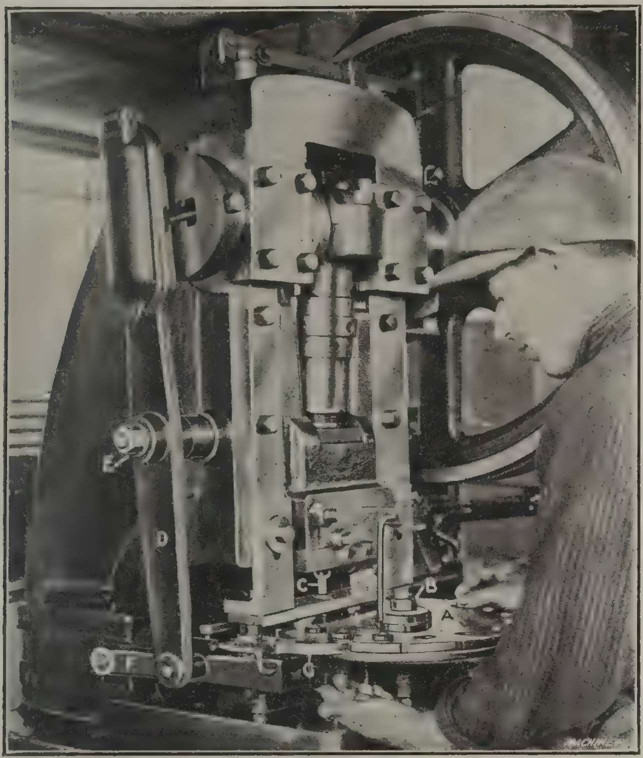

Fig. 4. Broaching the Holes

is clamped upon the work by the foot pressure of the operator. In re-drilling it is only necessary to remove enough metal to clear out the chips and leave the bottom of the hole clean. While re-drilling the blank set-screws from the one end, a forming tool is countersinking and shaping the point of the set-screw, and when taken from this machine the set-screw has assumed the shape shown at *C* in Fig. 3, and is ready for threading.

The threading of Foster safety set-screws is performed on Geometric threading machines, and the details of the thread-

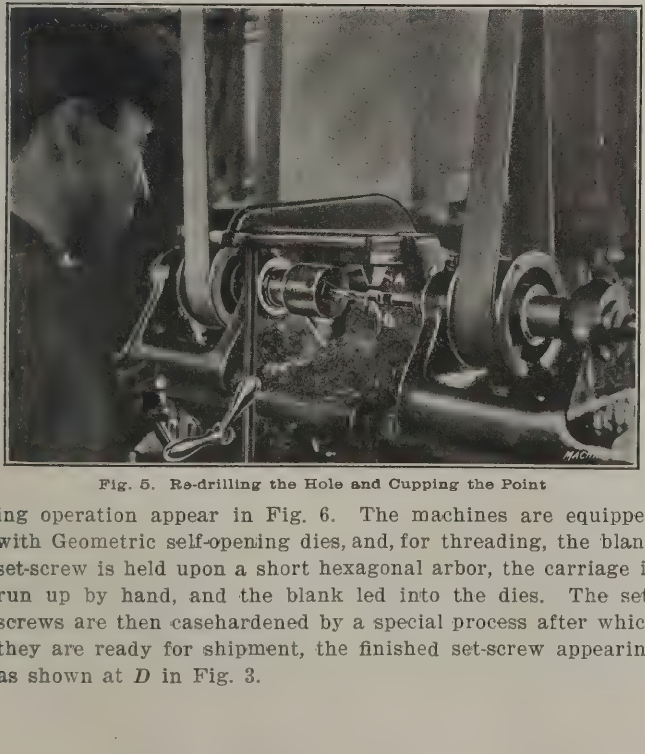

Fig. 5. Re-drilling the Hole and Cupping the Point

ing operation appear in Fig. 6. The machines are equipped with Geometric self-opening dies, and, for threading, the blank set-screw is held upon a short hexagonal arbor, the carriage is run up by hand, and the blank led into the dies. The set-screws are then casehardened by a special process after which they are ready for shipment, the finished set-screw appearing as shown at *D* in Fig. 3.

GENERATORS FOR THE KEOKUK POWER PLANT

The General Electric Co., Schenectady, N. Y., is building a number of very large electric generators for the hydro-electric power plant at Keokuk, Iowa, where ultimately 300,000 horsepower will be developed from the water power of the Mississippi River. This hydro-electric development has been made possible by the building of the greatest power dam ever constructed. The dam is built entirely from concrete. It has a total length of 9096 feet and rises 50 feet above the average river bed. The initial electric installation consists of fifteen alternators connected to the same number of vertical hydraulic reaction turbines of the single runner type. Each turbine and generator form an independent unit. The turbines are mounted on vertical shafts 25 inches in diameter, and will operate at a speed of 57.7 revolutions per minute, the normal capacity being 10,000 horsepower. The generators are installed on the top of the wheel pits directly over the turbines and will generate a three-phase alternating current at 11,000 volts. Transformers will be installed for stepping up the voltage of the current which is to be distributed over the high-tension transmission lines to 110,000 volts. The power will be distributed within a zone of 150 miles radius. Owing to the slow speed of the generators, their dimensions are very large. They are 32 feet in diameter and 12 feet high, the total weight being over 300 tons. One of the cities to

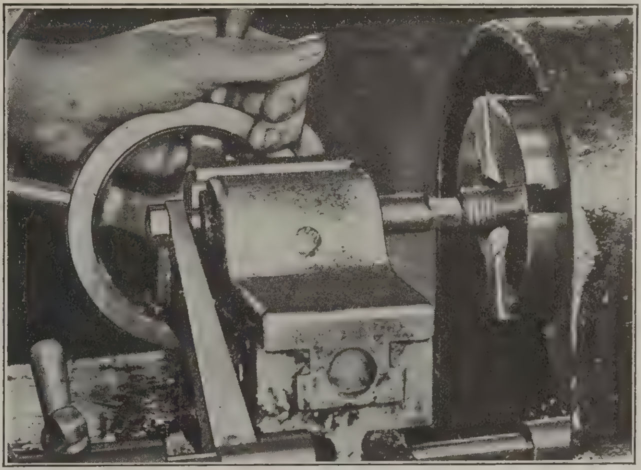

Fig. 6. Threading the Screws

avail itself of the power developed is St. Louis, located 135 miles from Keokuk. The street railway and electric light companies in that city have already contracted for 60,000 horsepower.

TEST ON SECTIONAL FIREBOX BOILERS

An interesting demonstration of a new type of boiler was recently made at Coatesville, Pa., under the direction of Dr. W. F. M. Goss, dean of the College of Engineering, at the University of Illinois. Two full sized locomotive boilers, designed for high-speed passenger service, were each subjected to severe low water tests. Both boilers were identical in size and design except that one was provided with a Jacobs-Shupert sectional firebox built by the Jacobs-Shupert Firebox Co., while the other had an ordinary radial stay firebox. The observations were taken from a safe location 200 feet away from the boilers. After the boilers were in normal operation, the feed water supply was shut off, the crown sheet and other portions of the heating surface being still subjected to the heat of the fire. The boiler having the Jacobs-Shupert sectional firebox was tested under these severe conditions for 55 minutes without failure, notwithstanding the fact that the level of the water fell to a point more than 25 inches below the crown sheet. The ordinary stay boiler exploded after the test had continued for 23 minutes, the water level having fallen to 14½ inches below the crown sheet. The crown sheet and the stays which hold it in place, having become highly heated, pulled away from each other and released the pressure in the boiler. The damage to the boiler was such as to make entire reconstruction necessary.

EFFICIENCY OF WORM GEARING FOR AUTOMOBILE TRANSMISSION*

RECORDS OF A NUMBER OF TESTS MADE ON VARIOUS TYPES OF WORM GEARING

The investigations recorded in the following were made at the plant of the Brown & Sharpe Mfg. Co., Providence, R. I., for the purpose of determining the efficiency of three types of

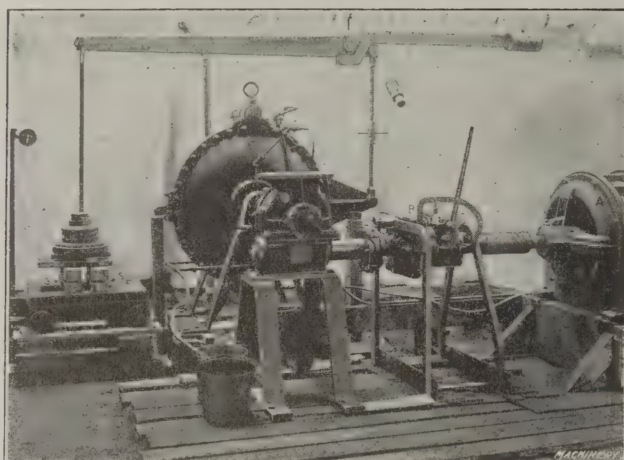

Fig. 1. Arrangement Used for Testing Efficiency of Worm and Gear Drives

worm gearing for use in an automobile transmission system, and the heating effect due to continuous running. The power for these tests was obtained from a 50 H. P. induction motor, running at approximately 870 R. P. M. at full load. Between

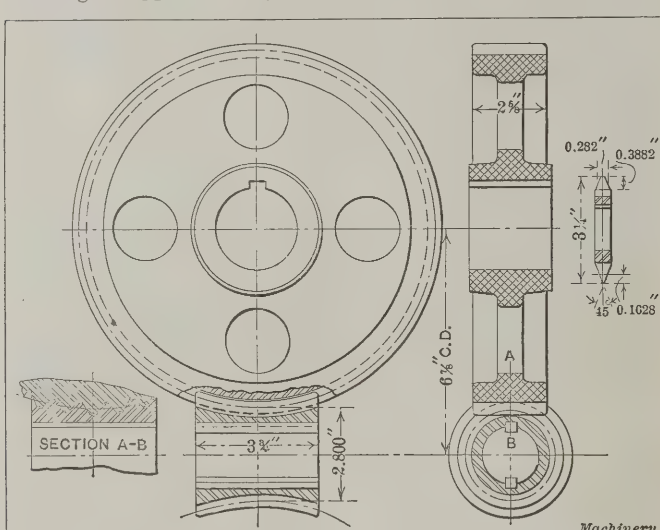

Fig. 2. Worm-gear Drive No. 1

the motor and the worm-gear case was placed an automobile transmission-gear case to enable tests to be made at two lower speeds. Between this and the worm-gear case was placed a transmission dynamometer designed by the author. (See

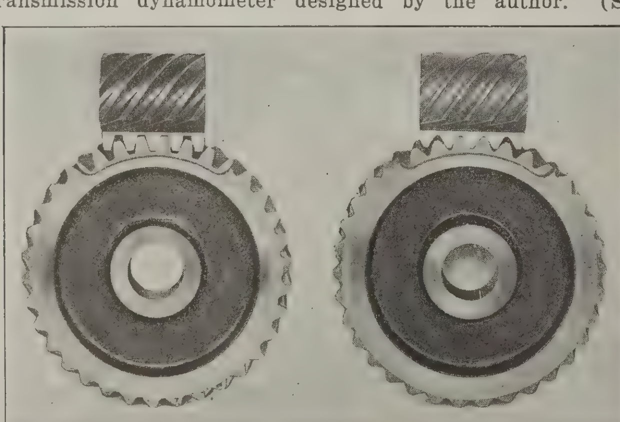

Fig. 3. Section through Teeth, Drive No. 2

Fig. 4. Section through Teeth, Drive No. 3

MACHINERY, June, 1909, engineering edition, for description of this device.) An Alden brake was used to absorb and measure the power transmitted by the gears under test. The apparatus is shown in Fig. 1 as arranged for testing worm gears; A is the motor, B the automobile transmission-gear case, C the transmission dynamometer, D the case containing the worm gear under test, E the Alden brake, and F the platform scale which measured the load on the Alden brake.

The apparatus was so arranged that as the load was imposed, the weight on the platform scale was removed, and all vibration of the scale beam was eliminated by interposing springs S between the blocks G which sustained the weight

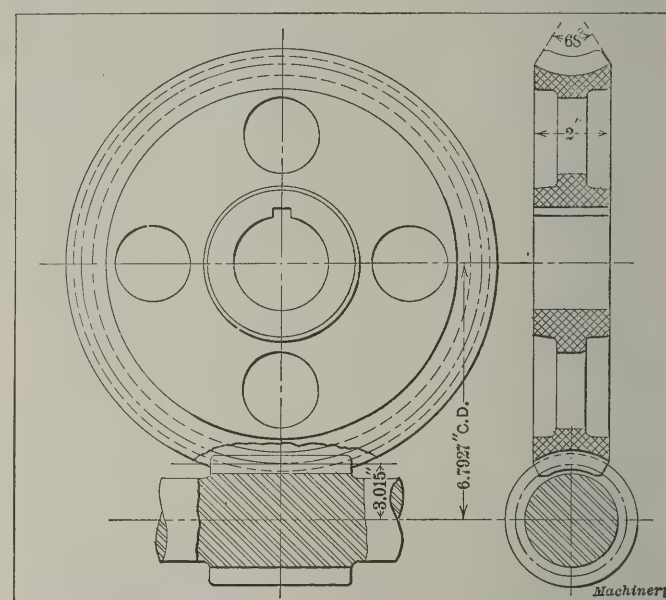

Fig. 5. Worm-gear Drive No. 3

on the scale, and also by suspending by a wire from the weight at the end of the scale beam a plate which dipped into a pail of oil, thus acting as an efficient dashpot. It was found possible by careful manipulation to maintain a steady and easily read load on both the transmission and absorption instruments.

With this arrangement of the transmission dynamometer and brake, runs were made at various loads, and the torques corresponding to horsepowers per 100 R. P. M. marked on the dial

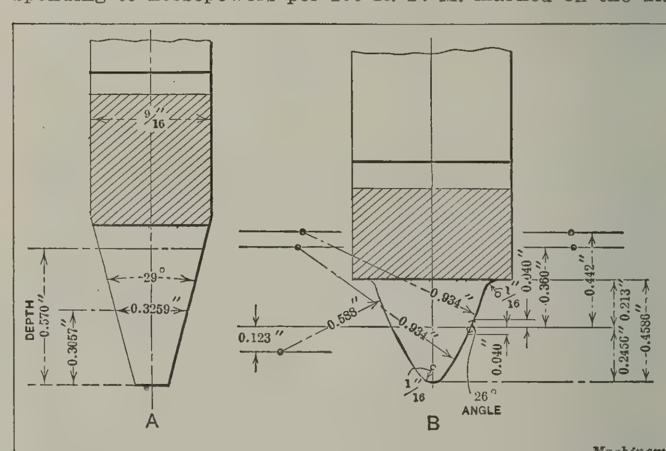

Fig. 6. A, Cutter for Gear No. 2; B, Cutter for Gear No. 3

of the transmission instrument, corresponding to similar loads as indicated on the brake. It is evident that by this method of comparison the two instruments must check each other exactly. A thermometer placed in the oil-well at the back of the worm-gear case D indicated the temperature of the oil, and another thermometer placed on the wall near the apparatus indicated the room temperature. The oil employed to lubricate the gears was one intended for use with superheated steam, having a specific gravity of 26 Baumé, a flash point of 625 degrees F., and a viscosity at 212 degrees F. of from 260 to 265. The case contained about five quarts of the oil.

In all the trials the worm was located underneath the gear.

* Abstract of a paper by Prof. Wm. H. Kenerson, of Providence, R. I., presented before the American Society of Mechanical Engineers.

Fig. 7 shows a section through the gear case. As indicated, both shafts are mounted on ball bearings and end-thrust ball bearings take care of the thrust on the worm and worm-wheel. All the worms were made of machine steel, casehardened, and the worm-wheels of phosphor-bronze.

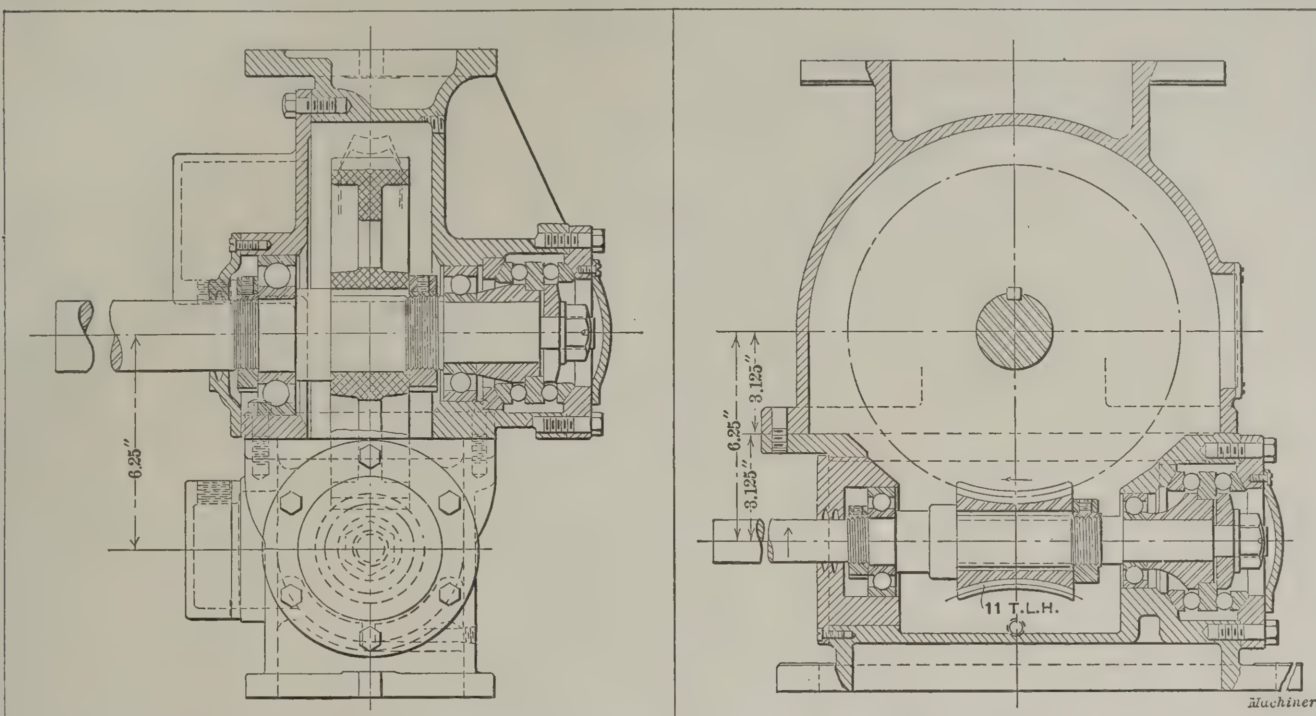

Fig. 7. Section through Gear Case used for Testing Worm-gear Drives

The first worm and wheel tested are shown in Fig. 8, and are similar to those used for driving the spindle on the Brown and Sharpe automatic spur gear machines. This pair of gears is an unusual case of the worm and worm-wheel. The smaller gear is hobbed with a hob of the size of the larger gear, thus making possible adjustment of the larger gear, which would not otherwise be the case. While in appearance this gear resembles a Hindley worm, it is not of this type. The smaller gear will be called the worm and the larger, the worm-wheel, in the following description. Fig. 2 gives the dimensions of the worm and gear shown in Fig. 8. The specifications for this pair of worm and worm-wheel are as follows: worm-wheel, phosphor-bronze; No. of teeth, 43 left hand; pitch diameter, 10.95; outside diameter, 11.28; circular pitch, 0.800; angle of teeth with axis, 45 degrees; normal circular pitch, 0.5657; pitch of cutter, 5.553; addendum, 0.1628 (not standard); thickness of tooth, 0.282; whole depth, 0.3882; included angle of cutter, 45 degrees. The worm-wheel was cut with the cutter shown, and the shape of the teeth on a section through the worm and worm-wheel, parallel to the axis of the worm, is also shown.

The general appearance of pairs Nos. 2 and 3 are shown in Figs. 9 and 10, and the dimensions in Fig. 5. The difference between gears Nos. 2 and 3 is principally one of shape of the worm threads. This difference is clearly brought out in the

sections of the worm and wheel shown in Figs. 3 and 4. The specifications for the No. 3 worm and worm-wheel are as follows: Worm-wheel, phosphor-bronze; number of teeth, 40; pitch diameter, 10.5704; throat diameter, 10.9964; circular pitch, 0.8302; angle of teeth with axis, 38 degrees 16 minutes; normal circular pitch, 0.6518; pitch of cutter, 4.8196; addendum, 0.213; thickness of tooth, 0.3568; whole depth, 0.4586. Worm: Aurora steel, casehardened; number of teeth, 9; pitch diameter, 3.015; outside diameter, 3.441; circular pitch, 1.0524; angle of teeth with axis, 51 degrees 44 minutes; thickness of tooth, 0.295; lead, 7.4719; ratio of wheel to worm, 40 to 9.

The shape of the teeth on the worm in Fig. 3 was produced with a cutter, the included angle of which was 29 degrees, and the depth of tooth 0.570 inch. This depth was based on the axial pitch, whereas the usual method on multiple worms is to base the depth on the normal pitch. The object in using this cutter was to obtain as many teeth as possible in contact at one

time and also a shape that could be ground with a straight-sided emery wheel. The teeth of the worm in Fig. 4 were cut with a cutter shaped as shown at *B* in Fig. 6, which is an arbitrary shape made to produce the greatest effective breadth possible.

In conducting the trials, the load was maintained at the desired point by one observer who adjusted the brake. Readings were then taken on the transmission instrument by two independent observers. The speed of the motor was observed in each case, and from this, knowing the gear ratio, all the other speeds were easily computed. Temperatures were taken immediately following each series of observations. For purposes

degrees 56 minutes; angle of face, 13 degrees 47 minutes; outside diameter, 10.4627.

Table I is a record of one set of observations, typical of the series. Tables II, III, IV and V summarize the results of all the trials, and the curves of Fig. 11 show the average efficiency of the different gears at the various loads and speeds. In conjunction with the efficiency trials, a series of runs was made to determine the heating effect due to continuous running. In these trials, which were in effect endurance tests, a constant load was transmitted through the gearing, and the temperature of the oil in the gear case and the temperature of the room noted at frequent intervals. From these observations it was found that at the beginning of the run the oil temperature rose rapidly and somewhat irregularly. As the run continued, however, the rise became much more gradual and regular. In the runs where the smaller amounts of power were transmitted a point was reached where the temperature remained constant. This indicated that radiation was sufficient to carry away the heat due to power lost through friction in the gearing, or in other words, that the gears would run indefinitely at that load. The heat curves of the No. 1 worm and gear are shown in Fig. 12.

The higher loads indicated were abnormal for the gears under consideration, and would not occur in any use to which the gears would normally be put. The fact that these trials continued for from 60 to 80 minutes without failure indicates that the structure is both strong and enduring and that, should such temperatures be reached for any accidental reason, the gears would not be destroyed. The result of the trials was of particular interest because of the very high efficiency and carrying capacity of the gears tested.

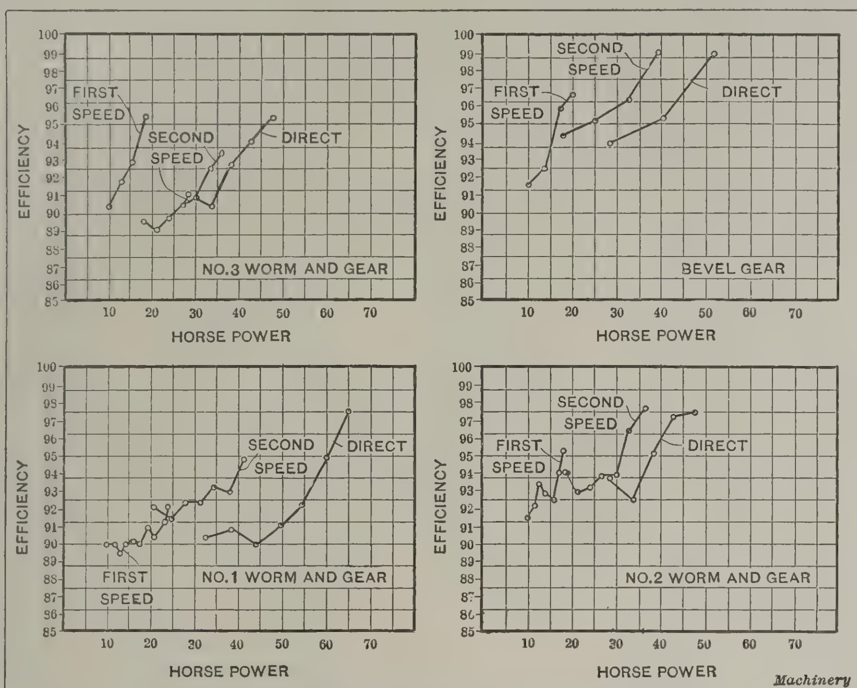

Fig. 11. Efficiency Curves at Various Loads and Speeds

Every possible precaution was taken to secure accuracy in the results, and the high degree of accuracy obtained is due largely to the skill and care of Mr. B. F. Waterman of the Brown & Sharpe Mfg. Co., under whose personal supervision the apparatus was erected and all the trials were conducted.

* * *

A new development in pneumatic tires of a revolutionary nature promises to make considerable improvement in what now is the weakest member of the automobile. The ordinary pneumatic tire is inflated with air, compressed to a pressure of about eighty pounds per square inch. In the new tire the

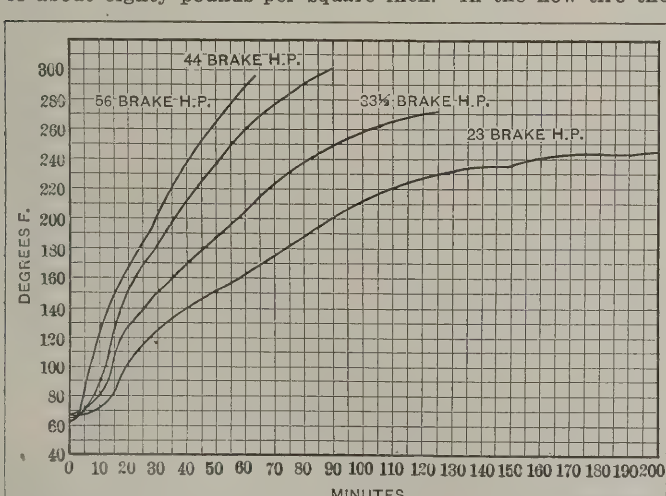

Fig. 12. Heat Curves for No. 1 Worm and Gear

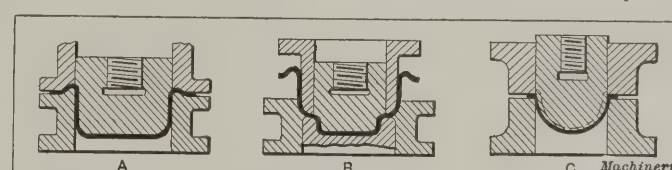
condition of air pressure is reversed, the air being pumped out, leaving the internal pressure at about eight pounds absolute. The external pressure, of course, tends to collapse the walls, which are so shaped that the internal cross-section assumed is a flattened ellipse with the long axis vertical. Load on the tire tends to separate the sides and press them outward against the external or atmospheric pressure. Thus the tire rides on external air pressure instead of internal pressure, as in the common type.

PREVENTION OF WRINKLES IN DRAWN WORK

The formation of wrinkles in drawing operations is a source of great trouble, and there are many pieces of drawn work which could be performed in a single operation were it not for the wrinkles that would inevitably appear. In drawing operations, the tendency to wrinkle starts with the first contact of the punch upon the metal.

The usual method of preventing wrinkles is to provide the punch with a blank-holder which is operated by springs of sufficient tension to allow the metal to be pulled from beneath it for drawing, but maintaining pressure enough to keep the metal free from wrinkles. At *A*, in the accompanying illustration, reproduced from the *Zeitschrift für Werkzeugmaschinen und Werkzeuge*, appears a section of a simple drawing die in which it will be noticed that the die is provided with a raised ridge around its opening, the blank-holder having a corresponding depression. Consequently, the sheet metal being drawn is pulled over this ridge, and as the space between the blank-holder and the top of the ridge is purposely made slightly less than the thickness of the metal, it will be seen that as the stock passes through this opening any wrinkles are "ironed out." At *B*, the shell from the dies at *A* is shown undergoing a second operation.

For strength and protection in hardening, as well as to facilitate the drawing operation, the ridge is provided with a fillet where it joins the flat surface of the die. It is obvious that the addition of this ridge to the drawing die occasions a little extra work in the die-making, but this work is offset by the fact that the blank-holder and upper surface of the drawing die do not have to be ground perfectly smooth and parallel, as is ordinarily re-



A Method of Drawing Sheet Metal by Means of which Wrinkling of the Stock is avoided

quired. The size of the ridge around the die should be in proportion to the diameter of the shell. A shell 4 inches in diameter is most easily drawn with a die having a ridge of 7/16 inch radius. For a shell of 8 inches diameter the radius of the ridge should be ½ inch. For a shell 12 inches in diameter the radius of the ridge should be ⅝ inch. For a shell 16 inches in diameter the radius of the ridge should be ¾ inch, and a shell 20 inches in diameter would require a ridge having a radius of 1 inch.

It is obvious that the completed shell will have a ridge left at the edge. On work which is to be wired or for work on which the edge is to be turned over, this additional ridge is no detriment as it can be made use of directly. Moreover, if a succeeding operation is to follow, deepening the shell slightly, this ridge will provide the surplus metal required. This point is illustrated at *C*. In other cases, the extra metal left at the edge may be removed when the shell is trimmed. It is claimed that this improvement in drawing dies is being employed with success. By its use, wrinkles are absolutely prevented, and, moreover, the drawing operation puts less stress upon the metal.

The J. N. Lapointe Co., Marlboro, Mass., maker of broaching machinery, recommends the use of the following compounds when broaching steel: 2½ pounds of soda-ash; 3 gallons of mineral lard oil; and 50 gallons of water. Mix the soda-ash and the lard oil with 10 gallons of water, and add the other 40 gallons afterward.

CENTERING DROP-FORGED CRANKSHAFTS

The usual method of centering drop-forged crankshafts for the lathe, *viz.*, by marking off on centers and surface plate is very slow when a great number of crankshafts are to be centered. The method described in the following is considered by the writer to be an improvement upon previous methods.

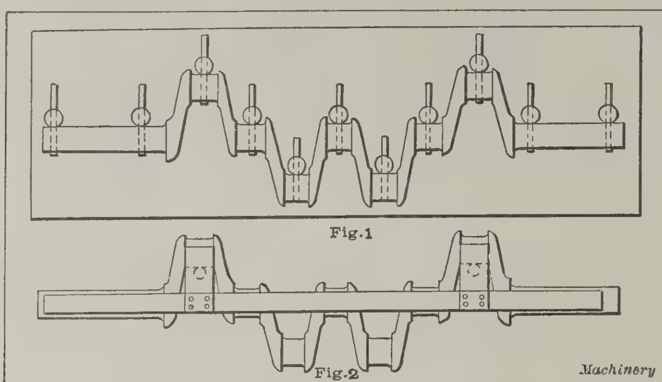

Fig. 1. Plate used for Correcting Warped Crankshafts. Fig. 2. Gage for Cutting off Crankshaft to Right Length

The drop-forgings are first tested for alignment, as they often warp slightly in hardening. This warping should be corrected by the aid of a plate fitted with pegs, as shown in Figs. 1 and 3. The pegs are a good fit in the holes in the plate and correspond to the correct outline of the crankshaft. Each peg has a piece of steel rod projecting through it at each side and resting on the surface of the plate. The drop-forging is placed on these projecting rods and is straightened until each journal and throw has a reasonably close contact with them, the variations allowed depending upon the amount of material left for machining in the drop-forging. The small steel rods keep the webs of the crank from touching the plate, while the vertical pegs give the correct alignment to the throws and journals in planes at right angles to the plate.

The ends are next sawed off to within ¼ inch of the finished length; a simple templet, as shown in Fig. 2, is used for marking this length correctly. The crank is now ready to have the centers put in. This is done on a sensitive drilling machine, the column of which is provided with a pivot carrying the centering jig shown in Fig. 4. This jig consists of a

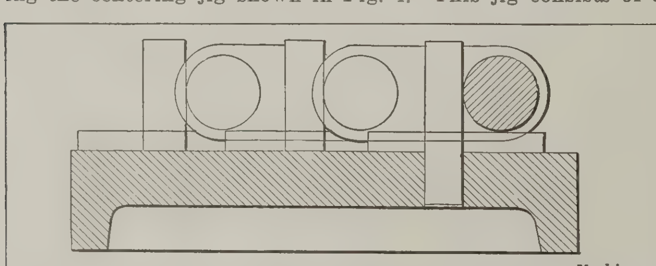

Fig. 3. Section of Plate and Crankshaft in Fig. 1 in Enlarged Scale

stiff cast base or bar, pivoted at the center, with a T-slot along its full length. At each end a bracket is mounted, the position of which is adjustable to suit the length of the crankshaft. These brackets are fitted with bushings to suit the diameter of the center drill. One end of the bushing is enlarged to form a cap for the end of the crankshaft. The hole in this cap should be larger in diameter than the diameter of the largest drop-forging likely to be used. The ends of the crankshaft are held in this cap by means of four set-screws.

Setting gages are used as indicated in Fig. 4. These are bolted in the T-slot at the correct position for each throw and journal. These gages are made of thin spring-steel blades of suitable length, allowance being made for the material to be left for machining. They can be easily changed for different sizes of crankshafts and are cheap to make.

One end of the crankshaft is now placed in the cap at the bottom. The top bracket is raised to allow the crankshaft to enter into its cap, and then the crankshaft is secured in the caps by the set-screws. When clamped it is turned and tried against the steel blades, the set-screws being adjusted until the best average position is obtained. Then the center is drilled at one end, the jig swiveled around, and the center drilled at the other end. It would be a still further improvement to mount the jig horizontally and use a simple drill head at each end of the crankshaft. In this case, a swiveling jig would not be required and both centers could be drilled at the same time.

It will be found that in addition to having obtained a better and quicker method of centering than is afforded by the usual

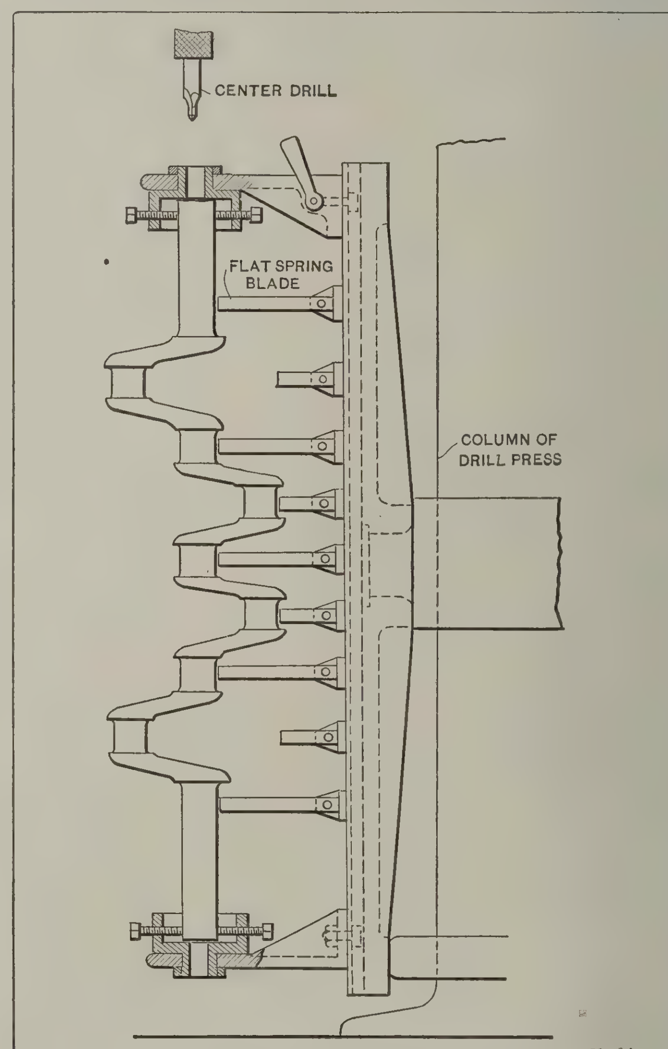

Fig. 4. Centering the Crankshaft in the Drill Press

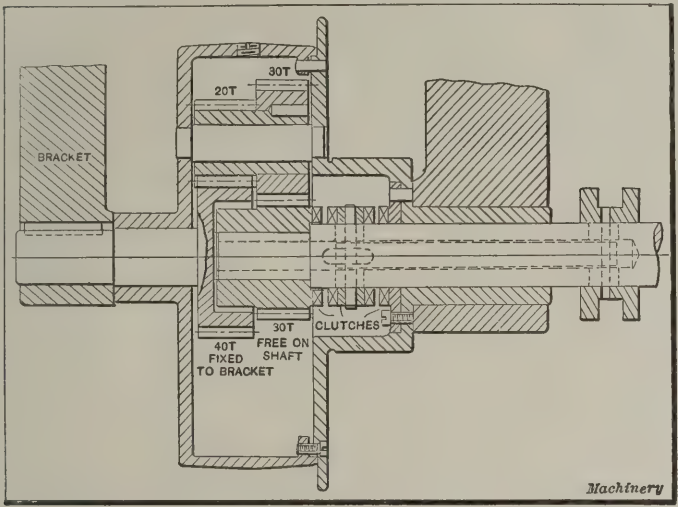
marking-off method, there will be fewer broken center drills, owing to the fact that the crank is held steadily and its weight is not taken by the weak point of the drill. G. R.

PLANETARY GEARING—OIL-PUMP TROUBLES

A writer in the May number of MACHINERY mentions an instance of the successful employment of planetary or differential gearing as a speed reducing mechanism. That gearing of this type may be successful at low speeds such as cited (120 revolutions per minute) is, no doubt, possible, but when the speed rises to say 500 revolutions per minute, the experience of the present writer goes to show that it ought not to be employed. In one case a number of machines furnished by a high-class concern were driven in one direction by a direct drive. To obtain a reverse drive certain clutches were used to throw into action a train of epicyclic gears. All gears were regular spur gears, no in-

ternal gear being used. The accompanying illustration shows the arrangement of the gears. All the gears ran in oil, but, nevertheless, the noise, right from the beginning, was more than normal, and it increased the longer the machines were used. Finally an examination disclosed that the teeth of some of the gears had worn so badly that they had broken off; the wear was also very unequal. It was assumed that the gears were too weak, and, hence, they were replaced by carefully made hardened steel gears. These, however, were so noisy that it was finally decided to eliminate the planetary gearing and use a reverse countershaft.

There seems, at first, to be no good reason why planetary gearing should cause any more noise or wear than ordinary gearing, but that some reason exists is certain. The writer believes that the trouble is due to the fact that the resultant of the various forces is a constantly changing one, due to



Arrangement of Clutches and Epicyclic Gearing

the varying positions of the planetary gears in their motion. Sometimes the forces will tend mainly to draw the centers closer together; at other times there will be forces tending to force them further apart. Hence, there is a constant sliding movement between the teeth of the meshing gears which accounts both for the excessive wear and the noise, particularly at high speeds. In some cases the trouble may be due to the pull of the belt and the pressure from the gears being in different planes, thus tending to tilt the gears, the amount of this tilting action varying according to the varying direction of the resultant force. As the various shafts and bearings wear, this creeping between the teeth with accompanying noise and wear, will become intensified.

The variations in the resultant force will not be so great when three, four, or more planetary gears are used, but then the manufacturing difficulties are greatly increased; in fact, so many factors require attention as regards accuracy, as to make it almost impossible to insure that each planetary gear would bear its fair share of the duty. Take the case of four planetary gears as an example. Here we have the possible inaccuracies of four radial distances and of the four center-to-center distances between the planetary gears themselves; then there are ten gear diameters to be taken into account, the errors in which may or may not balance each other. Furthermore, each of the double planetary pinions must have their teeth exactly in the same relation on each gear. In fact, the only possible way to get anything like an equal load on each gear is to allow plenty of freedom in all running parts, but this would tend neither to freedom from noise nor from wear.

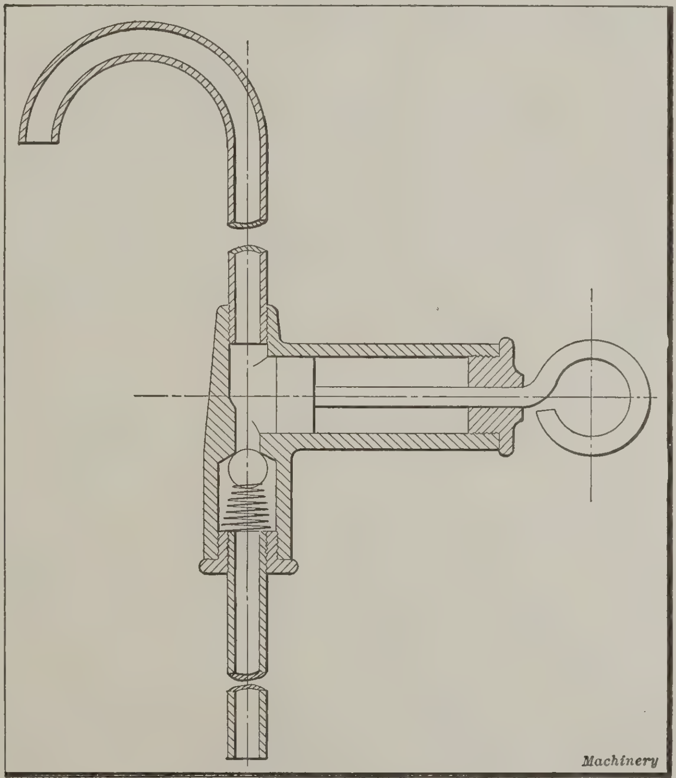
A little incident which occurred in connection with the same machines affords a good example of how small points are apt to be neglected. After the machines were put into operation with a reverse countershaft, it was found that the oil-pump failed to act on the reverse drive, owing to the change in direction of the rotation of the driving pulley. It was, however, necessary to supply oil while the machine was running in the reverse direction also. One remedy, of course, would have been to replace the pump by a reversible one. However, one of the operators conceived the idea of replacing the pump pulley by two pulleys side by side, each bearing a bicycle free-wheel or coaster fixed to drive in opposite directions. Two belts, one open and one crossed, were used to drive the pulleys. Then, no matter which way the machine was running, one of the free-wheels would drive the pump.

E. P. Ciclick

DEVICE FOR EMPTYING OIL DRIP-CUPS

On advertising page 177, in the July number of Machinery, the following "Don't" for machinists is given: "Don't work on any machine if the countershaft hangers are loose." While the writer does not know of any case where anyone has been hurt by the countershaft falling down, he does know of cases where the oil drip-cups have come down. These drip-cups must be emptied at intervals, and, apparently, they are not always put back in position as tightly as they ought to be. Perhaps, also, the looseness is produced by their being removed and put back again at frequent intervals. To empty them, it is necessary to go up on a ladder, which is, in itself, dangerous.

The accompanying engraving shows a device by means of which the oil drip-cups can be emptied without removing them, and much more rapidly than by the ordinary methods. This device the writer has seen in use "on the other side of the pond." The device consists of a long length of piping projecting from the top of the main body, and having a bent or hooked end. The piping used is ⅜-inch gas pipe. At the bottom end a short straight length of piping projects. The ball in the valve shown is held in position by a light spring, just strong enough to support its weight. To the right is a projection containing a pump piston.



A Convenient Device for Emptying Drip-cups

The manner in which this device is used is as follows: The man emptying the oil drip-cups goes around with this device and a pail. To empty the oil drippers he simply hooks the pipe end onto the dripper and pulls out the piston once, so as to start a syphon action; after this the oil will empty into the pail very quickly. The ball valve stops the air from being drawn into the cylindrical section when the piston is drawn out, but it does not stop the oil from flowing past it when it comes down the long pipe. This device does away with the necessity of loosening the drippers; the action is quick, and no danger is attached to its use, as when a ladder has to be employed.

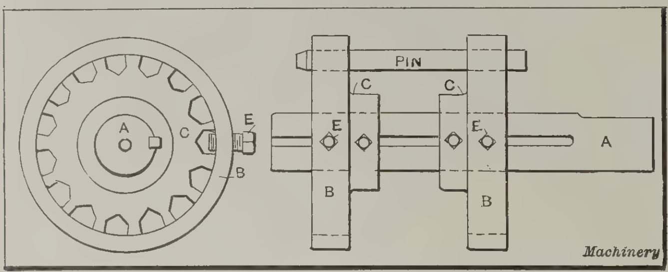
Pawtucket, R. I.

DEVICE FOR SIZING PRESSURE PINS

Many mechanics, in making combination cutting and drawing dies for single-acting punch presses, have undoubtedly experienced difficulties with trying to make pressure pins of an equal length. With the aid of the device or mandrel shown in the accompanying engraving, the old cut-and-try methods are entirely done away with, and a complete set of pins can be faced at both ends to equal length at one setting. The mandrel shown has a maximum capacity for fifteen ½-inch pins.

In the engraving, the mandrel *A* is made of tool steel, and has a flat milled for the set-screw of the driver. The collars

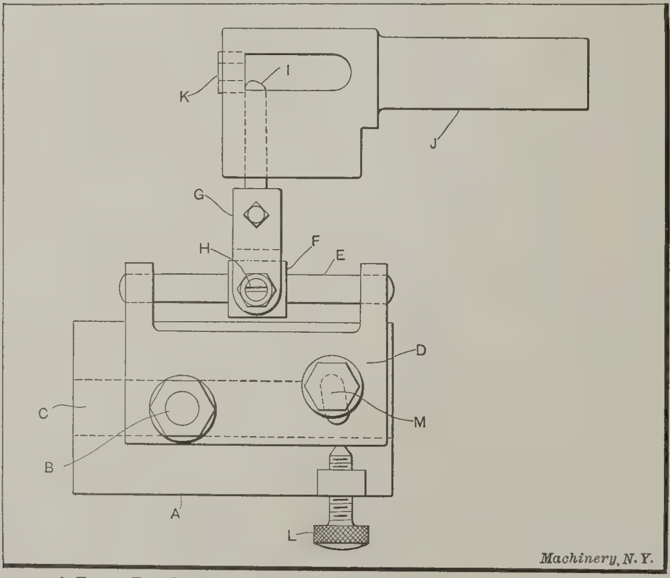


Mandrel for Holding Sets of Pressure Pins while Sizing

C are made of cast iron and have slots milled in them for the pins. They are fitted to the mandrel *A* by keys to insure rigidity, and the slots are milled after the collars are fitted to the arbor, so that the grooves will line up. The machine steel rings *B* carry set-screws *E*, which latter should be quite smooth and flat on the ends, so as not to mar the pins. Rings *B* are shrunk onto the collars. When using this device, it is advisable to keep the collars as close to the ends of the pins as possible, to insure good support. Light cuts should be taken, and a fine cross-feed used. A grinder is to be preferred to a lathe when such a machine is available. A. J. B.

A TAPER TURNING TOOL FOR THE AUTOMATIC SCREW MACHINE

The accompanying illustration shows a taper turning tool used in the automatic screw machine for turning taper pins. This tool, however, cannot be used where it is necessary to revolve the turret, and the feeding finger alone is used to govern the length of the stock. This device consists mainly of a base *A* held on the cross-slide, by a bolt and nut *B*, the



A Taper Turning Tool used in the Automatic Screw Machine for Turning Taper Pieces

base being located by the tongue *C*, which fits in the slot in the cross-slide. Attached to the base *A* is a member *D* which swivels on the bolt *B*. Driven into the member *D* is a pin *E* on which the bushing *F* slides. The tool-holder *G* is cut out to fit over the bushing *F*, and is held to it by two cone-pointed screws *H*. This tool-holder *G* holds the turning tool *I*, which slides freely in the member *J* held in the turret. A bushing *K* which has a hole in it of the same size as the diameter of the stock to be turned, is driven into the front end of the member *J* to support the work.

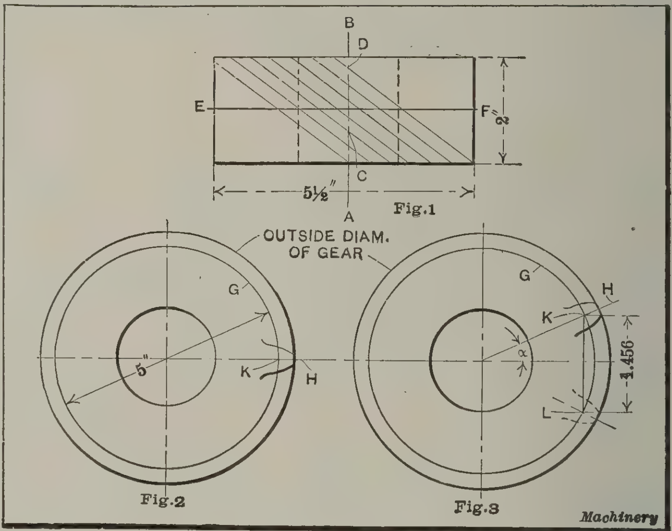
In operation, the cross-slide is held stationary, the turret alone advancing. The taper on the work is governed by swinging the member *D* to the desired angle, and when in the desired position, it is stopped by the knurled screw *L*, and clamped by the cap-screw *M*. A slot is cut in the swinging member *D* so that it can be adjusted to various angles. When the tool is set correctly, the feeding device is then set so that it will feed the stock out to the desired length. When the pin has been turned it is cut off by a circular tool held on the rear cross-slide. While the pins cut off vary slightly in length, they are close enough for most purposes.

Detroit, Mich. DAVID MELVILLE

DETERMINING THE LEAD OF SPIRAL GEARS

A spiral gear of 5½-inch diameter and 2-inch face was sent to the shop with the order, "Make a duplicate at once as something has happened to this one." This last assertion no one was inclined to dispute, as there was not one uninjured tooth on the gear, which, moreover, was broken into two pieces. The first requirement, in order to be able to duplicate the gear, was to find the lead of the spiral.

The usual method, to scribe a line *AB*, Fig. 1, parallel with the axis of the gear, measure with a height gage the distance between two intersections of tooth edges, as *CD*, multiply by



Figs. 1 to 3. Method used for Determining Lead of Spiral Gear

the number of teeth in the gear, and divide by the number of tooth spaces between *C* and *D*, is not always entirely accurate in practice, although admirable in theory. In this case, this method could not be employed as the gear was so injured that no place could be found where a line so drawn would cut the edges of two teeth.

The man to whom the job was given drew a line *EF*, Fig. 1, at right angles to the axis and midway between the end faces of the gear. He then tied the two halves together, inserted a size plug in the hole in order to obtain a center, and with dividers scribed a circle *G* as shown in Fig. 2 on each end of the gear. This circle was 5 inches in diameter. He then put the gear on an arbor clamped in a V-groove in the vertical face of a cube-shaped piece which rested on the surface plate. If this appliance had not been available, he could have put the arbor between the centers of a lathe, laying a parallel across the shears as a base from which to measure.

Setting the height gage to the center height of the arbor and using a lens to insure all possible accuracy, he scribed in the center of each end of one tooth a radial line as shown at *H* in Fig. 2, choosing a tooth which showed line *EF* on the top of it; then, turning the gear so that the intersection of *EF* and the center line on the top of the tooth were in a horizontal plane passing through the arbor center, he measured with the height gage to the point *K* on each end of the tooth. The difference between these measurements was 1.456 inch which represented the advance of each tooth in the width of the gear

face (2 inches). This advance is not 1.456 inch on the circumference of the circle but is the chordal distance KL, Fig. 3. Now the length of KL divided by the diameter of the circle G equals the sine of angle a.

$$\frac{1.456}{5} = 0.2912; \text{ hence } a = 16 \text{ deg. } 56 \text{ min.}$$

This angle is to 180 degrees as 2 is to the spiral lead L of the teeth. Hence:

$$\frac{16.93}{180} = \frac{2}{L}; \ L = 21.26 \text{ inches.}$$

As the gear was of 12 diametral pitch, this lead gives an angle of spiral of about 38 degrees.

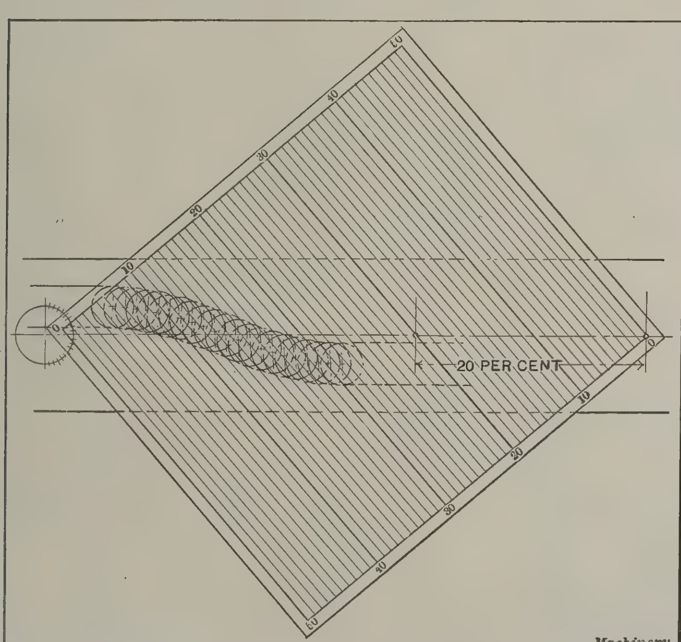
The accuracy of this method is limited only by the workman's ability to scribe and measure accurately, and with a sharp scriber in the height gage and painstaking care, very close results can be obtained. In this instance, the error was small, as subsequent correspondence with the maker of the gear showed that it had been designed for a lead of 21.262 inches, and very likely had been cut with a lead of 21¼ inches. The lead of spiral milling cutters often has to be determined in order that they may be recut. A similar method can be followed for these tools, the point K from which the measurement KL is taken being determined by the intersection of the circle drawn on the end of the cutter and the radial face of a tooth.

GUY H. GARDNER

Revere, Mass.

DEVICE FOR LAYING OUT DRUM CAMS

The accompanying illustration shows a simple device which is used in laying out drum cams. The writer has found this device to be a time-saver to draftsmen and believes it will prove of interest to some of the readers of MACHINERY. In laying out drum cams, it is necessary to lay out the percentages



Device for Laying out Drum Cams

of the cam movement on the center line of its lift. When doing this work in the ordinary way, the total length of the cam circumference is first laid out and then this length is divided up into percentages by some geometric method. This procedure, however simple, must be repeated for every section to be laid out.

The writer's method consists in having a piece of tracing cloth divided and ruled as indicated in the engraving, each tenth line being made slightly heavier than the others so as to make the counting of the divisions easier. This piece of tracing cloth is laid over the layout with the zero point at one of the ends of the line to be divided, and then the tracing cloth is swung around until the other end of the line to be divided coincides with the line on the tracing cloth numbered with the required number of divisions. The divisions to be laid out can then be pricked through onto the layout by the dividers. In the engraving is illustrated the method for laying out a 20 per cent cam movement. If two sheets are used, ruled with divisions 0.25 and 0.40 inch apart, respectively, these sheets will cover a large range of cam diameters.

ALFRED LAURENS

CURLING AND CLOSING DIE

The die shown in Fig. 1 is used for curling the hollow ring-shaped cup shown at A in Fig. 2 and locking the steel band shown at B within it. The punched cup shown at A, Fig. 2, is as it comes from the drawing die and trimming lathe, ready for curling and assembling with the band shown at B. The central portion of the cup A is left in place until

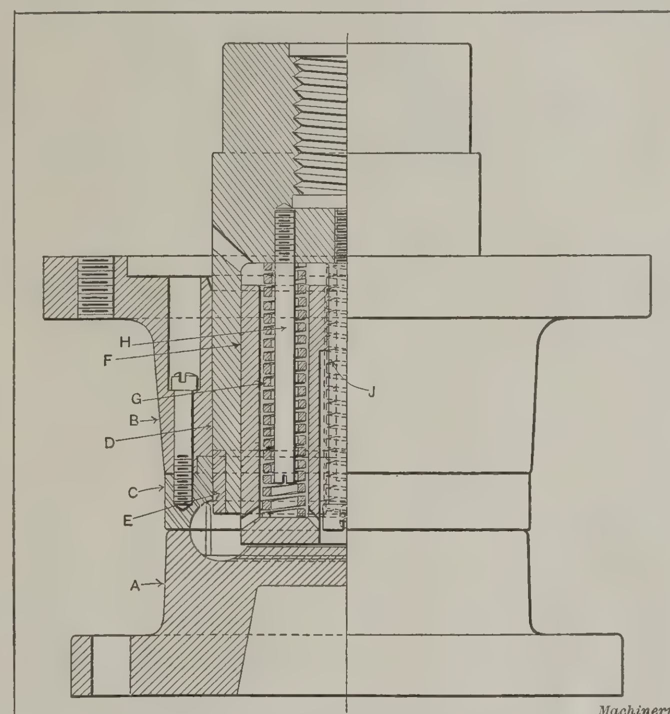


Fig. 1. Curling and Closing Die for Assembling

after the assembling operation is completed, as it serves to stiffen the work and enables it to be held more securely.

The base A of the die in Fig. 1 is an iron casting and is recessed in its upper surface to fit the cup, Fig. 2. As there is no rubbing or abrasive action in this die A, the cast-iron surface is of ample hardness, and saves the expense of inserting a steel ring. The upper portion of the tool consists of a cast-iron holder B, to the lower face of which is pivoted and screwed the curling die ring C, made from hardened tool steel. The closing punch-holder D is made of cast iron, bored out to receive the pressure pad F, which is acted upon by four stiff helical springs G, and is limited in its travel by the shoulder stud J.

The pilot studs H are of cold-rolled steel and are screwed

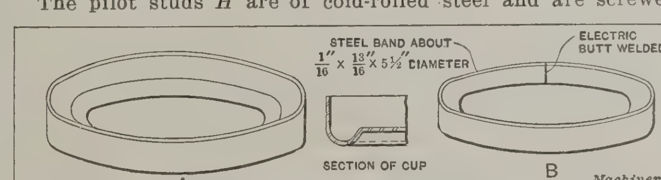

Fig. 2. (A) Cup before Curling and Closing. (B) Band to be assembled with Cup

into the punch-holder D for the purpose of guiding the helical springs into their pockets, and to prevent the pad F from rotating around the stud J. A steel band E is pressed onto the lower end of the punch-holder D to withstand the abrasive action to which it is subjected.

This die is held in a double-action press and is operated as follows: The cup A, Fig. 2, is placed in the groove in the base A, Fig. 1, and the band B is dropped into the cup. The punch descends, first holding the cup securely with the pressure pad F. Then the curling die descends, closing in the top of the cup, after which the closing plunger, which

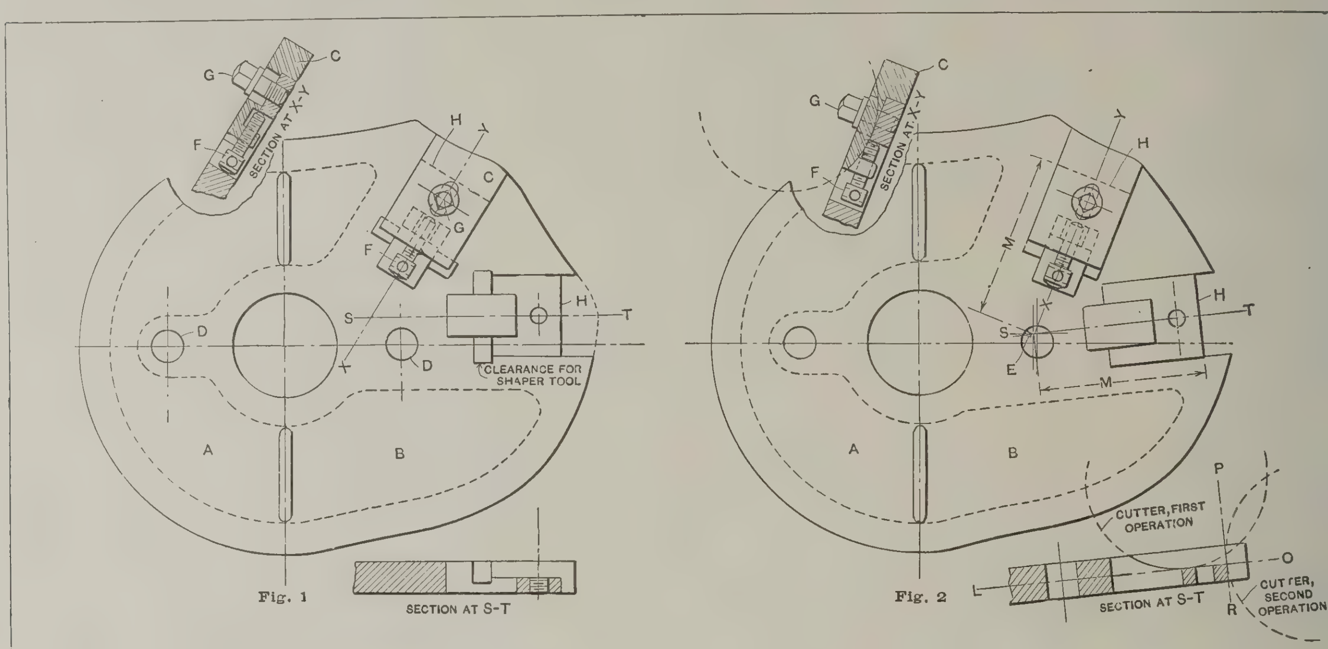
comes down slightly behind the curling die, operates and locks the band securely in place. The fact that the drawing punch of a double-action press descends after the blank-holder slide, combined with the necessity of holding the work when operating, in this case with the curling die first, makes it essential to use the long-stroke pressure pad and springs.

Detroit, Mich. ARON LAWRENCE

JIG FOR MILLING CAM SLOTS

In Fig. 1 is shown a cam used on a knitting machine. It consists of two halves, *A* and *B*, fastened to a flange, in the position shown, by the holes *D*. Part *B* is provided with two convenient manner The design of such a fixture, however, is not as easy as would be thought at first glance, since the center lines of the two slots in the cam intersect at a point which is not at the same distance from the edges *H* of the slots. In order to simplify the design of the fixture, the design of the cam was altered to that shown in Fig. 2. It will be seen that in the new cam the direction of the center lines of the slots is changed in such a way that the point of intersection *E* is at the same distance from the edge *H* of both slots. The parts *C*, however, remain at the same points on the outline of the cam.

Two operations are necessary for each slot. During the first operation the cutter finishes the top part of the slot, cutting



Figs. 1 and 2. Old and New Designs of Cam

slots which receive steel parts *C*. The latter fit exactly into the slots and may be adjusted by a hardened adjusting screw *F*. Another screw *G* is provided to hold parts *C* in their respective positions after being adjusted. These parts, however, are adjusted only at intervals, on account of the excessive wear at these points, although the adjustment also makes it possible to alter the shape of the cam to some extent when this is required.

along the line *LO*, while the second operation takes care of the front part and the correct length *M*, the cutter cutting along the line *PR*. The fixture used is shown in Figs. 3 to 6, inclusive, and is used for all the milling operations. It consists of a cast-iron base *A* (see Fig. 6) with two bearings *C*, each having a removable cap *D*. A cast-iron center piece *F* swings between these bearings by means of two journals *G* extending from *F*. These journals are cast hollow to reduce

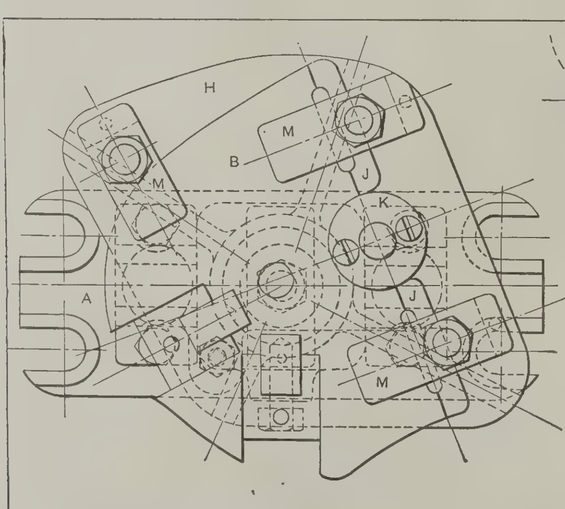


Fig. 3. Plan of Fixture

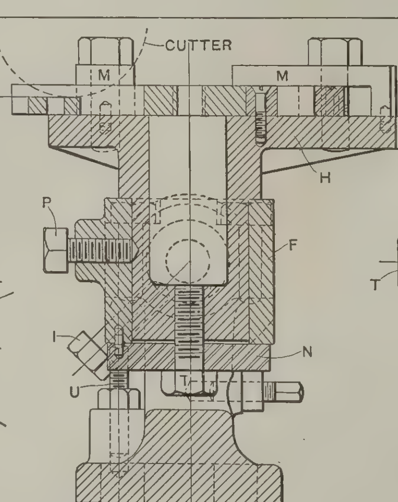

Fig. 4. Section of Fixture

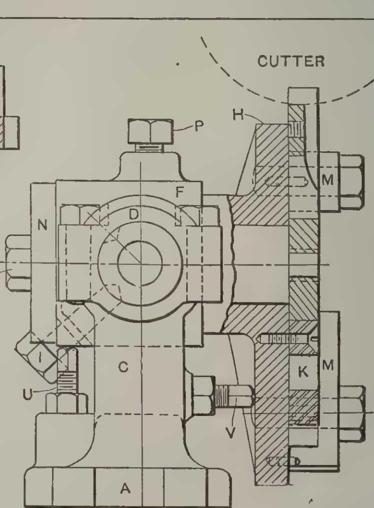

Fig. 5. Side View of Fixture

Some years ago the slots for these adjustable parts *C* were shaped and the parts made to suit, but as the cams were later used in large quantities, this method proved unsatisfactory and it was decided to mill both slots by one cutter, so as to be sure that they would be of the same width. The parts *C* were to be finished by straddle milling cutters set the required distance apart. It was then required to construct a jig for performing the milling operation for both slots in an easy and the weight. In *F* a finished hole is provided at right angles to the axis of bearings *C*, to receive the cast-iron table *H*, which revolves in *F* and is provided with two projections *J* and a round steel disk *K*, the latter of which suits the bore of half-cam *B*. The cam is located by means of lugs *J* and disk *K* in such a way that the intersection point *E* (Fig. 2) of the two center lines of the slots coincides exactly with the axis *L* of the journal bearing about which it revolves.

Clamps *M* serve to hold the cam in position while it is milled. The clamps are provided with small steel pins which prevent it from turning around their bolts. The table *H* may be fixed in two positions so as to bring the center lines of the two slots into line with the cutter. The hardened center point of screw *P* fits into two corresponding holes drilled into the journal of table *H* at the proper places. The table is rigidly held to the center piece *F* by means of screw *T* and the bridge piece *N*. The latter is also provided with a small pin *S* and thus fixed in its position with relation to the center piece *F*. Fig. 6 shows the top view of the table set for the first slot, while Fig. 3 represents the same view with the table turned to cut the second slot.

After the top parts of the slots are finished, the latter must be cut to the correct length, finishing the front part at the

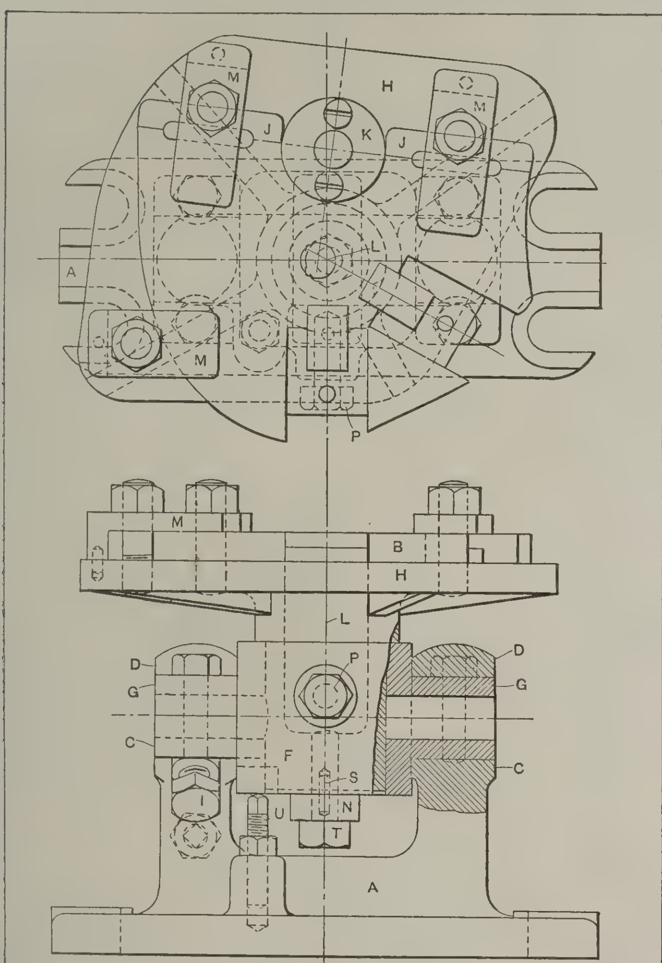

Fig. 6. Plan and Front View of Fixture

same time. To do this, the set-screw *I* is loosened and the center piece and table are swung around 90 degrees. In the first position, shown in the side-view section, Fig. 4, the center piece rests upon a screw *U*, while the top part of the slot is finished. When it is swung over, however, it rests against screw *V*, Fig. 5. Countersinks to suit screw *I* are drilled in the left side of the journal of the center piece *F* at the correct angles. The axis of *F* is arranged in such a way that the fixture is at once ready for the second operation, and no resetting of the cutter is necessary. To cut the front part of the second slot, table *H* is simply revolved as described before. It will be seen that in this way all the operations can be carried out rapidly and conveniently and without resetting the cutter or re-adjusting the milling machine table.

Wyomissing, Pa. CHRISTIAN F. MEYER

REPAIRING A CRACKED WATER JACKET

In the April, 1910, number of MACHINERY, a method of repairing a cracked water jacket of a gas engine cylinder was illustrated and described. In the following is given a different method for making repairs of a similar nature.

On the line of the fracture, drill and tap for a ⅜-inch threaded copper rod. This rod is screwed in firmly to a depth about equal to the thickness of the metal of the water jacket. Cut off the copper rod with a hacksaw, allowing it to project about 1/32 inch; then drill succeeding holes, each hole being drilled partly into the previously inserted copper plug, so that when all of the plugs are placed in the cylinder casting, they form a continuous band of copper along the line of the fracture. The copper plugs should now be peened down and trimmed off flush. The only possible chance for leakage, after having repaired the crack in this manner, is for the water to follow the joint between the metal of the jacket and the copper plugs, but, as the copper rods are threaded into the casting, it is not likely to occur. Should leakage take place, a little extra peening will suffice to prevent it.

Wilmerding, Pa. E. R. GROMAN

SEASONING CAST IRON

In response to the question in the "How and Why" section in the June number of MACHINERY, the writer would offer the suggestion that the best solution lies in so designing the parts that seasoning is either no longer necessary or so that the time required would be considerably reduced.

Every foundry-man knows that badly proportioned castings, that is, castings in which the metal cools at different rates, are subject to greater distortion than well proportioned ones. When cold, the stresses in the parts which cooled first are particularly severe, since added to their own stresses are the stresses due to contraction of the last cooled parts. Hence, if in any way an equal rate of cooling can be induced, castings less internally stressed will result. In the first instance, then, it is to the designer one must look for the cure, or rather the prevention. Let him see that the thick parts are reduced to the utmost possible extent, and then balanced by equally thick parts directly opposed. In certain cases the molder can influence the result by baring the thicker parts after solidification. He can also cast in proximity to the thin parts masses of metal to retard the cooling. The writer has often adopted this method. One case which migh be cited involved pulleys with a very thin rim, in which case a ring of metal was cast surrounding but not touching the rim. In another case of long angle bars, two bars of metal were cast along the two edges.

By any of these means the internal stresses are reduced; hence, their effect when metal is removed will be less also. But having attended to all these half remedies, there is another possibility. Take, for instance, a lathe bed, which by the best firms is always subjected to the ageing process. The top is planed and stresses are thereby released. It would, perhaps, be more correct to say that the metal under the severest stress is removed, and the planed surface is distorted by the pull from the metal at the opposite, that is, the bottom side. Why not remove an equal quantity of metal at the opposite side and so neutralize the effect? This is again a matter for the designer. As a rule, in a lathe bed, it is necessary to turn the bed over to plane the seatings for the legs. Why not extend the leg seatings the whole length of the bed? Then, before planing, lay out so as to insure an equal cut on both top and bottom. The writer has, in some instances, adopted this practice with the result that it was no longer necessary to season. FRANCIS W. SHAW

Manchester, England

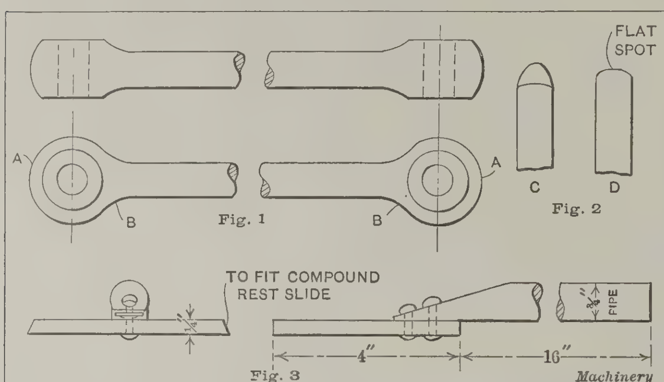
SPHERICAL TURNING

The spherical turning device described by Mr. C. Boella in the July number of MACHINERY, is probably good for the class of work for which it was designed, but the fixture is expensive and there are many classes of work that can be produced cheaper and simpler by the method described in the following.

In a large air-compressor plant where a great deal of spherical turning is done, various devices have been tried and discarded in favor of the simple method of using the compound rest as a spherical turning device. An example of the work done is shown in Fig. 1. This illustration shows a Corliss valve driving-rod having spherical surfaces turned at the ends *A* and fillets at *B*. When turning these, the compound rest on the

lathe is set so that the point about which it is swiveled is vertically beneath the center of the spherical section to be turned. The rest is then oscillated or swiveled so as to turn a spherical surface. The tool can be set at once to the desired radius when forgings are being turned having only a small allowance for finish. When, however, it is desired to take two cuts, the feed of the compound rest can be used for feeding in the tool for the second cut.

In order to be able to oscillate or swivel the compound rest, the binding screws are loosened enough so that an easy working fit is produced. The feed handle is removed and the operator uses the end of the compound-rest feed-screw as a means for swiveling the rest about its center, feeding the tool slowly around the work. Some operators reverse the compound rest so that the feed handle is at the back of the lathe, and then



Figs. 1 to 3. Work requiring Spherical Turning, and Tools used

use a handle as shown in Fig. 3. This consists merely of a piece of steel beveled to fit the slide in the rest and having a ¾-inch pipe about sixteen inches long riveted to it. This handle is inserted in the compound-rest slide and the pipe acts as a lever arm making it easier to swivel the slide about its center. In machining the fillet *B*, Fig. 1, the tool point, of course, must be moved past the swivel center, of the compound rest.

The points of the cutting tools are shown in Fig. 2, where *C* shows an ordinary round-nosed tool which is used for roughing cuts, and *D*, a finishing tool. This is ground off to a comparatively large radius and is flattened off about 3/32 inch at the end. This tool, with soda solution as a cutting lubricant, finishes and polishes the work in one operation.

New Britain, Conn. J. M. Henry

CUTTING TWELVE TEETH IN A THIRTEEN-TOOTH BLANK

In the June number of Machinery, engineering edition, Mr. G. R. Hulsberg, in commenting upon Wuest herringbone gears, takes exception to some of the methods adopted in calculating and cutting these gears. He concludes as follows:

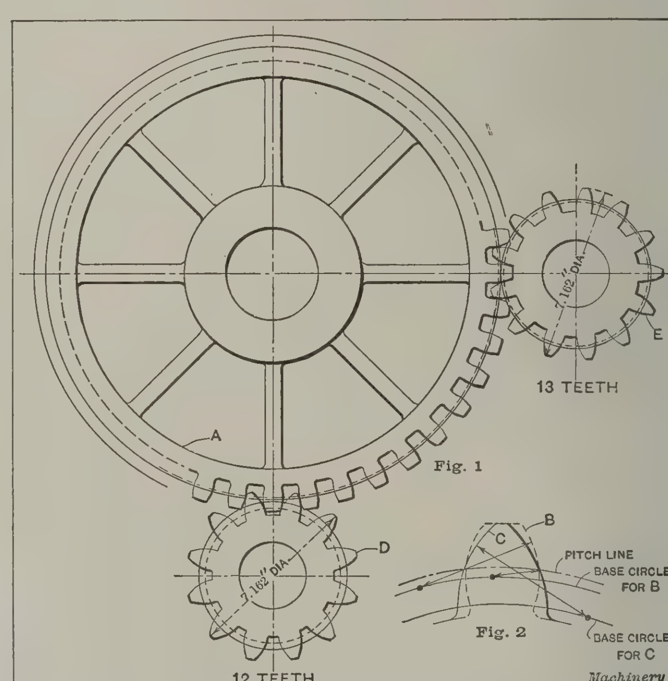
"Furthermore, in order to keep the center distance to some even dimension, the author simply reduces the pitch diameter of the gear to suit the center distance. By doing this, and keeping all the other quantities the same as before, the pitch of a gear is changed without changing the pitch of the pinion; hence, the gears will not mesh perfectly. The difference may be small, but interchangeability cannot be claimed on this basis."

The writer's experience with involute gearing indicates, however, that this supposition is not correct, and that, in fact, the diameter of the gears may be varied considerably from the calculated diameters without affecting the running qualities in the slightest degree, provided the proper method of forming the teeth is used. Some time ago a number of old planers were renovated, and, among other things, it was necessary to provide a complete set of new gearing and racks. The rack pinion was of mild steel, 13 teeth, 1½-inch pitch; the face width was 9 inches, the bore 3¼ inches, and the total length of bore 21 inches. It will be readily understood that the machining of the blank for this pinion from a solid 7¼-inch diameter steel bar involved considerable work, and that the finished gear was a fairly valuable piece. After the blank had been bored and turned the next operation was the cutting of the teeth. This was done in a gear-cutting machine, two cuts being taken.

Unfortunately, when gearing the indexing motion of the gear-cutting machine, the operator made one of those mistakes which seem almost inexplicable after they are discovered—he geared the machine for twelve teeth instead of for thirteen, and did not discover the error until one-half of the spaces had been roughed out. At first it seemed as if the only thing to do was to discard the blank and start on another. The writer remembered, however, that if a gear was cut in a generating machine (as distinct from a formed cutter machine) variations in the blank diameter were, within limits, unimportant. In fact, it is a recognized practice in some classes of work to increase the diameters in order to give the pinion teeth increased strength and durability. One firm in the town where this work was done had a generating machine large enough to cut pinions of the size mentioned. Arrangements were made with this firm, and in a few hours a finished gear was completed from the blank which had seemed to be only fit for the scrap heap. In fact, the pinion finished with twelve teeth was a better job than if it had had the full complement of thirteen teeth, as originally intended.

It may be suggested that the pinion could have been turned down to the correct diameter for twelve teeth and the teeth cut in the usual way. This, however, would have required another bull gear, and would also have left very little stock at the bottom of the teeth. Of course, the ratio of the gearing was affected by this alteration, but this was allowed for by a slight change in one of the other pairs of gears.

At *E* in Fig. 1, the pinion is shown as originally designed; *A* is the bull gear, and *D* is the pinion as actually made with



Figs. 1 and 2. Comparison of Tooth Forms in Pinions of Same Diameter with Twelve and Thirteen Teeth

twelve teeth. The dotted circles just inside of the pitch circles, in each case, represent the tooth curve base circles. It will be seen from Fig. 2 that the teeth of gear *D*, shown by full lines *C*, are stronger than the teeth of gear *E*, as shown by the dotted lines *B*. In this particular example we have the apparently paradoxical situation of a gear having 1½-inch pitch teeth accurately meshing with a pinion having 1⅝-inch pitch teeth, but there is no doubt whatever that if gears are cut by the generating process a slight variation in diameter makes no difference in their smooth working.

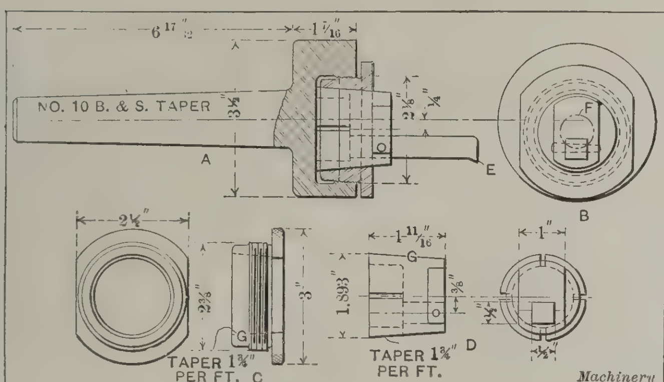
In conclusion the writer might mention that this twelve-tooth pinion has been in operation for about a year and the tool marks are still visible on the teeth. This is a good indication of the durability of the teeth when it is considered that the pressure on the teeth is about 9000 pounds during the cutting stroke and about 5000 pounds during the return stroke.

G. Ear

IMPROVED DESIGN OF BORING-TOOL HOLDER

The accompanying illustration shows a jig-boring tool that requires no set-screw to hold the tool. The use of set-screws, unless of the headless variety or those which do not project, is to be avoided in designing moving parts of machines or tools.

Referring to the illustration, *A* is the front elevation, shown partly in section; *B* is the end view of the assembled tool; *C* is a detail view of the locking nut; *D* shows the tool sleeve and *E* the tool, which can be made of any convenient dimension to suit the work. The shank of the tool-holder is tapered to fit the milling machine spindle. The head of the holder is



Improved Design of Boring-tool Holder

bored with an eccentricity of ¼ inch, and the square hole through the tool sleeve is also ⅜ inch off center. The circle *F* shows the amount of adjustment possible with the tool, which in this case is ¾ inch. The tool *E* is held in the tool sleeve by a taper pin.

In operation, this boring tool is similar to any other boring tool, except for the manner of varying the amount of eccentricity. This is accomplished by loosening the retaining nut, turning the tool sleeve and tool slightly, and tightening the sleeve again. The pressure of the retaining nut upon the tool sleeve holds the tool firmly, thus insuring an accurate cut.

Providence, R. I. ROBERT MAWSON

AN EFFICIENT ANGLE-PLATE FOR JIG WORK

When boring out jigs which require being clamped to the faceplate as well as to the angle-plate, strains are set up in the jig, so that when removed to drill a cross-hole, it will be found difficult to get the two holes in perfect alignment. An angle-plate which eliminates clamping strains, and does away with the necessity of clamping the work to the faceplate is

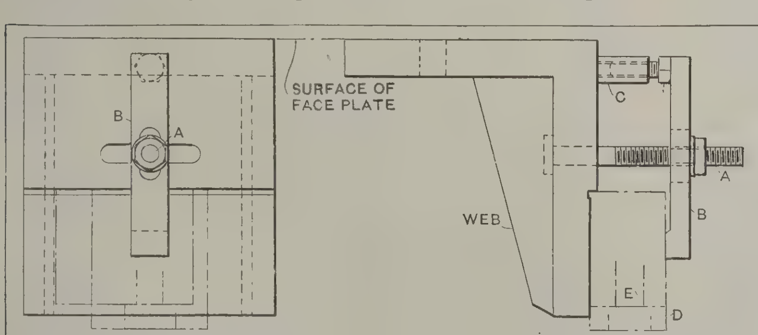


Fig. 1. Efficient Angle-plate for Jig Work

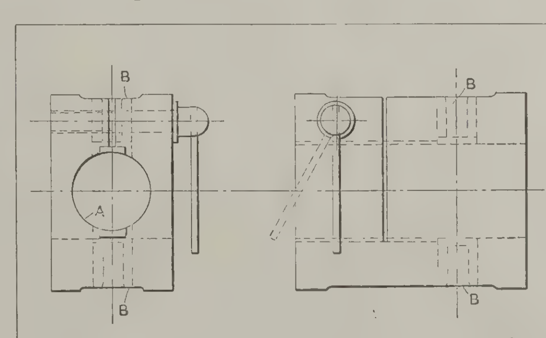

Fig. 2. Block Jig illustrating Application of Angle-plate in Fig. 1

shown in Fig 1. This plate differs from the ordinary plate only in that it is provided with a clamping bolt *A*, strap *B*, and is planed out on the front end as shown, so that the jig will have a seat or shoulder to bear up against. A jack consisting of a stud and nut *C* is also provided to block up the strap.

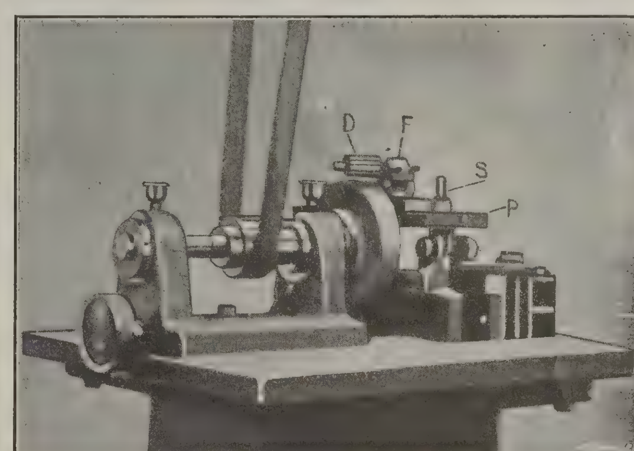
A jig which illustrates the application of this angle-plate is shown in Fig. 2, this being used for drilling and reaming a hole through a round bar. This is a simple jig, and is shown merely to illustrate one use of the angle-plate. In Fig. 1, the dot-and-dash lines *D* indicate the jig block in position for drilling, boring and reaming the large hole *A* in the jig, Fig. 2, while the dot-and-dash lines *E* show the jig block in position for drilling the small holes *B* in the jig Fig. 2. It is important when clamping the jig block to the angle-plate, that the block when changed from one position to the other should always have the same side in contact with the angle-plate, thus insuring that the holes will be in perfect alignment. JOHN R. JARVIS

New Haven, Conn.

EMERY-WHEEL TRUING DEVICE

The grinder shown in the accompanying illustration is used for grinding a special edge tool made in large quantities, the tools being gripped in a fixture reciprocated on the table *P*, the table being set at just the right height to clean up the face of the tools as they pass by the grooved surface of the wheel. These tools are ground with their faces straight and parallel within 0.001 inch, and hence the horizontal planes of the wheel, fixture, and table must be parallel. It was found that an adequate device must necessarily be provided for truing the wheel.

The table *P* swings about a horizontal axis through a short arc, and is held in position by lock-nuts on the stud *S*. The adjustment permits the wheel to be followed up at the pre-



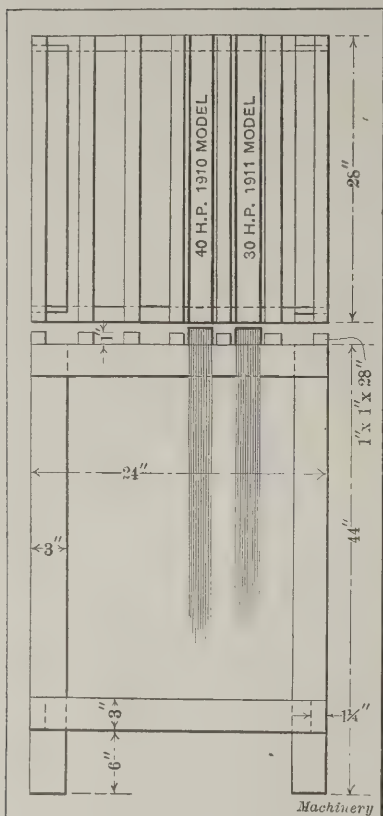
Device for Accurately Truing Emery Wheels

determined distance as its face wears off. No diamond was at hand for the truing of the wheel, and an ordinary emery-wheel dresser was out of the question for producing a straight parallel surface with sharp corners. The device shown in the illustration was, therefore, made, consisting of the cast-iron base *F* which is quickly attached to table *P* by thumb-screws, a half-inch shaft, and the dresser *D* which is made of a piece of carbon steel having a U. S. standard thread cut on its exterior, and then slotted longitudinally so that an end view has the appearance of a star wheel with sharp points. This tool is hardened but not drawn, and the hole in it is lapped to fit the shaft. When the base is attached to the table, the latter is lowered by the adjusting nuts until the wheel just touches the dresser, the machine being in motion. The dresser is then fed across the face of the emery wheel a couple of times. This device has proved very satisfactory, and produces a straight, sharp-cornered free-cutting face.

Middletown, N. Y. DONALD A. HAMPSON

DRAWING CABINET

The accompanying engraving shows a cabinet or rack for holding drawings or blueprints that have been bound together in volumes and are used regularly in the shop. It is simple in construction, but answers the purpose better than many more elaborate drawing cabinets and racks. It does not take a great deal of floor space, as the drawings are hung in a vertical position, while in most cabinets the drawings are laid flat, in a horizontal position. The title of each set of drawings is written on the back of the cover, so that it is always in plain sight and easily read. The top of the rack can be used as a reference table, it being level and of the proper height for that purpose. The construction of this rack is so simple that it can easily be made by any ordinary carpenter. The dimensions can be arranged to suit the conditions.

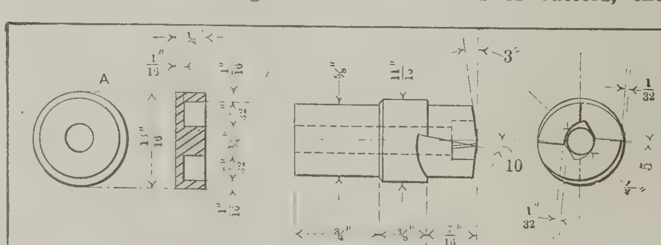


Useful Rack for Bound Volumes of Blueprints

Providence, R. I. ROBERT MAWSON

COMBINATION HOLLOW MILL AND COUNTERBORE

The accompanying illustration shows at *A* a section of a part made on the screw machine which, at first, appears to be a rather "mean" job. It will be seen that the recess is not very wide and the principal difficulty, obviously, is that when running at anything like an economical feed, a tool point small enough to do the work would spring slightly, cramp and break off. Having tried several forms of cutters, the



Combination Hollow Mill and Counterbore and Piece made by it

two-toothed mill shown was finally adopted and has given excellent results. It will be observed that one tooth cuts the outside of the recess, and the other finishes the cylindrical surface of the hub. Thus, with each tooth finishing a surface of its own, there is no cramping action. By having only two teeth, it is possible to make them strong enough to stand up and cut to size without springing. The large body of the tooth serves at the same time to rapidly dissipate the heat generated. The face angle is five degrees, the clearance three degrees, and the rake ten degrees. The work was done on a No. 2 Brown & Sharpe automatic screw machine.

P. A. FREDERICKS

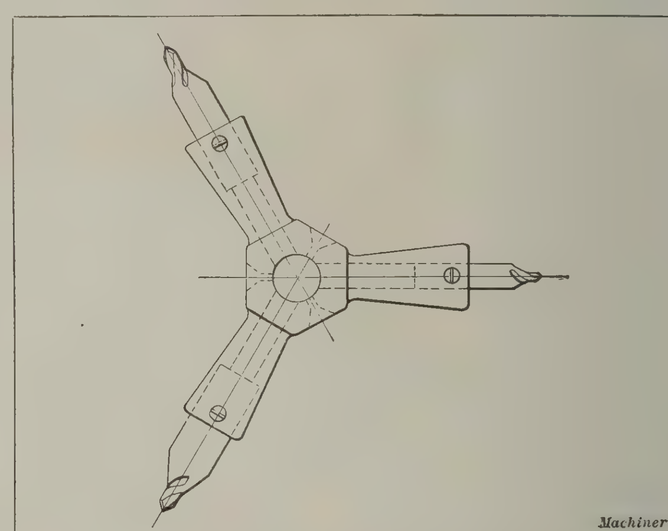
ERASING INK MARKS FROM TRACINGS

Inked-in tracings are easily discolored, marred and sometimes ruined through lack of proper treatment when making changes, but disfigurement of the tracing is not at all necessary if the alterations are made in a suitable manner. The above-mentioned faults can be avoided by observing the following rules. Always allow the ink to dry thoroughly, and do not use a blotter. In rubbing out, constantly turn the eraser so that different edges will be presented to the drawing. Using one portion of an eraser heats it up, and it will soon burn a hole in the tracing. After erasing a line or other inked-in part, rub the section slightly with soapstone. This will restore the finish to the cloth and prevent the ink from spreading. A small piece of soapstone will last an indefinite length of time and should be in every draftsman's kit. It is far superior to a knife handle and other similar contrivances which are sometimes used for this purpose. The above method of erasing will be found efficient if used with discretion.

Los Angeles, Cal. L. R. W. ALLISON

A CENTER REAMER HOLDER

A center reamer holder which will be found useful in connection with lathe work is shown in the accompanying illustration. It saves the trouble of chucking the center reamer every time it is necessary to drill a center in the end of a piece. The holder is held up against the tailstock center of the lathe and the reamer fed into the work. The three



Holder for Various Sizes of Center Reamers

holders make provision for accommodating center reamers of various diameters. The holder itself can be made from a 3½-inch round bar by cutting it off to the required thickness and then milling and turning it to form the three arms. Holes to suit the shanks of the center reamers can then be drilled, and 5-32-inch screws supplied for holding them.

C. E. D.

CUTTING WORMS OF STEEP PITCH IN THE LATHE

When cutting worms of steep pitch in the lathe, it is sometimes found impossible to drive the lead-screw through the usual train of gearing on account of the heavy stress that is placed on the first gear in the train, which frequently strips the teeth. The writer has overcome this difficulty by driving the lead-screw directly from the cone gear, using an attachment which would permit of this. The back-gears being in use, the cone on the lathe referred to had a velocity ten times that of the spindle; with the cone gear used as the driving gear in the train for the lead-screw, this had then ten times the velocity that the driving gear would have had if the drive were through the usual gearing. Hence, the stress on the teeth was proportionately reduced. Assume that a worm having 3½-inch lead is to be cut with a lead-screw having four threads per inch. The ratio of the spindle speed to that of the lead-screw is 14 to 1, but, by driving directly from the cone gear, the ratio will be 14 to 10, which makes it easy to obtain the gears; in fact, some leads could not be cut in any other way, as it would not be possible to obtain the required ratio by the gears available.

Brooklyn, N. Y. GEORGE E. OWEN

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

AMERICAN TOOL-ROOM LATHE

The American Tool Works Co., Cincinnati, Ohio, is manufacturing a new design of high-duty tool-room lathe, which is made in 14-, 16-, 18- and 20-inch sizes. These lathes have many features common to the standard design built by this company, including the drop-V bed, double-plate apron, quick-change mechanism giving 48 thread and feed changes, phosphor-bronze bearings, etc. In addition, the lathe is fully equipped with the various attachments required for tool-room work, such as taper, draw-in, and relieving attachments. It also has a pan for retaining the lubricant, as shown by the accompanying illustration Fig. 1. In case all of the attachments mentioned are not needed, any one of them can be furnished separately.

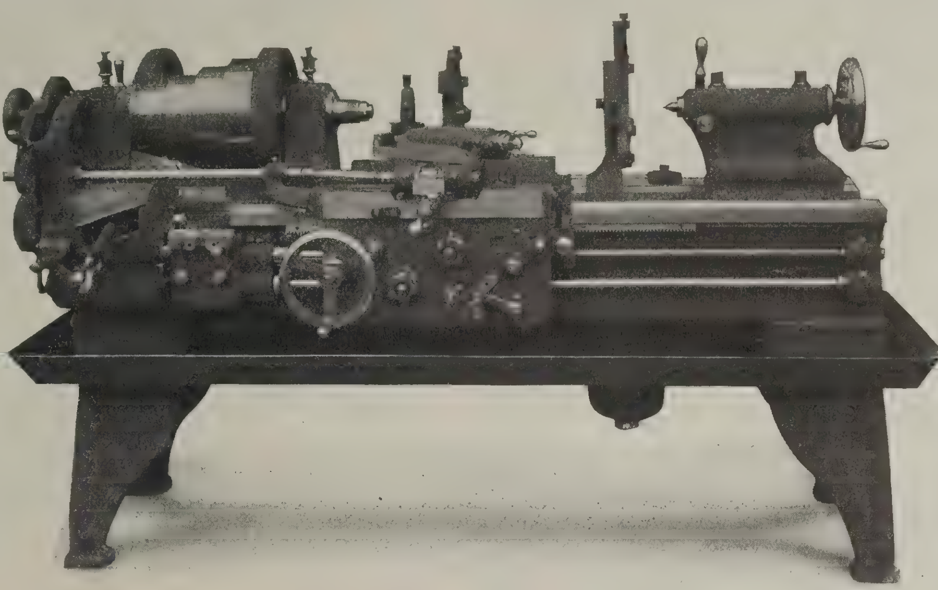


Fig. 1. American High-duty Tool-room Lathe

The taper attachment is simple, both in design and operation, and it is rigidly constructed, thus insuring accurate work. The attachment is bolted to and travels with the carriage, and can be engaged quickly at any point along the lathe bed, by simply tightening one binding nut on the clamping dog. When arranged for taper work, the sliding shoe is directly connected with the bottom slide of the tool-rest by a heavy cast-iron yoke which may be seen in Fig. 2. This construction eliminates lost motion and insures accuracy. The nut for engaging the sliding shoe is arranged to slide in a slot in the connecting yoke, and it is attached or released by tightening or loosening a single screw. Accurate graduations are provided and there is a hand-screw having a graduated collar for obtaining fine adjustments.

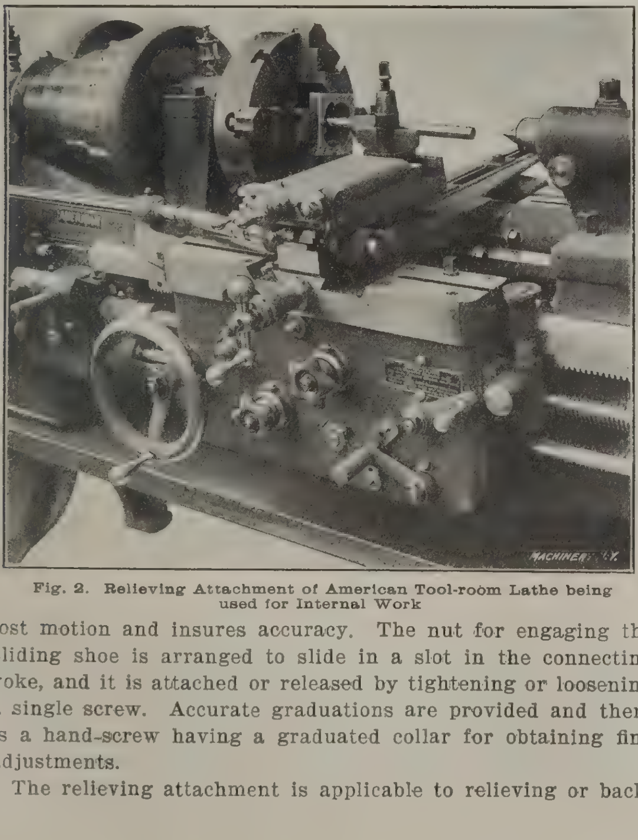

Fig. 2. Relieving Attachment of American Tool-room Lathe being used for Internal Work

The relieving attachment is applicable to relieving or backing off the flutes of cutters, taps, reamers, end mills, hollow mills, dies, etc. This attachment is universal in its operation, and end or internal relieving can be done just as easily as straight work. It has a direct drive and is of simple construction. The change-gear mechanism is supported by a bracket located on top of the quick-change gear-box, as shown in Fig. 1. The change gears are carried by a small quadrant which is used to disengage the drive when not required.

The power is derived from a spur gear located on the end of the main spindle, and motion is transmitted through the change-gear mechanism to the driving shaft which extends through the supporting bracket on the quick-change gear-box, and is journaled at the other end in a bracket fastened to the left side of the carriage as shown. Between the carriage bracket and tool-rest there is a universally jointed telescoping shaft which permits cross movement of the tool-slide.

The driving shaft revolves constantly in one direction until the rotation of the spindle is reversed, at which time the driving shaft ceases to reciprocate the tool-slide; consequently, the latter remains stationary when the direction of the carriage travel is reversed while the half-nuts are engaged. This feature is obtained by interposing a clutch connection between the cam and driver, which is operative in one direction only. Therefore, the reversal of the driving shaft causes the clutch, which is held into engagement by a spring, to be withdrawn from the cam with the result that the cam remains stationary. In order to cover the entire range shown by the relieving attachment index plate, three cams having one, two and four

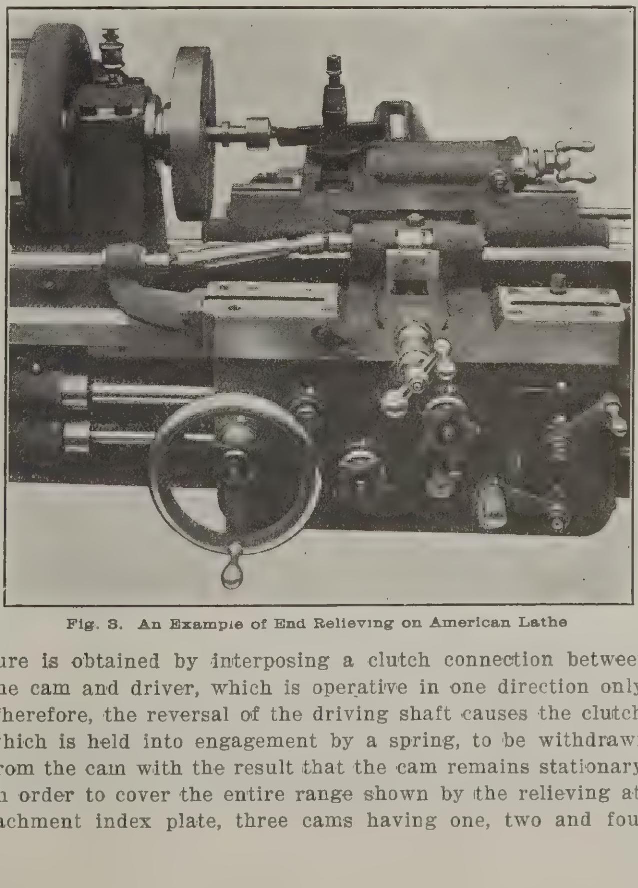

Fig. 3. An Example of End Relieving on American Lathe

rises, respectively, are provided in addition to the change gears. These cams can readily be interchanged, and they run in an oil bath.

This attachment permits the tool-slide to be operated at positions 30 degrees apart, thus providing twelve operating positions within a circle. This feature makes it possible to relieve side cutters, end mills, and various other tools. Fig. 2 shows the lathe being used for internal work and Fig. 3 its application to end relieving. Aside from adjusting the tool-slide to its proper position, no change or re-adjustment of the mechanism is required for internal or end relieving. Convenient means are provided for obtaining the various degrees of relief for either external or internal work. Adjustment is made at the front of the tool-slide by means of a thumb-screw, and the depth of relief is indicated by a graduated scale. This attachment can be applied and operated independently of the taper attachment.

A standard compound rest is furnished in addition to the special relieving rest, the former being recommended for general work. The compound rest can quickly be interchanged with the special tool-slide. The attachment can be arranged for relieving taps or hobs having spiral flutes by the addition of extra gears. In the construction of this attachment high-grade materials are used throughout. The cam yoke is forged and the cams, cam shoe and crank members are of tool steel, hardened and ground. The index bar in the top slide is of forged steel, and all shafts and gears are well proportioned. All gears are covered for the protection of the operator.

The draw-in attachment furnished with this lathe can be equipped with collets for holding stock up to 7/8 inch diameter on the 14- and 16-inch sizes, and up to 1 inch diameter on the 18- and 20-inch lathes.

COMBINED DOUBLE-HOUSING AND OPEN-SIDE PLANER

The planer illustrated in Figs. 1 and 2 was built for the Gas Traction Co. of Minneapolis, for planing the engine base castings used by that company in the manufacture of tractor engines. These bases require planing on the bottom, top and on both angular sides, as well as on the ends. As they are over six feet long, a standard planer, if used for planing the ends as well as the other surfaces, would, of course, have to be wide enough to permit the casting to pass between the housings, unless some form of extension tool were used, which would be undesirable. As the castings have a width of less than three feet at the top, the planing of the sides on such a wide planer would be objectionable, because of the distance to which the side-heads would have to be extended. Moreover a rigid support for the tools was desired to permit taking heavy cuts when planing the angular surfaces.

The planer illustrated herewith was especially designed for this work by Mr. C. C. McConville (general superintendent of the Gas Traction Co.), assisted by the engineering departments of the Rockford Machine Tool Co. and Jos. T. Ryerson & Son. This machine has two heads on the cross-rail, two side-heads and, in addition, an auxiliary housing carrying a single head and located approximately four feet in front of the main housings. The engine bases are machined by first planing them on the bottom, two castings being finished at one setting. They are next mounted one at a time on a fixture which is pivoted in the center and can be accurately located in the different positions required by a heavy stop-pin. This fixture with an engine base mounted on it, is first placed parallel with the planer table and the top and two angular sides of the work are planed simultaneously. Fig. 2 shows the special tool bars or holders which are attached to the standard side-heads for this operation. This view also clearly shows the brackets which are clamped to the housings to provide a rigid support for the tool bars directly back of the cutting tools. After the sides are planed, the fixture carrying the castings is swiveled to a right-angle position and the end of the casting is finished by means of the head mounted on the auxiliary housing. This housing, which is shown in detail in Fig. 3, is located back far enough to permit the casting to clear it without changing the position of the work.

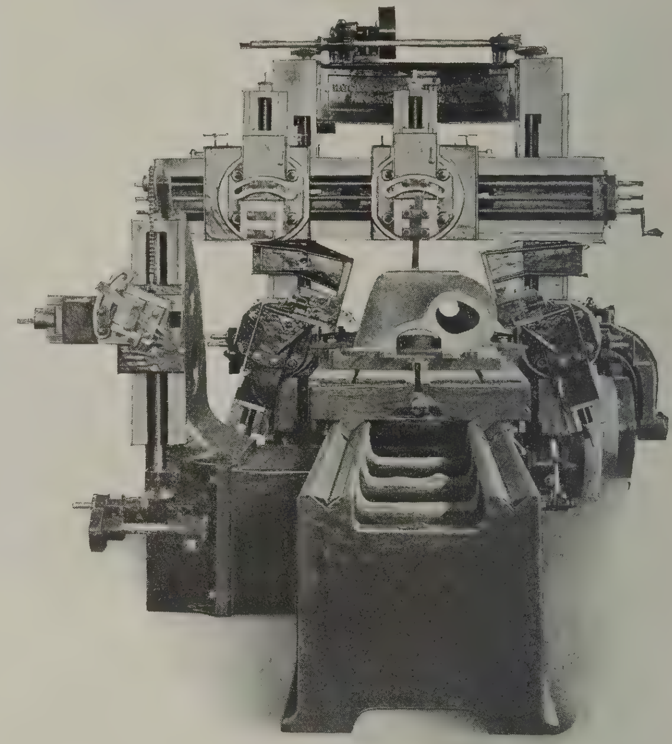

Fig. 2. End View of Combined Double-housing and Open-side Planer

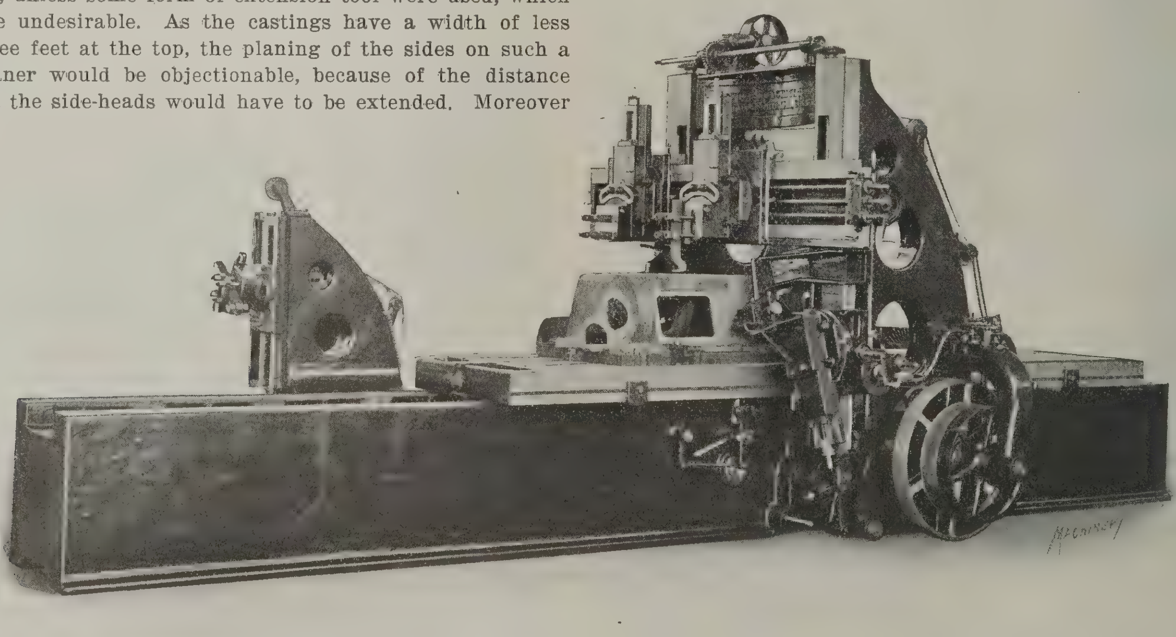

Fig. 1. Special Planer built by Rockford Machine Tool Co., Rockford, Ill.

The bed of this planer is a deep pattern, thoroughly braced by box form cross-girders, and it is further strengthened where the gearing and uprights are mounted. The length is such that there is very little overhang of the table when planing on full stroke. The table is of unusual thickness and the

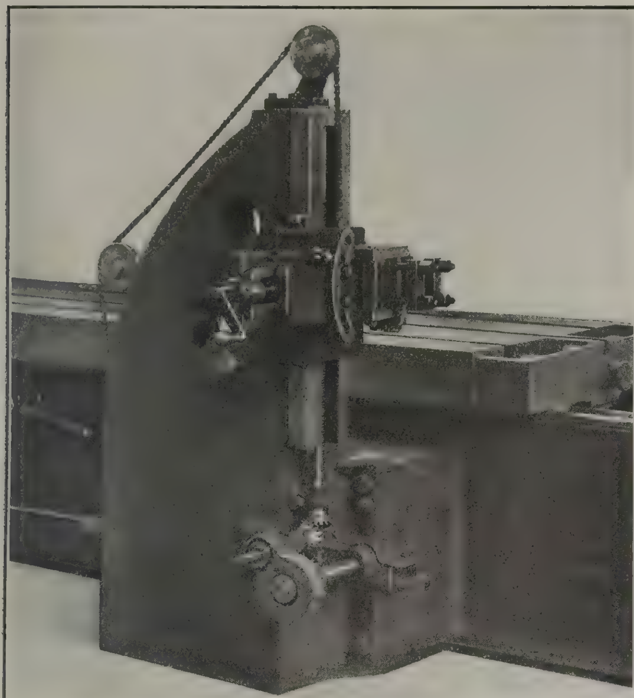

Fig. 3. Auxiliary Housing of Planer shown in Fig. 1

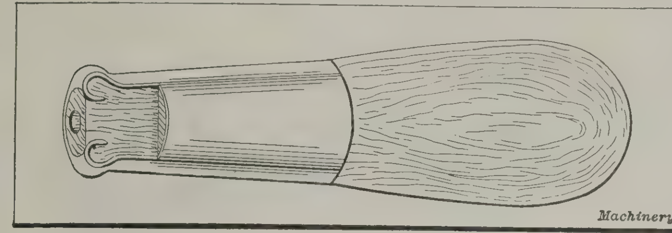
T-slots are exceptionally deep and planed from the solid. The cross-rail is of extra depth, and the down feed to the heads is unusually long. The saddle is graduated in degrees around the entire circle for angular adjustments. The side-heads are provided with vertical, horizonal and angular power feeds, and can be run below the top of the table when not in use. The down feed screws have micrometer dials, which are very convenient for making rapid and accurate adjustments for depth of cut. The shifting device is simple and is designed to transfer the belts quickly and noiselessly. There are shifter levers on both sides of the planer so that the operator can control the motion of the table without walking around the machine. Aluminum driving pulleys are used and all feed racks, pinions, and driving gears are of steel.

REINFORCED FILE HANDLE

The file handle illustrated herewith is a non-splitable type just placed on the market by the Doane Mfg. Co., Boston, Mass. This handle has a heavy pressed-steel ferrule which is enlarged at the end and curved inward as shown by the sectioned part of the illustration. When the ferrule is driven into place the end of the handle is locked within the enlarged or beaded end. These handles are made in five different sizes. The smallest



Non-splitable File Handle

size takes files from 4 to 6 inches, whereas the largest size takes 18- and 20-inch files.

HIGH-SPEED SLOTTING MACHINE

The slotting machine, front and rear views of which are shown in Figs. 1 and 2 respectively, was designed for slotting keyways in milling cutters and small parts such as are used in the manufacture of motorcycles, firearms, typewriters, sewing machines, etc. This machine has a vertical tool-slide and a horizontal work-slide which is gibbed in the body of the machine and serves as a fixture for holding the work. By turning a small handle in the front of the machine, this slide can be removed whenever it is desired to replace it with another slide or fixture especially designed for a given class of work.

The feeding movement, as well as the relieving of the tool, is accomplished automatically by the motion of the work-slide. This slide is advanced for feeding the work to the tool, in intermittent steps between which there is a short reverse motion for withdrawing the work from the tool during the upward stroke. This feeding movement and reverse motion is derived from the tool-slide, which has two lugs on the left side as shown in Fig. 1. These lugs alternately engage a short lever or finger attached to a rockshaft which, in turn, is connected with the feed mechanism by a vertical rod, as shown in the rear view.

The action of the feed mechanism is as follows: When the tool-slide reaches the end of its downward stroke, the upper lug strikes the finger of the rock shaft, thus imparting a vertical reciprocating motion to the rod in the rear. This rod has a cam-shaped end which transmits the motion to a horizontal feed bar and the latter, in turn, gives a reverse movement to the tool-slide for relieving the tool on the upward stroke. When the top of the stroke is reached, the lower lug on the tool-slide engages the finger of the rock shaft and the resulting motion operates a ratchet and pawl mechanism, which, in connection with a screw on the feed bar, serves to advance the work-slide automatically a distance equal to the feed desired.

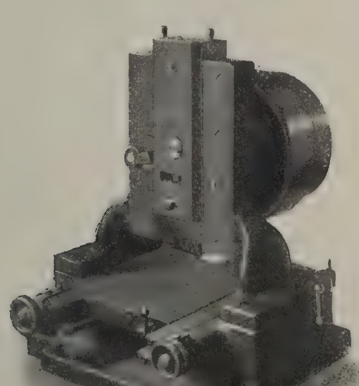


Fig. 1. Slotting Machine built by Swind Machinery Co.

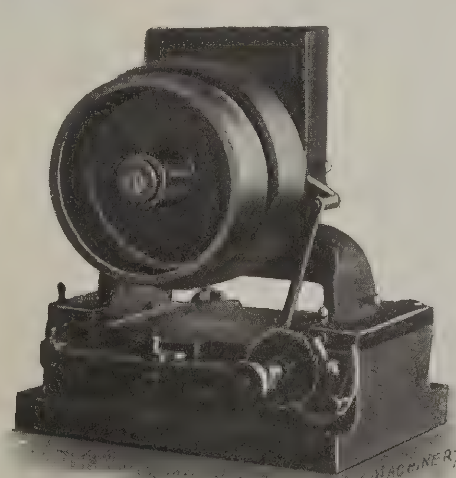

Fig. 2. Rear View of High-speed Slotting Machine

The feed mechanism has an automatic stop which can be set for any predetermined depth of cut and enables parts to be duplicated within close limits. The tool-head or slide is made of steel and is carefully scraped and gibbed. The vertical motion for the slide is obtained from a crank and connecting-rod driven by the two-step cone pulley in the rear. This machine has a capacity for cutting 3/8-inch keyways in cast iron and 5/16-inch keyways in steel. The maximum length of stroke is 2 inches, and a bench space of 16 by 16 inches is required. It is manufactured by the Swind Machinery Co., Bourse Bldg., Philadelphia, Pa.

EXTENSION HACKSAW FRAME

The hacksaw frame shown in the accompanying engraving is a style just placed on the market by the West Haven Mfg.

Co., New Haven, Conn. The back of this frame, instead of being collapsible, is made of a solid piece of 3/4 by 3/16-inch cold-rolled stock, thus eliminating any buckling action. The handle of this new frame is another noteworthy feature. It is

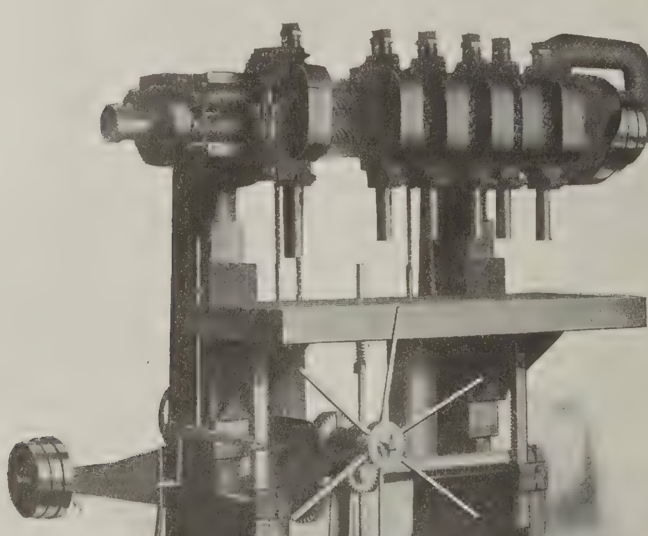
West Haven Mfg. Co.'s Hacksaw Frame

molded from a special composition and is made to fit the hand so as to give an easy, natural grip. The frame is polished and nickel-plated and can be adjusted for blades varying from 8 to 12 inches in length.

MOLINE BORING AND DRILLING MACHINE

The Moline Tool Co., Moline, Ill., has added to its line of drilling machinery a No. 12D heavy type boring and drilling machine adapted for rod boring and similar work. This machine has the double spiral drive which is regularly used by this company, but instead of having the lower spindle bearing vertically adjustable, the spindles run through the lower bearing full size. The lower bearing is bronze bushed and split so that the spindle wear can always be taken up, making in effect a lathe spindle construction. The spindles can be adjusted vertically by means of the upper bearings which are threaded, and they are equipped with ball-thrust bearings.

The heads are planed and scraped to an exact thickness and they can be equipped with tie-rods and spacer washers for setting them accurately to any distance along the rail. This is not necessary, however, for the general run of work, as the heads can be securely clamped in any position. The spindles



Moline Heavy Type Boring and Drilling Machine

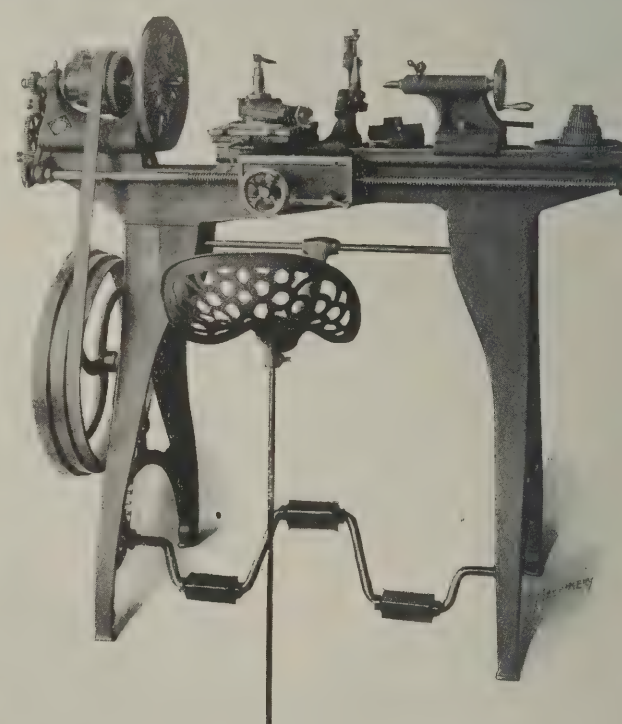
can be furnished with the Morse taper extending entirely below the bearing and with a regular driving slot for moving the drills, or with short hollow spindles so that a knockout rod can be used. In the latter case, the Morse taper extends up into the bearing. The spindle shown at the left is back-geared for extra heavy boring.

As the illustration shows, the cone pulley is provided with an outboard bearing. A plain table having five T-slots is recommended for cast iron work, but for steel a table that has three T-slots and is entirely surrounded by an oil groove, is furnished. In either case, the table is counterbalanced and it is fed by double, steel racks and pinions. The pinions are cut integral with the feed shaft and the latter is driven by steel and phosphor-bronze 4-pitch spiral gears. The table is provided with an automatic trip, a spring down stop and a positive depth gage. The hand feed is back-geared, and for facing operations the automatic trip can be set to disengage slightly ahead of the depth gage, for feeding the table up to the positive depth gage stop by hand. By pulling the pilot wheel out, a quick return is secured for the table.

BARNES NO. 5 GAP LATHE

The W. F. & John Barnes Co., 231 Ruby St., Rockford, Ill., is now manufacturing a No. 5 gap lathe of 11–15-inch swing. The particular lathe shown in the accompanying illustration is equipped with a foot-power drive, but a friction-clutch countershaft can also be furnished for power driving. This lathe is a screw-cutting type and the change-gears provided can be combined for cutting threads ranging from 4 to 40 per inch. In addition, other pitches not given on the index-plate can be cut.

The carriage has a compound rest, and the tailstock is the offset type which permits the compound rest to be set parallel with the bed. The compound table has transverse T-slots for clamping parts that require boring or milling operations. This



Barnes No. 5 Gap Lathe

is a very convenient and valuable feature, especially when the lathe is to be used for a wide range of work. The headstock boxes are accurately fitted to the spindle and provision is made for taking up wear. The spindles of both head- and tail-stocks are of steel and have accurate taper holes for the reception of the centers. The gearing is accurately cut from the solid, and the works are carefully protected from chips and dirt.

The No. 5 gap lathe is made in one style only and with one length of bed. The swing over the bed is 11 inches; over the tool carriage, $6\frac{5}{8}$ inches, and in the gap, 15 inches. The width of the gap from the faceplate is 5 inches, and the maximum distance between the centers, 29 inches. The net weight of the lathe is 500 pounds.

LEBLOND HEAVY-DUTY CONE-TYPE MILLING MACHINE

The R. K. LeBlond Machine Tool Co., Cincinnati, Ohio, has brought out a new line of cone-type milling machines. Figs. 1 and 2 show the side and front views, respectively, of a No. 4 size of the plain type. The distinctive feature of this design is that the machine is essentially right-handed. A study of productive and non-productive movements resulted in placing all the controlling levers on the right-hand side and grouping them for right-hand manipulation. The operator can control

every function of the machine without changing his position, unless the range of a machine is so large as to make this impossible.

The column is a one-piece heavy-ribbed box casting and it is cast integral with the base in order to transmit the strains due to heavy milling through the vertical walls to the base.

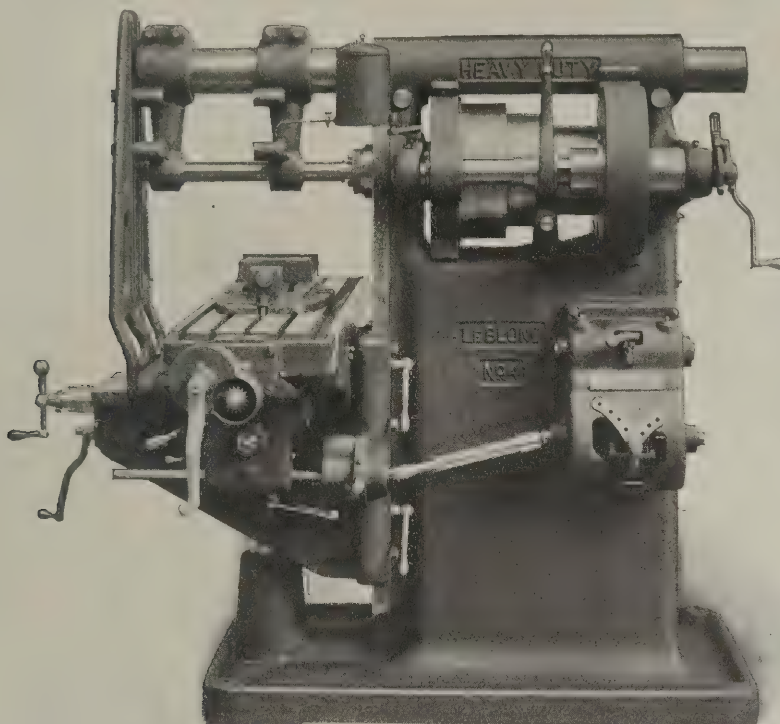


Fig. 1. The Le Blond No. 4 Cone-type Milling Machine

The back-gears are of the double-friction type. They are thrown in and out of mesh by a conventional eccentric shaft arrangement, and are clutched to the back-gear shaft by a powerful friction in the hub of each gear. This friction consists of three parts, *viz.*, a hardened steel double-taper key, a hardened steel plug with an acute taper, and a cast-iron friction ring. When the key is drawn against the plug, the friction ring is expanded in the gear hub. This ring is snapped over the hub to prevent any drag when the clutch is released, so that the lever may be used for starting and stopping. The change from a high to a low ratio can be made while a cut is being taken, and the driving tension can be varied by regulating the pressure on the lever.

The feeding movements are all derived from a single self-contained unit attached to the side of the column. Front and rear views of this feed-box are shown in Fig. 3. The initial drive is from a gear, mounted on the cone so that any change in the driving speed also effects a change in the feeds. The initial shaft is given three speeds; first, with the open belt drive, second, with the low ratio back-gear, and third, with the high ratio back-gear engaged. The feed-box is controlled by the two levers shown. The changes are advanced in small steps by the lower lever, whereas the upper one is used for compounding. Sixteen changes are obtained in the feed-box, and as there are three speeds for the initial driving shaft, a total of forty-eight changes, advancing by small increments, is available. The feeds are inversely proportioned to the speeds, thus obviating speeds that are detrimental to the gear-box. When high spindle speeds are used, the box is driven by a pinion, and when heavy cuts are being taken, thus necessitating large cutters and coarse feeds, the box is driven by a large gear, which increases the speeds about eight times. The gears are all made of crucible steel and they are brought into mesh by peripheral and sliding engagement. The sliding gears have rounded teeth to facilitate meshing, and the tumbler gears have pointed teeth and a heavy root section.

A universal shaft transmits power to the feed trip and reverse box. From this point, motion is imparted to the table through accurately cut spiral gears and spur gears. The feeds are tripped by a single plunger having a direct lever arm action. The trip acts directly on the releasing lever which drops into a neutral position after being tripped. Depressing this lever, feeds the table to the right, and elevating it feeds the table to the left.

The spindle is made of 60-point carbon, crucible steel. For the front bearing, a hardened steel taper bushing is pressed over the spindle and runs in a special close-grained cast-iron box that is drawn into the column by a nut on its rear end. The journals soon become highly polished as the result of contact with the hardened steel spindle, which, in conjunction with the thorough lubrication, reduces the bearing friction to a minimum. The rear bearing is a bronze mixture and has a straight fit in the journal, but is tapered on the outside so that it can be drawn into the column to adjust for wear. There are large cored pockets under each bearing from which the oil is drawn through a piece of felt by capillary attraction. In this way, the bearing is supplied with a flow of filtered lubricant and the flow increases as the speed increases.

The steps of the cone pulley are unusually large in order to use a wide belt operating at rational speeds. The countershaft is so speeded that a shift from high to low is always intermediate to a change on the cone pulley. This enables the countershaft speeds to be kept close together so that on the slow speeds, when the most power is required, the countershaft is operating at a high speed, and maintaining a high belt velocity and high initial torque. This also permits the eighteen spindle speeds to be obtained successively, with but eight belt shifts.

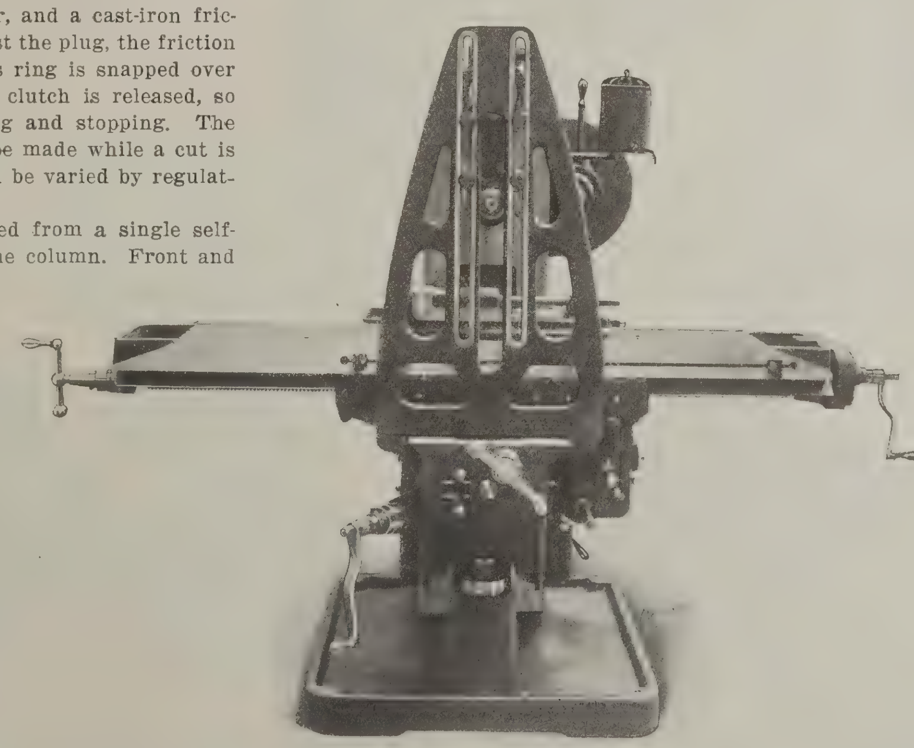

Fig. 2. Front View of Le Blond Milling Machine

The knee is a full box section, ribbed laterally and transversely to resist torsional and collapsing strains. All the openings have been reduced to a minimum and are located so

as not to impair the strength. The ribbing divides the casting into a series of box-section compartments. The cross-feed screw is in the center of the knee so that there are no unbalanced strains. The saddle is a heavy well-ribbed casting that occupies as little vertical space as is consistent with the required rigidity. The design of the saddle is shown in Fig. 4, which is a detailed view with the table removed. The knee and saddle are bound in their respective positions by heavy

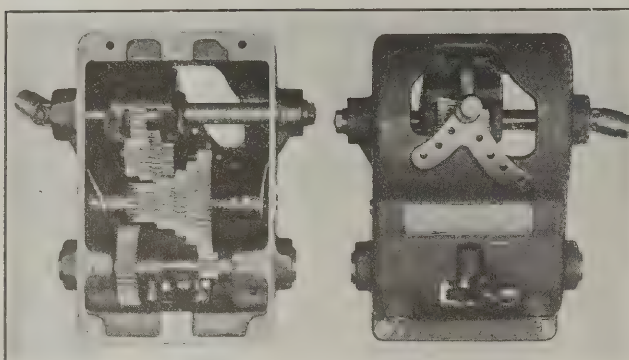

Fig. 3. Feed Mechanism of LeBlond Milling Machine

binder handles. By means of these handles a double-angle gib is operated which draws the parts together against the solid angles and at the same time maintains a continuous metal-to-metal contact.

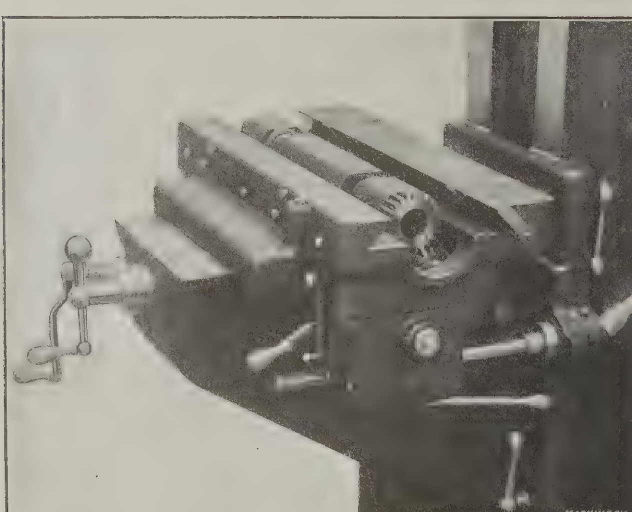

Fig. 4. Saddle and Knee of LeBlond Machine

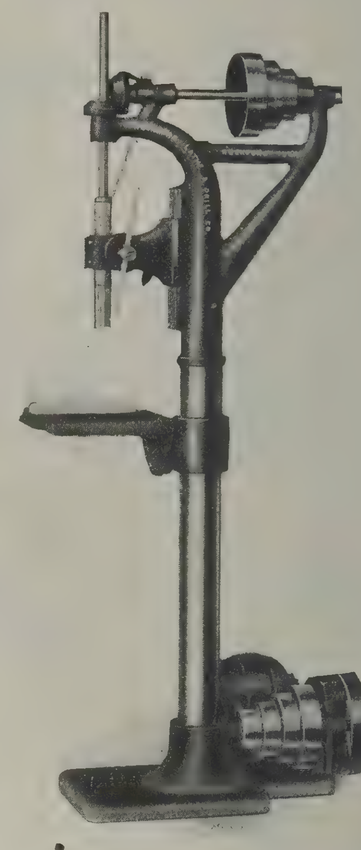
The table is a semi-steel casting, having considerable vertical depth to resist buckling when the work is clamped to it. An oil channel is cast completely around the table and there is a pad at the extreme end for mounting the dividing head. In this way the capacity between centers is increased about eight inches. The feed-screw is cut from a 50-point carbon, crucible steel bar and has a lead of 2/5 inch. The brace, which is clearly shown in Fig. 2, is a solid casting designed to resist the strains to which it is subjected. The overarm is a solid steel bar which is accurately ground to size. This new line of milling machines includes sizes from No. 0 to No. 4, in both plain and universal designs.

ROCKFORD 14-INCH MOTOR-DRIVEN DRILL

The motor-driven drilling machine shown herewith is an improved design brought out by the Rockford Lathe & Drill Co., Rockford, Ill. This machine is driven by a ½-horsepower motor which can be furnished to run on either a direct or alternating current of any required voltage. The power is transmitted to the lower cone pulley through a train of gears containing a rawhide idler which gives a silent drive. There is a tilting table which can be securely clamped at any angle. This feature, in conjunction with an angular bracket on the table, makes it comparatively easy to do many difficult drilling jobs.



Rockford 14-inch Motor-driven Drilling Machine

The spindle is of high-carbon steel, forged and ground. It is fitted with a ball thrust bearing and is counterbalanced either by a weight and chain or a quick-return spring. The distance from the column to the center of the spindle is 7¼ inches; the diameter is ⅞ inch; and the diameter of the sleeve 1⅝ inch. The spindle has a vertical travel of 5½ inches, and the maximum distance from the end of the spindle to the table is 35 inches. The head has a vertical adjustment of 9 inches. The table is 11 inches square. The largest and smallest steps on the cone pulleys have a diameter of 7¾ inches and 3⅝ inches, respectively, and the steps have a face width of 1⅝ inch. The machine has a ¾-inch capacity, and its net weight is 355 pounds.

CLEVELAND FRICTION CLUTCH

The friction clutch shown in the accompanying illustrations is made by the Cleveland Clutch Co., 224 High Ave., Cleveland, Ohio. This clutch is an expanded-ring self-oiling type. The principal advantages claimed for the design are, durability, simple construction, smooth positive action, ease of adjustment, adaptability and high efficiency. In addition, it is dust-proof and oil-tight and is well balanced.

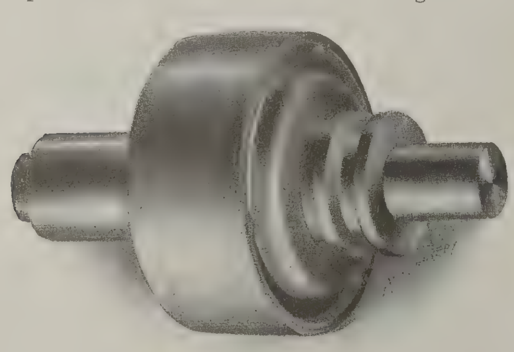


Fig. 1. Cleveland Friction Clutch

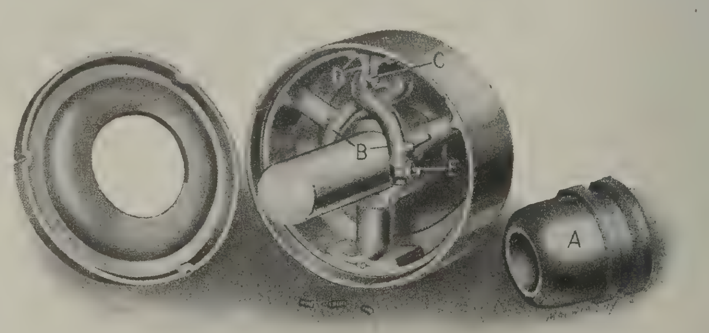

Fig. 2. Interior View of Cleveland Clutch

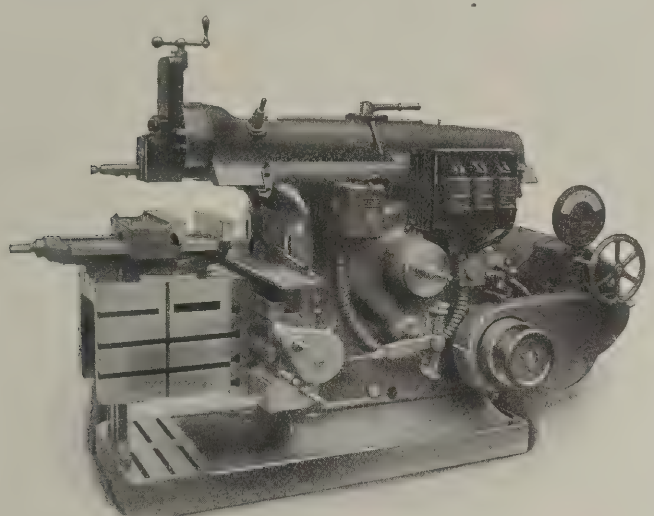
Fig. 2 shows clearly the construction. The spider is keyed to the shaft and the clutch is operated by shifting cone *A*, which engages fingers *B*. The latter are held by a floating center *C*, which causes points *D* to move along the same arc as the friction band. Both casing and spider are made of cast iron. The expansion band is of semi-steel and the fingers are

drop-forgings. The cone is of Bessemer steel and the pins are of casehardened steel.

Provision for easily adjusting the clutches for a given load is made by set-screw and lock-nut *E*. The friction surfaces have metal-to-metal contact and no wood or fiber is used in the construction. A film of oil has to be displaced before the clutch is fully engaged, so that it takes hold gradually but releases instantly. After the clutch is once oiled, it can be operated for months without further attention. It is not affected by centrifugal force and is adapted to either high or low speeds.

GOULD & EBERHARDT 24-INCH SHAPER

Gould & Eberhardt of Newark, N. J., has recently designed a new line of shapers adapted to the heavy work required in steel mills, railroad shops, drop-forging shops, etc. The bull gear of this new design has been raised considerably and it



Gould & Eberhardt Shaper with Variable-speed Motor Drive, Automatic Starter, and Dynamic Brake Control

is a new patented construction. This improved feature is said to greatly increase the mechanical efficiency of the shaper. In addition to this change in the design, there are the following improvements: The outside diameter of the bull gear hub has been increased from 3¾ to 6 inches; there are larger V-bearings, and the gib is so arranged that there is a solid metal-to-metal construction on each side of the ram bearing; the main lever has a solid top; the overhang of the crankpin has been reduced to a minimum; the crankpin thrust is taken by solid walls in the bull gear similar to the ways of the ram; the ratio of the "double-train gear drive" has been increased; the front table support is of heavier design; and the head, ram and frame are of more massive construction.

In the design of the V-gib bearing, which gives a solid metal construction on both sides of the ram, a taper gib is provided having two parts. These can be adjusted independently of each other from the side, near either the front or the back end. This adjustment is in an upward direction between the ram bearing and the solid bearing in the frame, and it is effected by means of set-screws. The arrangement is such that the ram has a solid metal-to-metal bearing for all positions of the adjustable gibs.

In order to determine the relative merits of the V-form of ram, as compared with the square-gib type, a test was made at the University of Michigan with two Gould & Eberhardt shapers, one having the V-ram and the other the square-gib construction. A partial report of this test is as follows:

"The results show the V-form of ram to be superior in all but one of the points investigated. In the horizontal deflections, the square machine has a uniform advantage. In vertical deflections, wear, efficiency and convenience, the V-shaper shows a marked superiority, and it is the author's opinion that a more thorough and exhaustive test would place the V-slide even further in the lead as an accurate, efficient and economical means of transmitting linear motion."

The V-gib of this new shaper has an angle of 55 degrees instead of 45 degrees. This angle was adopted as being better able to withstand the horizontal strains of the ram, without sacrificing the advantages of the V-type bearing for taking the vertical strains. The amount of bearing surface has also been increased in order to further preserve the alignment and accuracy of the ram.

The main lever, instead of having a hole at the top for use when keyseating long shafts, has been made solid to increase the strength, and means are provided for keyseating by placing a hole in one side of the frame, through which shafts up to 3 inches in diameter can be passed. This arrangement is patented. By reconstructing the main bull gear, the overhang of the crankpin, with relation to its distance from the large gear hub bearing in the frame, has been reduced to a minimum. Straps and bolts for holding the crankpin to the large bull gear have been done away with, and solid V-ways similar to the ways of the ram are provided. This forms a solid dovetail bearing for the crankpin, which is superior for taking the strains and thrusts.

The ratio of the double-train gear drive has been increased by giving the shaper a greater initial speed and increasing the ratio of the gearing. This gives more power to the machine when running in single gear or with the back-gear engaged. The ratio of the single gearing is 6.64 to 1; the ratio of the back-gearing, 32.06 to 1.

This shaper weighs 4800 pounds, and is shown in the illustration with a direct-connected, Reliance, variable-speed motor, an automatic starter and dynamic brake control. The horizontal travel of the table is 28¼ inches and the vertical travel, 14 inches. The maximum distance from the ram to the table is 17½ inches and the tool-head has a vertical movement of 8 inches. The vise jaws measure 14½ by 3 inches and the vise has a maximum opening of 16 inches.

NEW BRITAIN AUTOMATIC MULTIPLE SPINDLE CHUCKING MACHINE

The "size 33" automatic multiple spindle chucking machine shown herewith (which is built by the New Britain Machine Co., 64 Bigelow St., New Britain, Conn.) embraces several improvements, and also permits the machining of pieces which heretofore could not be done on this machine. It will be noticed by referring to Fig. 1 that this machine is of the single-head type.

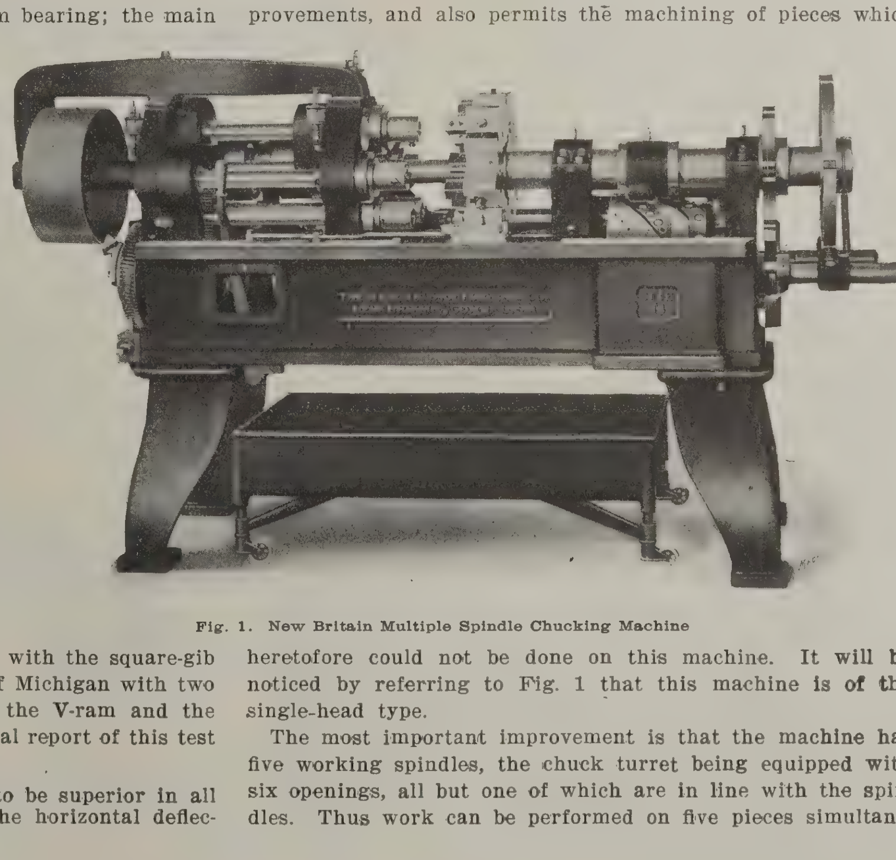


Fig. 1. New Britain Multiple Spindle Chucking Machine

The most important improvement is that the machine has five working spindles, the chuck turret being equipped with six openings, all but one of which are in line with the spindles. Thus work can be performed on five pieces simultane-

ously. If desired, either of the last two spindles can be used plain for reaming, or if fitted with frictions, either or both may be used for threading. As on other machines of this type, the time for completing a piece equals the time required for the longest single operation; and as it is possible to distribute long operations over the different spindles, it will be seen that such operations can be performed in the time required for a comparatively short operation.

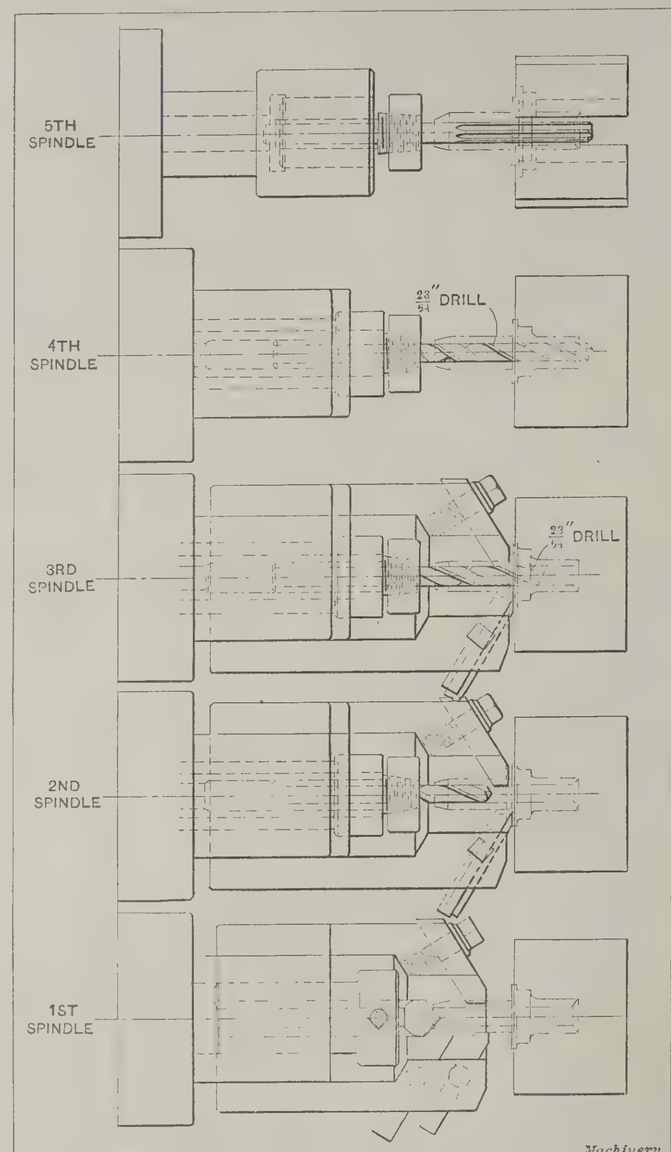

Fig. 2. Example of Work done on New Britain Chucking Machine

On the size 33 machine, an overhead arm has been added which securely ties the two heads together, and, moreover, extends so as to form an outboard bearing for the driving pulley, thus equalizing the belt pull upon both ends of this bearing. It is interesting to note the method used in tying this overhead arm to the two heads, the construction being such that the heads are held rigidly but without subjecting the attaching bolts to a shearing strain. This is done by providing the two bearings of the overhead arm with longitudinal tongues which fit into corresponding slots which have been milled in the two head bearings. In addition, the bolt holes are fitted with hardened steel bushings which extend into the heads and thus protect the attaching bolts from shearing action.

The cam roll yoke which was formerly held in a fixed position on the turret barrel, is now adjustable lengthwise. The yoke runs on a split sleeve which is clamped to the turret barrel by two tangent screws. The advantage of this feature lies in the fact that if it is desired to advance the action of all tools a short distance, it can be done by simply moving the position of the yoke upon the barrel. Formerly it was necessary to move each tool or to change the cam position to secure this result. The size of the turret barrel has been materially increased, thus providing for handling heavier turrets or faceplates with fixtures. The turret bar, or shaft upon which the turret slides as it moves forward, is supported at one end in the head of the machine and at the other in a ground hole in the turret barrel.

A steadyrest of the sliding-key design automatically locks the chuck turret in both directions while the tools are in operation. This steadyrest, which can plainly be seen in Fig. 1, is actuated during indexing by a cam and roll action which is entirely automatic. The faces of the steadyrest are adjustable to compensate for wear, and maintain the accuracy of the machine by supporting the turret chuck near the working position. By supporting the turret at that point, the turret barrel is relieved of all torsional strain and the indexing mechanism from pressure.

The working range of the machine covers pieces requiring a cam stroke of 3¾ inches, and diameters up to 1½ inch can be turned or bored. Larger diameters may be finished when the length of cut is less than the full stroke of the cam.

As an illustration of a typical job which may be handled on the size 33 machine when equipped with high-speed drilling spindles in the No. 2-3-4 spindles, the tool lay-out for a valve stem guide is shown in Fig. 2. These valve stem guides are 3 inches long, the maximum diameter is 1⅜ inch, and they are finished at the rate of 50 per hour. The material is cast iron. It is required to drill and ream a hole 23/64 inch in diameter: chamfer the outside of one end; turn a ⅝-inch diameter for a distance of 1⅜ inch, and face the side of the shoulder adjacent to this turned section. A second chamfering operation is performed on the opposite end of the piece, but this tool lay-out refers simply to the first operation. At the first spindle position, the piece is spot-centered, the end chamfered, and the outside turned for half its length. At the second spindle position, one-third of the length of the hole is drilled, the remainder of the ⅝-inch section is turned and the flange rough-faced. At the third spindle position, another third of the 23/64-inch hole is drilled and the flange is finished-faced. At the fourth spindle position, the remainder of the hole is drilled. At the fifth spindle position, the full length of the hole is reamed thus completing the operations on the piece.

NEW BRITAIN ADJUSTABLE DRAFTING TABLE

The drafting table illustrated herewith is a high-grade design having both vertical and angular adjustments. The front and side views clearly show the construction. The board

New Britain Adjustable Drafting Table

measures 36 by 48 inches and is equipped with a Keuffel & Esser parallel attachment. The board is firmly secured to cast brackets which are pivoted to the vertical supporting mem-

bers. The table is rigidly held in an angular position by tightening the hand lever shown in the view to the right. This lever binds against a segment of the supporting bracket and it is threaded to a long bolt, the head of which clamps the bracket on the opposite side. The table is adjusted vertically by the handwheel shown. This wheel is mounted on a cross shaft having pinions at each end, which engage teeth cut on the supporting legs. This table is a product of the New Britain Machine Co., 64 Bigelow St., New Britain, Conn.

BESLY 53-INCH VERTICAL-SPINDLE DISK GRINDER

A vertical-spindle disk grinder manufactured by Charles H. Besly & Co., Chicago, Ill., is shown in the accompanying illustrations. This machine is intended for "jointing or flatting" such work as stove doors, foundry flasks, meter cases, large gear cases, split shafting bearings, etc., or for other parts which do not have to be ground to a given size or angle. The work is laid on the horizontal disk wheel and is ground by gravity feed. Where work is too light to be ground satisfactorily by its own weight, the practice is to lay on weights. As many parts as the disk wheel will accommodate can be ground simultaneously. As soon as one piece is finished, it is taken off the wheel and immediately replaced by a rough piece. In this way the disk wheel is loaded constantly practically to its limit. When grinding castings for split shaft bearings, as many as thirty five are ground at once, and a laborer attends to the machine.

A hollow exhaust ring extends around the outer edge of the disk wheel for exhausting the grinding dust. This exhaust ring tapers from nothing to about five by five inches at the end where the exhauster is connected. This gradual increase of section is to give a uniform suction all around the disk wheel. The rear view, Fig. 2, shows the exhaust fan and the method of connecting it with the grinder. A removable guard ring which is cast in sections and projects two inches above the grinding face is provided around the disk wheel. This prevents the work from flying off the wheel while being ground, and aids in properly exhausting the grindings. Suitable wooden bars are usually secured to this guard ring as shown, to prevent the work from revolving with the grinding wheel. A section of the exhaust ring twenty-six inches wide, is removable, so that free access may be had to the edge of the disk wheel at this point, for grinding work which may have bosses or lugs projecting beyond the plane of the ground surface. This feature is very desirable, especially on stove work.

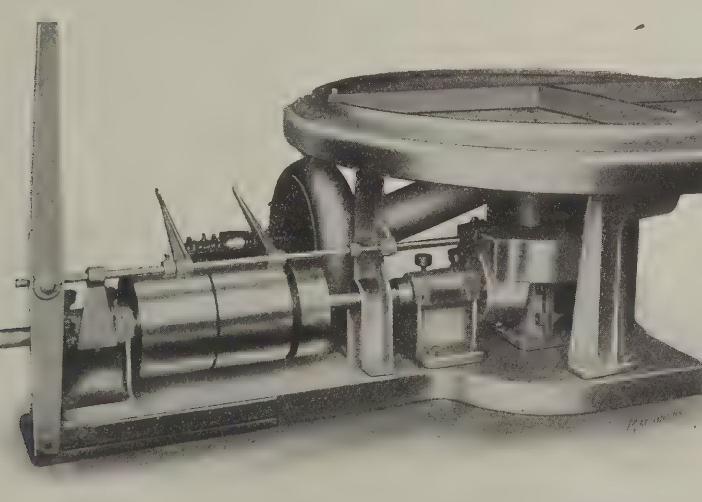

Fig. 1. Besly 53-inch Vertical-spindle Disk Grinder

The disk wheel is of wrought steel, 53 inches diameter by 1¼ inch thick. It is machined on both sides so that both faces of the wheel can be set up with circles. When the circle on one face is worn out, the disk wheel can be turned over and the opposite circle used. The machine is usually furnished with an extra steel disk wheel. A suitable press is also provided so that one wheel can be "set up" while the other is in use on the grinder. In this way the grinder can be operated continuously. The disk wheels weigh 800 pounds each. For convenience in handling, they are drilled and tapped to receive eye-bolts for connecting to a crane or hoist hook. The grinder and press are usually served by a chain hoist suspended from a suitable trolley.

The bevel gears for transmitting power from the horizontal driving shaft to the vertical spindle, are fully enclosed in a cast-iron gear case and run immersed in oil. All bearings are bushed. The tight-and-loose pulleys on the horizontal driving shaft are twelve inches in diameter and take an eight-inch belt. A countershaft is not necessary, as the machine can be driven direct from a lineshaft or motor located above or below it. A suitable pulley for driving the exhauster can be mounted on the horizontal shaft as shown in Fig. 1. The grinder is thirty-four inches high and weighs, complete with two disk wheels and a press, 6000 pounds.

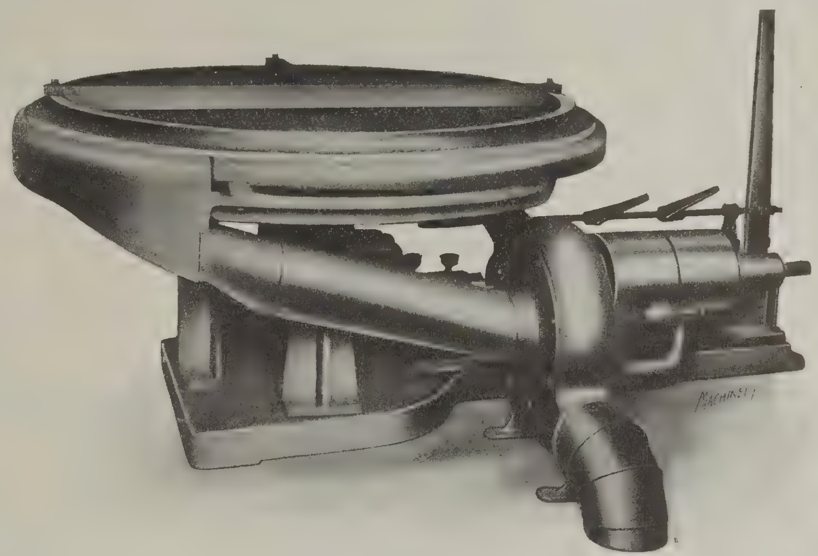

Fig. 2. Rear View of Vertical Disk Grinder, showing Exhaust System

On work for which it is adapted, this grinder is very efficient as is indicated by the following examples. When jointing cast-iron split shaft bearings, this 53-inch grinder does the work six times faster than was accomplished with two milling machines operated by one man. For facing narrow ribs on cast-iron boxes so large that a 53-inch disk wheel accommodates only four boxes at a time, the 53-inch machine does the work twenty times faster than by the profiling process formerly employed. For facing spots on power-pump bedplate castings measuring thirty-three inches by thirty-eight inches and weighing 115 pounds, the vertical disk grinder does the work ten times faster than by the former planing process.

INGERSOLL OPEN-SIDE HORIZONTAL-SPINDLE MILLING MACHINE

The Ingersoll Milling Machine Co., Rockford, Ill., has recently built and installed several open-side horizontal-spindle milling machines of the faceplate drive type. Fig. 2 shows the driving and operating side of this machine, and Fig. 1 is another view showing the machine in operation at the Dean Bros. steam pump works in Indianapolis.

The bed and table of this new design are of the standard planer-type construction. The table has twelve feed changes, and, in addition, a rapid power traverse in either direction, of thirty feet per minute. The feed motion for the table is transmitted through a Sellers rack and worm, the latter being immersed in oil. As the illustration shows, this machine has but

one main upright which is of heavy construction and is further stiffened by the addition of an auxiliary housing placed at right angles.

All the driving and feed gears and also the motor for driving the machine, are assembled upon the main housing. This means that the machine can be entirely controlled from the operator's working position. Perhaps the most interesting mechanical feature of the machine is the saddle. This is an entirely new construction. The main driving gear for the spindle, instead of transmitting the power through the spindle, delivers the full power of the machine directly to the cutter through a hardened steel driving pinion. The function of the spindle, in such a case, is simply that of supporting the driving gear, this being the arrangement when cutters of from 18 to 36

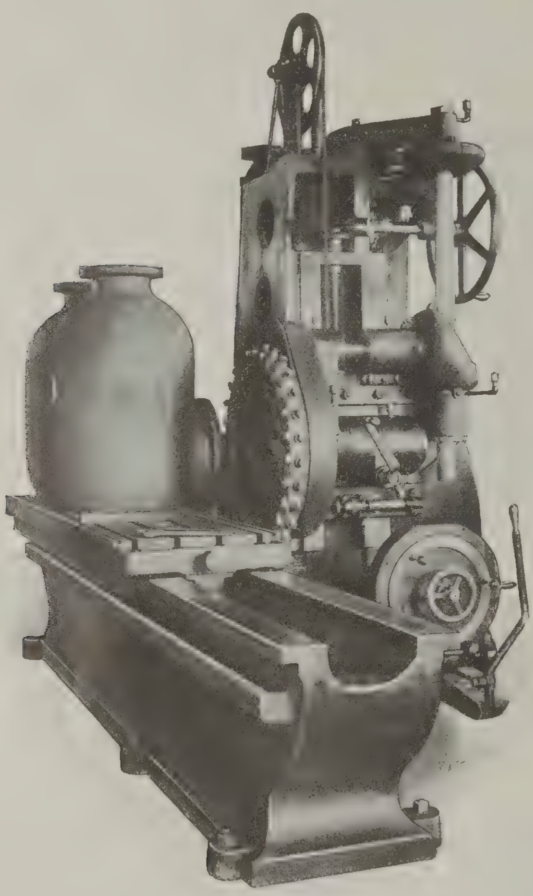

Fig. 1. Ingersoll Machine Milling Flanges of Steam Pump Air Chambers

inches in diameter are used. The cutters of smaller diameter are attached to the spindle by means of a shank and draw-in bolt, and the machine is driven by the main spindle gear.

The saddle has an in-and-out adjustment by hand, and in order to provide a fine adjustment, it is equipped with a patented micrometer stop. This stop gives accurate adjustments for any position within the travel of the saddle, so that cutters as large as 36 inches in diameter can be adjusted to a thousandth of an inch, just as easily as smaller cutters on a small tool-room milling machine.

WINFIELD ELECTRIC WELDING MACHINE

The Winfield Electric Welding Machine Co., of Warren, Ohio, is the manufacturer of the 36-inch spot welder shown herewith. This is a special design particularly adapted to the spot welding of pipe. It has a capacity for stock up to ¼ inch in thickness, and pipes ranging from 3 inches in diameter and up can be welded.

There is a swiveling head and a combination double-pole, non-arcing, automatic switch and circuit cut-out. The one-inch welder points are water cooled. In addition to a hand lever, the machine is equipped with a removable, adjustable foot-treadle having a stop. The transformer has a capacity for 16 kilowatts, and a single-phase alternating current is used. The voltage is regulated by a 10-point, self-contained regulator having an indicating dial at the side of the column, as shown.

Winfield Pipe Spot Welding Machine

This welder has an overhang of 36 inches and a die opening of 3 inches. The distance between the horns is 8 inches. The height from the floor to the center of the dies is 43½ inches. The lower horn is round and has a diameter of 2¾ inches. The welder requires a floor space of 26 by 42 inches, and its net weight is 2100 pounds.

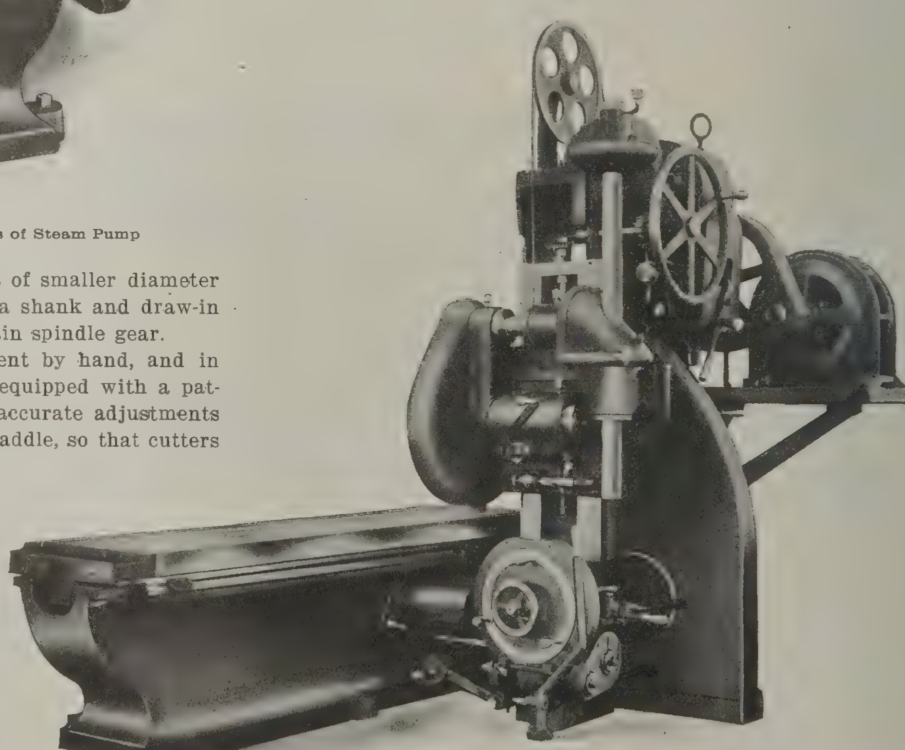

Fig. 2. Ingersoll Open-side Horizontal-spindle Milling Machine

* * *

A hexagon nut should always be used wherever the movement of the wrench is limited.

NEW MACHINERY AND TOOLS NOTES

Die-Stock: J. M. Carpenter Tap & Die Co., Pawtucket, R. I. Die-stock having holes in the handle which act as guides for the work. Twenty-two sizes of dies can be used in one stock.

Spacing Collar: Schuchardt & Schutte, Cedar and West Sts., New York. Adjustable spacing collar intended for spacing straddle mills. It is provided with graduations indicating an endwise movement of 0.002 inch.

Portable Grinder: Chicago Pneumatic Tool Co., Chicago, Ill. Portable pneumatic grinder which weighs 20 pounds and will take an 8 by 1 inch wheel. It is equipped with a grip handle and trigger similar to a pneumatic hammer.

Screw Driver: L. J. Watson, Port Huron, Mich. Screw driver made of spring-tempered steel and having a split end which, when pressed into the slot of a screw, holds the latter firmly while it is being entered into a hole.

Tool-holder: Double Grip Tool Co., Belleville, N. J. Tool-holder in which the cutting tool is held by a set-screw in the usual manner and also by a long gib on the top, which is forced down against the tool by the toolpost screw.

Horizontal Boring Machine: Newton Machine Tool Works, Inc., Philadelphia, Pa. Special machine for boring chords used in the construction of the new Quebec bridge. These chords have sections as large as 7 feet 10 inches, and weigh from 75 to 100 tons.

Belt Idler: Charles Miller, Industrial Bldg., Syracuse, N. Y. This idler is placed beside the driving pulley and has rollers on its periphery so that the belt can be easily shifted on or off. It is intended for use where a belt is not in continuous operation.

Tool-holder: A. O'Keefe & Sons, 353 Mulberry St., Newark, N. J. Combination tool-holder which will take three sizes of tools made of either round or square stock. The cutting tool can be held straight or tilted to the right or left for angular cutting.

Toolpost Grinder: G. Horvath, 190 Hague Ave., Detroit, Mich. Toolpost grinder consisting of an angle-plate which bolts to the tool-slide and carries the spindle head. The latter has a vertical adjustment, and can be arranged for internal as well as external grinding.

Automatic Planer Stops: Lamb Knitting Machine Co., Chicopee Falls, Mass. Two devices for automatically stopping a planer when the tool has reached a predetermined point. One stop operates by disengaging the feed gear, whereas the other shifts the belt on the countershaft.

Saw Sharpening Machine: Newton Machine Tool Works, Inc., Philadelphia, Pa. Automatic saw sharpening machine designed for either solid or inserted-tooth saw blades. The latter type are ground with the teeth in the blades, and the machine is so arranged that the rake of the teeth can be varied to suit conditions.

Multiple-Spindle Drilling Machine: Baush Machine Tool Co., 200 Wason Ave., Springfield, Mass. Multiple-spindle drilling machine designed for drilling bolt holes in steel-tired car wheels. This is an all-geared machine, power being transmitted from the main spindle of the drill through bevel gearing and shafts, instead of universal joints. There are twelve spindles each capable of driving a 1½-inch drill.

Convertible Open-side Planer: Detrick & Harvey Machine Co., Baltimore, Md. Open-side planing machine which may be converted into a double-housing type. The auxiliary housing is attached to the base and also at the cross-rail end by heavy bolts, and it is further secured by pockets in the base and rail end. The auxiliary housing can be quickly removed for work that cannot pass between the two housings.

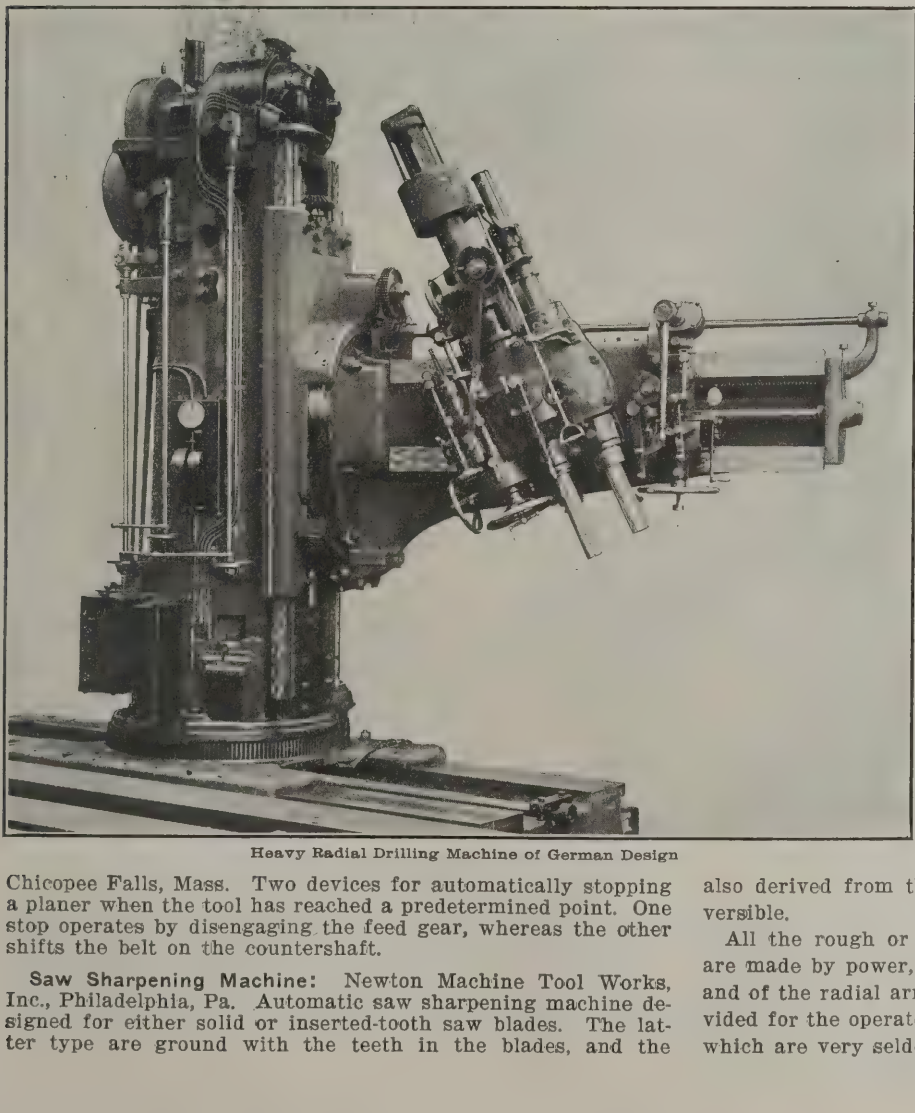
Screw-Plate: A. J. Smart Mfg. Co., Greenfield, Mass. A compact screw-plate which is only about half the size of an ordinary screw-plate of the same capacity. It is known as No. X5 and cuts threads 1/8, 5/32, 3/16, 7/32 and 1/4 inch in diameter. The stock is 5 inches long, and round adjustable dies ⅝ inch in diameter are used. A tap wrench fits into the die-stock, and the entire outfit with a set of plug taps is contained in a neat and compact box.

Cylindrical Boring Machine: Automatic Machine Co., Bridgeport, Conn. Four-spindle vertical boring machine for boring and facing engine cylinders and similar work, ranging from 4 to 10 inches in diameter and having a maximum depth of 24 inches. The time required for boring and facing a cylinder 7½ inches in diameter and 18 inches deep is 1½ hour, but with the four spindles, all of which are in operation part of the time, the actual time per cylinder is less than thirty minutes. The boring is done in four operations, including a roughing cut, a semi-finishing cut and two finishing cuts. This machine was designed for boring cylinders with such precision that grinding would be unnecessary, and also to insure economical production by utilizing the entire time of one operator with a single machine.

* * *

RADIAL DRILLING MACHINE OF GERMAN DESIGN

The accompanying illustration shows a large radial drilling machine built by the firm of Ernst Schiess of Düsseldorf, Germany. It differs in its design considerably from the conventional type of radial drilling machine, it being entirely universal and provided with every possible adjustment; nevertheless, all the operating handwheels and levers remain close to the operator at all times. The main column is mounted on a large base-plate which is provided with ways, about 18 feet in length, on which the column can slide back and forth, this movement being actuated by an electric motor. The inner column of the upright is fixed on the slide and provided with a large spur gear at the bottom which is used for turning the whole machine around. The power for this movement is derived from the main shaft in the horizontal arm. This construction makes it possible to swing the arm through a full circle of 360 degrees.



Heavy Radial Drilling Machine of German Design

An electric motor of 18 horsepower is placed on the top of the upright. This motor is of the variable speed type (400-1200 R.P.M.), the current being carried through a sliding contact in the base-plate. The motor drives, through suitable gearing, a vertical shaft, which, in turn, transmits power to the horizontal shaft located on the arm, both shafts being provided with keyways for their full length. The vertical movement of the slide carrying the radial arm is also derived from the main vertical shaft. The motor is reversible.

All the rough or approximate adjustments of the machine are made by power, while the fine adjustments of the spindle and of the radial arm are made by handwheels and levers provided for the operator on the spindle head. Some adjustments which are very seldom required, like the swinging of the arm

from the vertical plane, or swiveling of the spindle head itself, are effected only by hand through worm and worm-gears.

The spindle is 4 5/16 inches in diameter. From the main spindle a secondary spindle is driven by spur gearing. This is used only for thread cutting. A lever in the front is provided for reversing the motion of this second spindle. The feed is provided for by a gear box giving eight changes. In addition to the power arrangement for swinging the arm around the column, a pawl and ratchet construction is used for obtaining a fine adjustment of the arm. The machine is capable of drilling holes and cutting threads up to 4 inches in diameter in armor plate, using high-speed steel drills. The spindle makes from 2 to 72 revolutions per minute, and the feed varies from 0.0035 to 0.040 inch per revolution of the spindle.

The general dimensions of the machine are as follows: The horizontal movement of the upright along the baseplate, 9 feet 10 inches; maximum height of lower end of spindle over bed, 7 feet 6 inches; minimum height of lower end of spindle, 3 feet 11 inches; maximum distance of spindle from axis of column, 10 feet 4 inches; vertical movement of drill spindle, 22 inches; vertical movement of thread-cutting spindle, 9 inches; distance between spindles, 12 inches; total weight of machine, 45 tons.

* * *

WATSON-STILLMAN CAR COUPLER SHEARING AND RIVETING PRESS

The hydraulic shearing and riveting press shown in Figs. 1 and 2 has been designed by the Watson-Stillman Co., 192

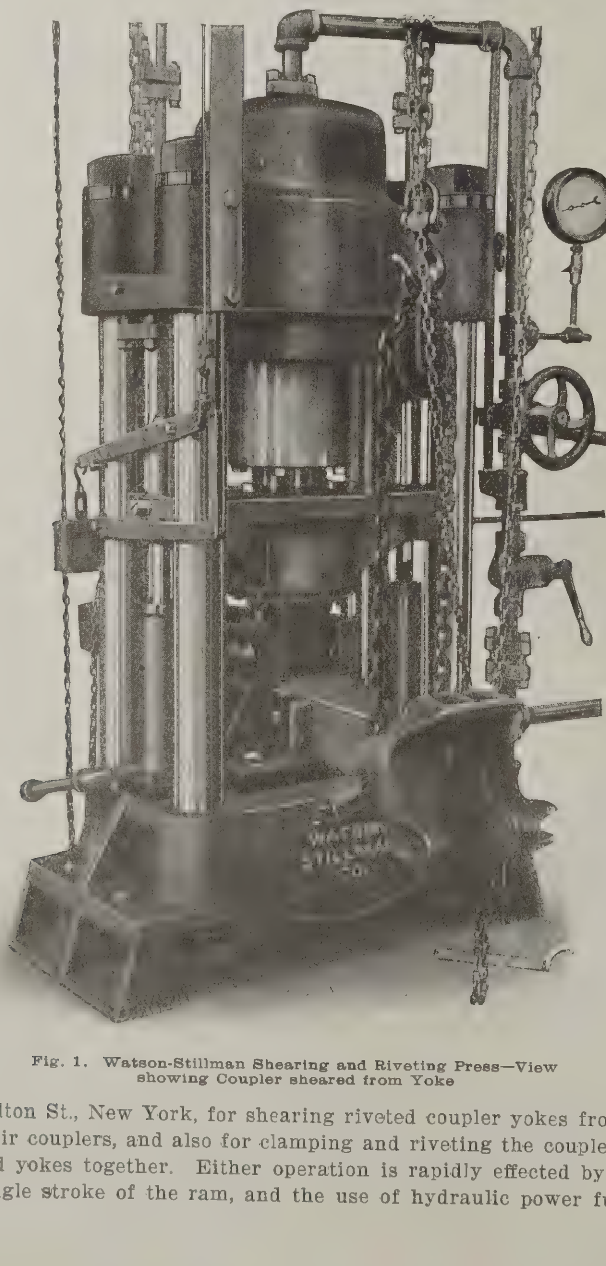


Fig. 1. Watson-Stillman Shearing and Riveting Press—View showing Coupler sheared from Yoke

Fulton St., New York, for shearing riveted coupler yokes from their couplers, and also for clamping and riveting the couplers and yokes together. Either operation is rapidly effected by a single stroke of the ram, and the use of hydraulic power further tends toward economy, as compared with the common practice of doing this work by hand and the pneumatic hammer.

In the operation of the press, the coupler is first sheared from its yoke. The yoke is placed upon supporting blocks which the coupler shank clears, and the ram descends upon the coupler shank, thus forcing it downward and shearing both ends of the rivets. Fig. 1 shows the position of the coupler and yoke after the shearing operation is completed.

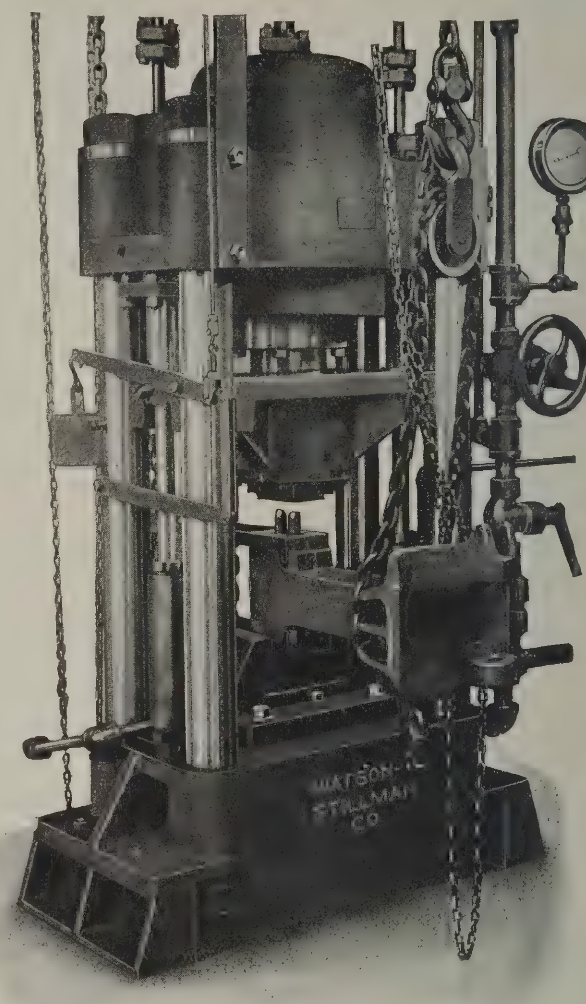

Fig. 2. Coupler and Yoke ready for Riveting

This view also indicates the method of handling the separated parts. Fig. 2 shows the coupler with the yoke and rivets attached and everything in readiness for heading the rivets. The main ram and clamping rams start downward simultaneously, the small rams first clamping the yoke to the coupler shank. The riveting die which is attached to the large ram, then descends upon the rivets and heads them.

This press is built with heavily-ribbed platens and has plenty of room for removing and replacing the work. There are two "push-back" rams for quickly and automatically returning the large ram. The diameter of the main ram is 12 inches and the stroke, 6 inches. The clamping cylinders have 3-inch rams with a 6½-inch stroke, and the push-back cylinders have 1¾-inch rams. The overall height of the press is 6 feet 8 inches; the complete weight 7858 pounds, and the capacity, 200 tons.

* * *

PERSONALS

William L. Wardleigh, formerly superintendent of the Baush Machine Tool Co., Springfield, Mass., is now superintendent of the Electric Goods Mfg. Co., Canton, Ohio.

Lieut.-Col. William S. Peirce of the ordnance department at Washington, D. C., has been appointed commandant of the U. S. Army at Springfield, Mass. Col. Peirce assumes his new duties in September. He succeeds Col. Stanhope E. Blunt.

A. M. Powell, president of the Powell Machine Co., Fitchburg, Mass., left August 6 on the *Franconia* of the Cunard Line from Boston, for an extended trip abroad in the interests of his company, and for the demonstration of the Powell patent high-speed planer.

Albert S. Smith, president of the Smith & Mills Co., Cincinnati, Ohio, shaper manufacturer, returned August 24, having made a trip around the world. Mrs. Smith accompanied him.

Adolph O. Krieger has resigned his position as publicity manager of the Busch-Sulzer Bros. Diesel Engine Co., St. Louis, Mo., with which he had been connected for a number of years, and has opened an office at 916 Victoria Bldg., St. Louis, for the sale of the Tacchella oil burning device.

C. J. Nyquist, superintendent of the Davis-Bournonville Co., was given a dinner by the New York officers and members of the sales force, and employes of the Jersey City shops, at Myers Hotel in Hoboken, July 17, Mr. Nyquist having returned from abroad the previous day. His trip abroad was made in the interests of his employers. He visited several cities in Germany, Denmark and France, investigating the progress being made in oxy-acetylene welding.

* * *

OBITUARIES

Harold R. Walker, secretary of the Union Caliper Co., Orange, Mass., died at his home, July 24.

Emil Von Wyck, of the Von Wyck Machine Tool Co., Cincinnati, Ohio, died suddenly in his office, July 11, aged forty-seven years.

Baxter B. Noyes, senior member of the firm of B. B. Noyes & Son, Greenfield, Mass., manufacturers of hardware specialties, small tools, blacksmiths' machinery and iron castings, died July 22, aged sixty-eight years, as the result of an accident, Mr. Noyes having fallen from a staging in the factory.

Joseph LeConte Davis, engineer in charge of design of direct-current railway type motors in the electric railway department of the Westinghouse Electric & Mfg. Co., recently deceased, was a graduate from the University of South Carolina in 1897 with the degree of electrical engineer. He was professor of physics at Bingham Academy High School, North Carolina from 1897 to 1900, and in 1904 was employed by the General Electric Co., Schenectady, N. Y. He was also at one time in charge of the developments of the National Electric Signalling Co., which embraces the Fessenden wireless system. Since 1904 Mr. Davis was with the Westinghouse Electric & Mfg. Co. He was regarded as one of the brightest and most promising of the younger electrical engineers of the present day. His work in connection with the design of the direct-current motors used on the Pennsylvania terminal electrification in Greater New York and many other large installations brought him into prominence before the electrical profession.

Charles A. Haney, vice-president and general manager of the Sloan & Chace Mfg. Co., Ltd., Newark, N. J., died after a brief illness August 10. Mr. Haney was born in Brooklyn, N. Y., July 27, 1867. He started to learn his trade with George Griswold, New Haven, Conn., at the age of fourteen years. From this time and until he became connected with the Sloan & Chace Mfg. Co. he was employed by a number of different manufacturing concerns as toolmaker, foreman and assistant superintendent. Among these concerns may be mentioned the Yost Typewriter Co., Bridgeport, Conn., the Mergenthaler Linotype Co., Brooklyn, N. Y., and the S. S. White Dental Mfg. Co., Staten Island, N. Y. At one time he was employed by Thomas A. Edison on making the early models of the phonograph. In 1902 he became general manager, vice-president and principal owner of the stock of the Sloan & Chace Mfg. Co. Through Mr. Haney's efforts and untiring energy the plant of this company was remodeled, new machinery replacing the older types, and the business grew considerably in volume, necessitating, in 1906, new and more spacious quarters. Mr. Haney was the inventor of a cyclometer and a typographical numbering machine. His unusually varied experience enabled him to successfully handle all kinds of mechanical problems. He was a member of the National Metal Trades Association, the National Machine Tool Builders' Association, and the Newark Board of Trade, as well as of a number of other organizations. He is survived by a wife and two children.

* * *

COMING EVENTS

September 2-7—Sixth congress of the International Association for Testing Materials at the Engineering Societies Building, 29 W. 39th St., New York. H. F. J. Porter, secretary, 1 Madison Ave., New York.

September 9-11.—Ninety-third meeting of the National Association of Cotton Manufacturers at the Griswold, Eastern Point, New London, Conn. C. J. H. Woodbury, secretary, Boston, Mass.

September 24-26.—Annual convention of the American Foundrymen's Association and allied bodies, in Buffalo, N. Y.; Hotel Statler, headquarters. Richard Moldenke, Watchung, N. J., secretary.

September 30-October 4.—Autumn meeting of the Iron and Steel Institute at Leeds, England. G. C. Lloyd, secretary, 28 Victoria St., London.

October 4-26.—International Machinery Exhibition at Olympia, London, England, organized by the Machine Tool and Engineering Association, Ltd.

October 7-11.—Annual convention of the American Electric Railway Association and allied associations in Chicago, Ill. The exhibit will be at Dexter Pavilion, 43d and Halstead Sts. H. C. Donecker, secretary-treasurer, 29 W. 39th St., New York.

October 16-18—Annual convention of the National Machine Tool Builders' Association in New York; headquarters, Hotel Astor. James H. Herron, general manager, Cleveland, Ohio.

SOCIETIES, SCHOOLS AND COLLEGES

NEWBERRY COLLEGE, Newberry, S. C. Catalogue for 1911-1912, containing 80 pages, 6 by 9 inches, of information relating to the departments and courses of instruction of the college. The catalogue is illustrated with a number of halftones showing the various buildings, as well as interior views.

AMERICAN SOCIETY OF SWEDISH ENGINEERS, 271 Hick St., Brooklyn, N. Y., announces two lectures for its meetings during September. On Sept. 7 at 8:30 P. M., Mr. L. Pelletier, advertising representative of MACHINERY, will speak on "Advertising in Its Relation to Engineering." On September 21, Mr. C. J. Nyquist, superintendent of the Davis-Bournonville Co., will speak on "Oxy-Acetylene Welding and Its Applications." Mr. Nyquist will be assisted by a demonstrator who will show the oxy-acetylene welding and cutting apparatus in action.

NATIONAL METAL TRADES ASSOCIATION, New England Bldg., Cleveland, Ohio. Pamphlet entitled "Industrial Betterment Activities of the National Metal Trades Association." The pamphlet outlines the history of the society and its constructive activities along the lines of industrial education, apprenticeship systems, cooperative profit-sharing plans, safety appliances, hygiene and sanitation, systematic compensation for industrial accidents, legislation, extension of transportation facilities and local branches and employment bureaus. It should be of interest to manufacturers generally, whether members of the association or not.

IOWA STATE COLLEGE, Ames, Iowa, announces that two new scholarships have been established in agricultural engineering, one being founded by the M. Rumely Co., of Laporte, Ind., and the other by the International Harvester Co., of Chicago, Ill. These scholarships are intended for young men qualified to do special research work along the lines of agricultural engineering, and amount to $250 a year each. They were established at the Iowa State College on account of the fact that this college was the first to institute a four-year course in agricultural engineering, and because instruction in this branch of engineering has been most highly developed at this college.

AMERICAN SOCIETY OF ENGINEER DRAFTSMEN, 116 Nassau St., New York, held its regular monthly meeting in the Engineering Societies Building, Thursday, August 15. A paper was read by Mr. W. T. Walters of Chicago, on "Safety Devices—Their Application and Design." Prof. Charles W. Weick of Columbia University spoke on "Practical Perspective," and the question of whether to place dimension figures on drawings perpendicular to the bottom of the drawing or perpendicular to the dimension line was discussed. The general opinion seemed to be that the figures should be placed perpendicular to the dimension line. The American Museum of Safety, which adjoins the society's meeting room, was thrown open for the evening to members and visitors, and an opportunity was afforded to inspect the collection of the museum.

NEW BOOKS AND PAMPHLETS

REPORT OF THE COMMISSIONER OF EDUCATION FOR THE YEAR ENDED JUNE 30, 1911. Volume II. 1407 pages, 6 by 9 inches. Published by the Department of the Interior, Washington, D. C.

THE PHYSICAL TESTING OF ROCK FOR ROAD BUILDING. By Albert T. Goldbeck and Frank H. Jackson. 96 pages, 6 by 9 inches. Published by the U. S. Department of Agriculture, Washington, D. C.

RAILROAD OPERATING COSTS. By Suffern & Son. Volume II. 144 pages, 8 by 11 inches. Published by Suffern & Sons, New York. Price $2.

This volume includes the reports on the operations of railways for 1911, and comprises a continuation of studies in operating costs of the leading American railroads, undertaken by the authors. The book is divided into eight chapters, of which the first is of a general introductory character; the second deals with the maintenance of way and structures; the third with maintenance of equipment; the fourth with freight car maintenance; the fifth with locomotive maintenance; the sixth with passenger car maintenance; the seventh with transportation expenses; and the eighth with fuel. The last chapter gives exhaustive information about the cost and amount of fuel required under various conditions.

HENDRICKS' COMMERCIAL REGISTER OF THE UNITED STATES. 1574 pages, 7½ by 10 inches. Published by S. E. Hendricks Co., New York. Price, $10.

This is the twenty-first annual edition of this most useful book for buyers and sellers in the architectural, mechanical engineering, contracting, electrical, railroad, iron, steel, hardware, mining, milling, quarrying, exporting and kindred industries. The aim of the book is to furnish a complete classification list of manufacturers of various products for the benefit of those who want to buy as well as for those who want to sell. It contains over 350,000 names and addresses of manufacturers and dealers, arranged under nearly 40,000 business classifications. One of the main features of this book is the complete index of classifications included, which covers 122 pages with about 350 classifications on each page. The most important and valuable feature of this commercial register, outside of its unusual completeness, is the simplicity of its classifications, making it possible to locate a manufacturer of any product very quickly. Another valuable feature is that the trade names of all articles classified in the book have been included as far as it has been possible to secure them. These trade names appear in parentheses between the names and addresses of the manufacturers under the classifications where they appear. The new edition has been considerably enlarged, an addition of 155 pages having been made. As there are 230 pages of concellations, etc., omitted from the present edition, there is a total of 385 pages of new matter. The book should prove very useful to any business firm who has dealings with manufacturers or dealers in any of the lines mentioned above.

NEW CATALOGUES AND CIRCULARS

STANDARD MFG. CO., Bridgeport, Conn., manufacturer of gear cutting machines, has issued a new catalogue.

EMERSON ELECTRIC MFG. CO., St. Louis, Mo. Bulletin No. 3711 on laboratory lathes for alternating and direct currents.

TEMCO ELECTRIC MOTOR CO., 99 Sugar St., Leipsic, Ohio. Folder showing applications of the Temco portable electric drill.

L. S. STARRETT CO., Athol, Mass. Booklet descriptive of the Chicago store of the L. S. Starrett Co., illustrated with halftones.

BAUSCH & LOMB OPTICAL CO., Rochester, N. Y. Catalogue describing large photomicrographic apparatus for laboratory work.

BOSCH MAGNETO CO., 223-225 W. 46th St., New York. Catalogue describing the Bosch magneto ignition for one-cylinder motor-cycles.

CONTENTS FOR SEPTEMBER

The first column of page numbers applies to the Engineering and Railway Editions; the second to the Shop Edition.

Kerr Turbine Co., Wellsville, N. Y. Bulletin No. 26 describing the "Economy" steam turbine. Steam consumption curves are shown and size comparisons made.

Fulton Machine & Vise Co., Lowville, N. Y. 1912 catalogue of vises and centrifugal pumps. The catalogue illustrates and describes the Star, Peerless, F. & R., and Fulton types of vises.

Beaudry & Co., 141 Milk St., Boston, Mass. Catalogue of "Beaudry" power hammers comprising the Beaudry Champion, 50- to 500-pound rams, and the Beaudry Peerless, 25- to 200-pound ram.

Sprague Electric Works of General Electric Co., 527-531 W. 34th St., New York. Bulletin No. 902 describing and illustrating Sprague electric grab-bucket cranes, and showing examples of their use.

Gould & Eberhardt, Newark, N. J. Circular illustrating and describing the "Invincible Type" 24 inch shaper, designed to take care of extra heavy work required in steel mills, railroad shops and drop forging die shops.

American Stoker Co., 11 Broadway, New York. Bulletin B-1, entitled "The Class 'E' Stoker," illustrating and describing in detail the devices made by the company for obtaining high efficiency in the burning of coal.

Triumph Electric Co., Cincinnati, Ohio. Bulletin No. 491, describing direct-current steel frame motors. The construction of the various parts is shown in detail, and instructions for starting and operating electric motors are given.

Crocker-Wheeler Co., Ampere, N. J. Bulletin No. 153 on direct-current lighting and power generators from 200 to 1500 kilowatts; Bulletin No. 154 on oil insulated, self-cooled and water-cooled power transformers from 50 to 5000 KVA.

Gilbert & Barker Mfg. Co., Springfield, Mass. Catalogue B of gas furnaces, showing various types of furnaces built by the company, and giving information regarding the work for which they are adapted and tables of dimensions and capacities.

Autogenous Welding Equipment Co., 41 Bay St., Springfield, Mass. Circular containing a reprint from *The Locomotive* of an article entitled "Autogenous Welding for Repairing Boilers," together with additional material on autogenous welding.

Crocker-Wheeler Co., Ampere, N. J. Bulletin No. 149, illustrating and describing direct-current motors and generators of 50 horsepower and larger. Details of the magnet frame, bearing brackets, armature laminations, armature and armature core are shown.

Fort Wayne Engineering & Mfg. Co., Fort Wayne, Ind. Catalogue No. 2022 illustrating and describing the "Paul" non-storage system of water supply, pumping water direct from well; Catalogue No. 2023 on "Paul" pneumatic systems of water supply.

Standard Electric Tool Co., Cincinnati, Ohio. Bulletin G-5 on Standard high-power small portable electric grinders, including tool-post electric grinders, parallel grinders and bench grinders; Bulletin No. D-6 of Standard high-power ball-bearing electric drills.

American Blower Co., Detroit, Mich. Bulletin No. 324, "The 'A B C' High-pressure Exhaust Fan, Type P"; Bulletin No. 344, "The 'A B C' Cast-iron Blowers and Exhaust Fans, Type V"; Bulletin No. 347, "Unit Heaters," adapted to all types of factory buildings.

Industrial Instrument Co., Foxboro, Mass. Bulletin No. 67 of differential recording gages. The bulletin shows the application of the instrument to boilers; reproductions of records made by it are included, as well as a table giving general dimensions of the device.

General Electric Co., Schenectady, N. Y. Lithographic poster in colors showing, full size, all the Edison "Mazda" lamps made by the company. The "Mazda" lamps range in capacity from 5 watts (for signs) to 500 watts (used for street lighting, railway terminals, etc.).

Hess-Bright Mfg. Co., 17 E. Erie Ave., Philadelphia, Pa. Data sheets: No. 47A, Thrust Collar Bearings; No. 59A, Driving Clutch Thrust Bearings; No. 82, Ball Bearings in Horse Vehicles; Nos. 83, 84 and 85, Ball Bearing Mountings for Vertical Armature Shafts of Electric Motors.

A. J. Kelting Engineering Works, 459 Carroll St., Brooklyn, N. Y. Catalogue entitled "Positive Pressure Blowers," containing a comparison of the different methods of moving air for high, low and intermediate pressures, and a complete description of the Kelting pressure blowers.

Watson-Stillman Co., 192 Fulton St., New York. Catalogue No. 87 describing and illustrating hydraulic coupler yoke shearing and riveting press. This type of machine shears riveted coupler yokes from their couplers or clamps and rivets the couplers and yokes together with a single stroke of the ram.

Dayton Pump & Mfg. Co., Dayton, Ohio. Bulletin No. 15 illustrating and describing duplex double-acting power pumps and water supply systems for service conditions where the vertical suction lift does not exceed twenty feet. These pumps are built in twelve sizes, with capacities from 3 to 60 gallons per minute.

Eugene Dietzgen Co., 214-220 E. 23rd St., New York. Circular of the "Premier" ellipsograph for drawing ellipses and circles. The instrument is adapted for either pen or pencil work and is useful for draftsmen on cams, wheel spokes, apertures, projections, etc.; also circular of the "Dietzgen" fountain ruling pen.

Ingersoll-Rand Co., 11 Broadway, New York. Bulletin No. 8007 illustrating and describing "Little David" pneumatic drills adapted for general drilling, reaming, tapping, flue rolling and wood boring. Illustrations showing the valve action of the drill are included, as well as several halftone illustrations showing the drill in actual use.

Winter Bros. Co., Wrentham, Mass. Catalogue No. 7 of high-speed steel taps and dies. This catalogue contains, in addition to price lists of taps and dies, considerable valuable information relating to tapping and threading, brief, concise paragraphs on such subjects as the size of taps, lead, speed of operation, lubrication, form of cutting edges, etc., being included.

Bullard Machine Tool Co., Bridgeport, Conn. Circular V-21 illustrating and describing the turret head of the Bullard vertical turret lathe. The illustrations show the construction of the turret in detail, giving the names of the various parts and describing the features of the new turret design and its advantages. An interesting record of tests for the accuracy of indexing and registry is included.

Gould & Eberhardt, Newark, N. J. Catalogue of high-duty automatic gear hobbing machines for spur, helical and worm gears. This catalogue contains a complete description of the design and operation of the Gould & Eberhardt automatic gear hobbing machines, as well as illustrations and specifications of the four sizes of machines built, ranging from 12 by 10 inches to 36 by 14 inches capacity.

E. Horton & Son Co., Windsor Locks, Conn. 1912 catalogue of lathe chucks, faceplate jaws, and drill chucks. This catalogue contains illustrations and descriptions of all the chucks designed and made by the S. E. Horton Machine Co., and the E. Horton & Son Co., which are now made by the consolidated company known by the latter name. The catalogue covers a wide line of independent, universal and combination chucks, two jaw chucks, drill chucks, and planer chucks.

Cleveland Hardware Co., Cleveland, Ohio. Safety poster in English and German illustrating hospital room, caring for an emergency case, safety device for trimming presses, danger from carelessly operated trucks, lineshaft dangers; danger to female operators running drill presses, etc. The poster carries blanks to be torn off and filled out by employes whenever defects in machinery or conditions injurious to health are noted; also reports of accidents when workmen are injured.

Ingersoll-Rand Co., 11 Broadway, New York. Catalogue form 75 entitled "Water Lifted by Compressed Air." During recent years considerable progress has been made in the development of compressed air pumping apparatus. The air lift has been found especially useful for asylums, hospitals, plantations, railway water tanks, etc. The catalogue describes the various methods employed for utilizing air for lifting water, and gives figures showing cost of operation of various installations.

New Britain Machine Co., 64 Bigelow St., New Britain, Conn. Catalogue of multiple-spindle automatic chucking machines. This catalogue contains 38 pages, 9 by 12 inches, describing in detail the main features of the New Britain automatic multiple-spindle chucking machines. It is profusely illustrated with both halftones and line engravings and contains specifications and tables of capacities of the various sizes of these machines, as well as illustrations of the work for which these machines are peculiarly adapted.

Westinghouse Electric & Mfg. Co., East Pittsburg, Pa., Circular No. 1516 illustrating and describing Baldwin-Westinghouse electric locomotives; Circular No. 1524 describing switchboard indicating meters; Leaflet No. 2494 describing synchronous booster rotary converters; Leaflet No. 2499 describing commutating-pole direct-current motors; Leaflet No. 2480 containing rules for the selection of machine tool motors; Leaflet No. 3505, on motors for paper mill service; Leaflets Nos. 2465 to 2471, on various kinds and types of meters.

Whitman & Barnes Mfg. Co., Akron, Ohio. Catalogue No. 82 of twist drills, reamers, drop-forged and screw wrenches, spring cotters, flat spring and riveted keys and drill chucks. This catalogue comprises 170 pages, 6 by 9 inches, and covers completely the extensive

line of machinists' supplies manufactured by the company. Directions for drill grinding are included, as well as a number of useful tables giving speed and feed of carbon and high-speed steel drills, etc. A novel feature of the catalogue is that the prices of carbon and high-speed steel drills are given side by side on the same page, the latter being printed in red.

NEWTON MACHINE TOOL WORKS, INC., 24th and Vine Sts, Philadelphia, Pa. Catalogue No. 47 of cold saw cutting-off machines. This catalogue comprises 95 pages, 6 by 9 inches, devoted exclusively to cold saw cutting-off machines. In addition, a number of pages are inserted showing halftone illustrations of other lines of machine tools built by this company. The catalogue contains information relating to cutting compounds to be used with the machines described, and on the speed and feed to be used for various materials. The types of machines illustrated and described are as follows: Bar type saw; I-beam saws; internal cold saw cutting-off machines: combination type saw; crankshaft saw; girder rail saw; duplex type saw; steel foundry type saw; armor plate saw; and multiple cold saw cutting-off machines. In addition, the catalogue illustrates independent and automatic saw sharpening machines.

TRADE NOTES

AMERICAN EMERY WHEEL WORKS, Providence, R. I. Program of the second annual outing of the employes, held at Emery Park, Auburn, R. I., Saturday, June 22.

WELLS BROS. CO., and WILEY & RUSSELL MFG. CO., Greenfield, Mass. Program of the first annual field day of the employes of these two companies at Island Park, Brattleboro, Vt., Saturday, August 3.

Gisholt Grinder is the name of a publication issued by the employes of the Gisholt Machine Co., Madison, Wis. It is published and edited entirely by the employes of the company, and contains personal items and announcements of interest to those connected with the concern.

J. N. LAPOINTE CO., Marlboro, Mass., builder of broaching machinery, will move to New London, Conn., on October 1. A factory of concrete and brick construction, two stories high, with an ell extension, which will provide a total floor space of 20,000 square feet, is now being built.

VULCAN ENGINEERING SALES CO., Chicago, Ill., has taken the selling agency for the line of structural and plate working machinery, punches, shears, rolls, bulldozers, etc., manufactured by the Rock River Machine Co., Janesville, Wis. In addition to this line, the Vulcan Engineering Sales Co. now controls the product of the Hanna Molding Machine Works, the Mumford Molding Machine Co., and the Q. M. S. Co.

NEW DEPARTURE MFG. CO., Bristol, Conn., is building additions to its factory, which will increase the present floor space by nearly 75,000 square feet. The new additions will be available for use late in the fall of the present year. This increase in manufacturing facilities has been necessitated by the fact that the plant is at present running 127 hours a week in all departments and 152 hours a week in some departments, in order to meet the demands of the market.

DAVIS-BOURNONVILLE CO., 97 West St., New York, used oxy-acetylene cutting torches for cutting away the wrecked steel in the crushed bow of the Fall River Line steamship *Commonwealth*, which has been in dry dock at Hoboken since her recent collision with the United States battleship *New Hampshire* in Long Island Sound. The cutting required the time of several operators for two days but the oxy-acetylene torches made short work of what would otherwise have been a much more difficult task.

SETTING THE WALSCHAERTS VALVE GEAR*†

PRACTICE IN ERECTING DEPARTMENT OF BALDWIN LOCOMOTIVE WORKS

THE advantages of the Walschaerts valve gear, as compared with the Stephenson link motion, are familiar to railway machinists, but comparatively few understand how the Walschaerts gear is set. This may be due to the fact that this gear does not need to be adjusted very often, because it is constructed to "stay put" when the locomotive is assembled, and the shop men have little to do with it afterwards. Furthermore, comparatively little has been written on this type of valve gear, whereas countless articles and many books have been published on the Stephenson motion. This article explains briefly the practice followed at the Baldwin Locomotive Works in setting the Walschaerts gear.

The complete mechanism consists of the following parts: Valve *A*; valve stem *B*; combining lever *C*; crosshead link *D*; radius-rod *E*; reverse shaft *F*; lifting link *G*; reach-rod *H*; reverse lever *K*; reverse link *L*; eccentric rod *M*; and eccentric crank *N*. The motion is of the radial type. Link *L* is trunnioned at its center and is rocked by means of eccentric rod *M* which derives its motion from return-crank *N* secured to the main crankpin. The movement of the link is transmitted to valve stem *B* by radius-rod *E* having a length equal to the link radius. This radius-rod is pinned to a sliding link-block and can be raised or lowered by the reverse lever *K*. When the block is above the link center, the engine runs in one direction, and when it is below the center, the motion of the engine is reversed, as will be explained subsequently.

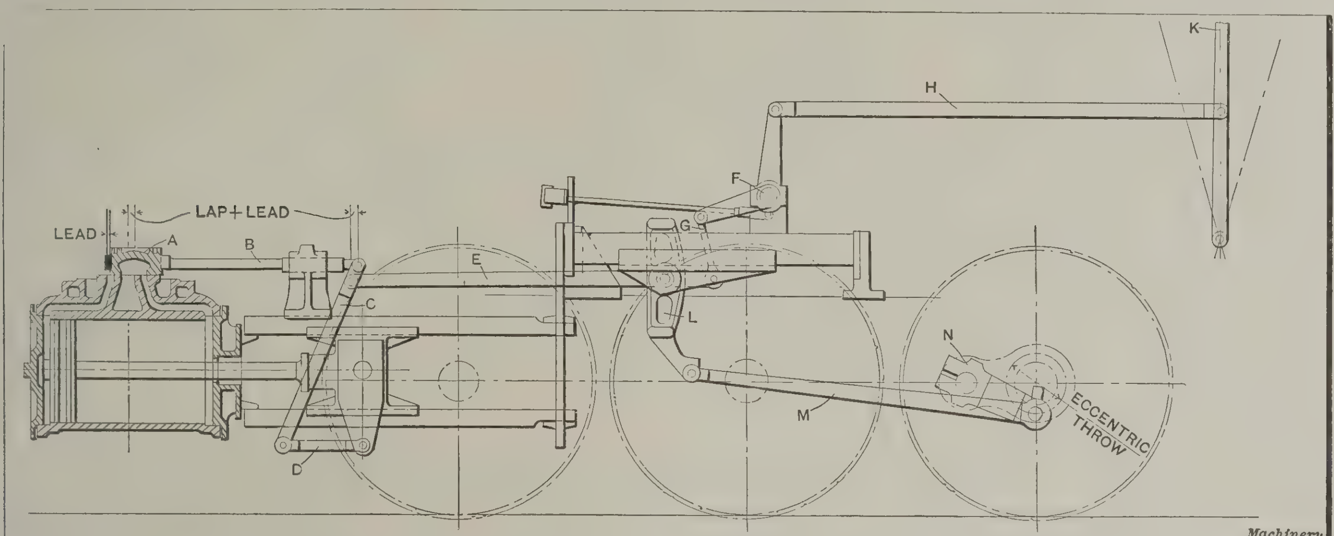

Fig. 1. Diagram showing Arrangement of Walschaerts Valve Gear for Outside-admission Valves

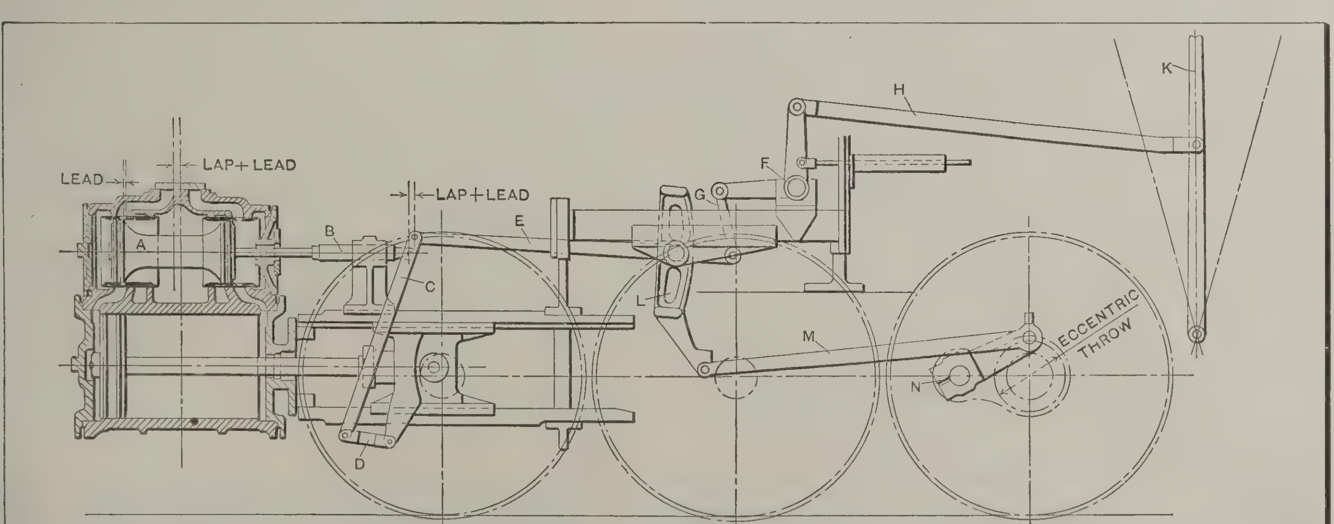

Fig. 2. Walschaerts Valve Gear arranged for Inside-admission Piston Valves

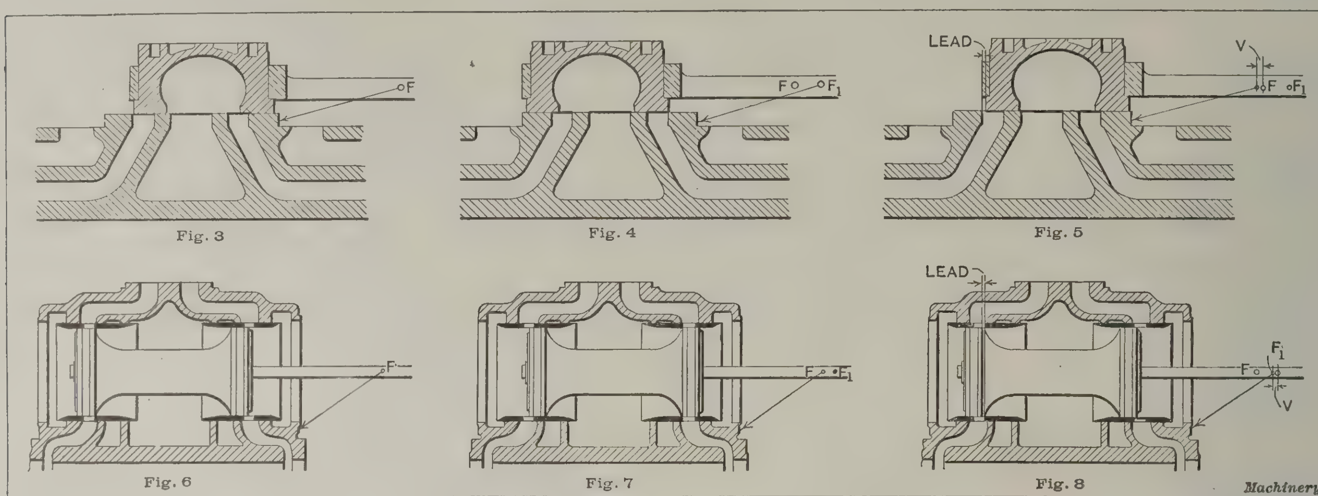
Fig. 1 represents the arrangement of Walschaerts motion as used with outside-admission slide valves, and Fig. 2 illustrates the design used with inside-admission piston valves.

The return crank on the main pin (sometimes known as the eccentric crank) is so set that when the piston is at the extreme end of its stroke, the link *L* stands in its central position. Now if the radius-rod were attached directly to the valve stem, the valve would also be in its central position, but when the piston is at the end of the stroke the valve must be displaced from its middle position by an amount equal to the lap plus the lead. With the Walschaerts

* Abstracted from Record No. 70, "Walschaerts Valve Gear," issued by the Baldwin Locomotive Works, Philadelphia, Pa.

† For additional information on the Walschaerts valve gear see the following articles previously published in MACHINERY, railway edition: "Making Walschaerts Valve Gear Parts"; "Locomotive Building at Altoona," June, 1910; "The Walschaerts *vs.* the Stephenson Valve Gear," October, 1906; "Nomenclature of Walschaerts Valve Gear," September, 1906; "Setting Valves with the Walschaerts Gear," January, 1906; "Setting Valves with Walschaerts Gear," February, 1906; "The Walschaerts Valve Gear," May, 1906.

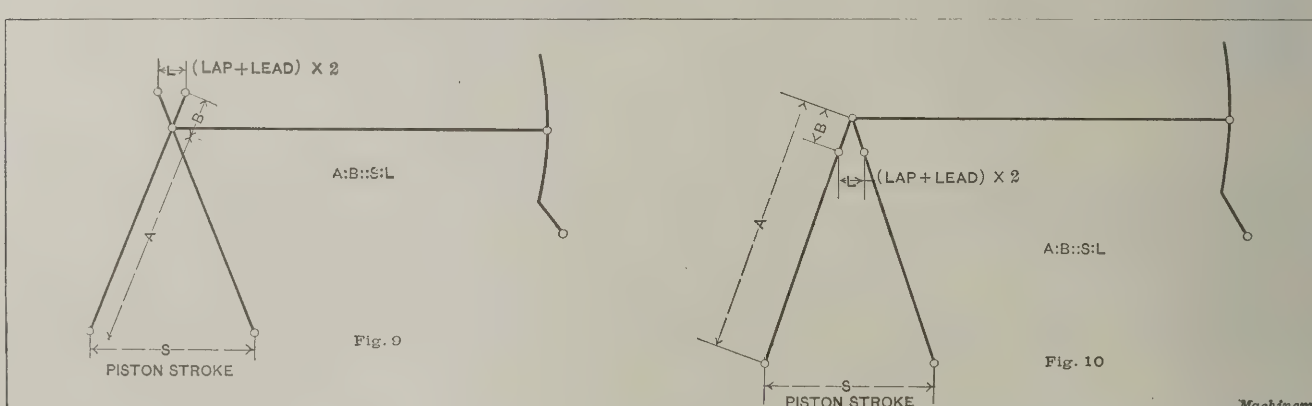
gear the valve is given lead (the amount of port opening when the piston is at the end of the stroke) by combining lever *C*, which is attached to valve stem *B* and radius-rod *E* and is also connected by link *D* with the crosshead. This combining lever is so proportioned that if the point of its connection to the radius-rod is a stationary fulcrum, and the



Figs. 3 and 4. Slide Valve set at Points of Cut-off Front and Back. Fig. 5. Slide Valve set for Lead Opening. Figs. 6 and 7. Inside-admission Piston Valve set at Points of Cut-off Front and Back. Fig. 8. Piston Valve set for Lead Opening

piston is moved a distance equal to the stroke, the valve will be shifted an amount equal to twice the lap plus the lead. Therefore, when the piston is at the end of its stroke, the valve is displaced from its central position a distance equal to the lap plus the lead.

In both Figs. 1 and 2, the main pin is shown on the for-



Figs. 9 and 10. Diagrams showing Proportions of Combining Lever Arms, for Outside and Inside Admission

ward "dead center", and the reverse lever is in its middle position with the link-block in the center of the link. A study of the diagrams shows that with a valve having *outside admission*, the valve rod is connected to the combining lever at a point above the latter's connection to the radius-rod, and, if the block is in the lower half of the link when

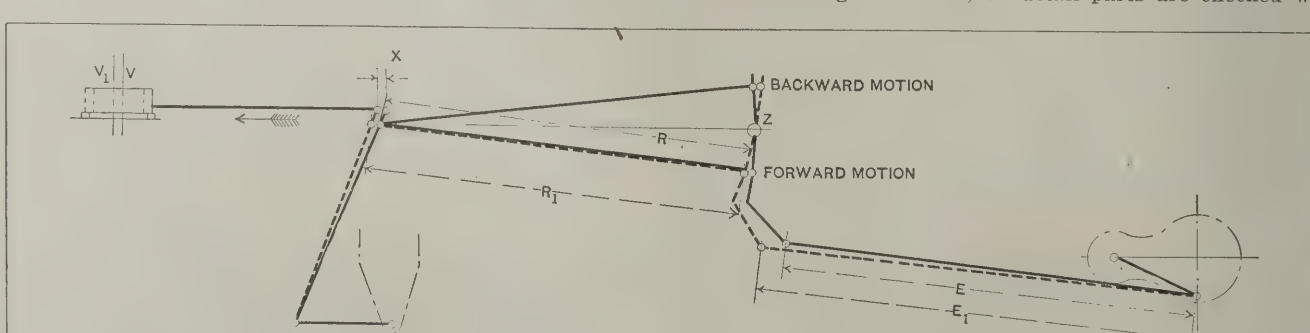


Fig. 11. Diagram showing Movement of Valve effected by Lengthening Eccentric Rod

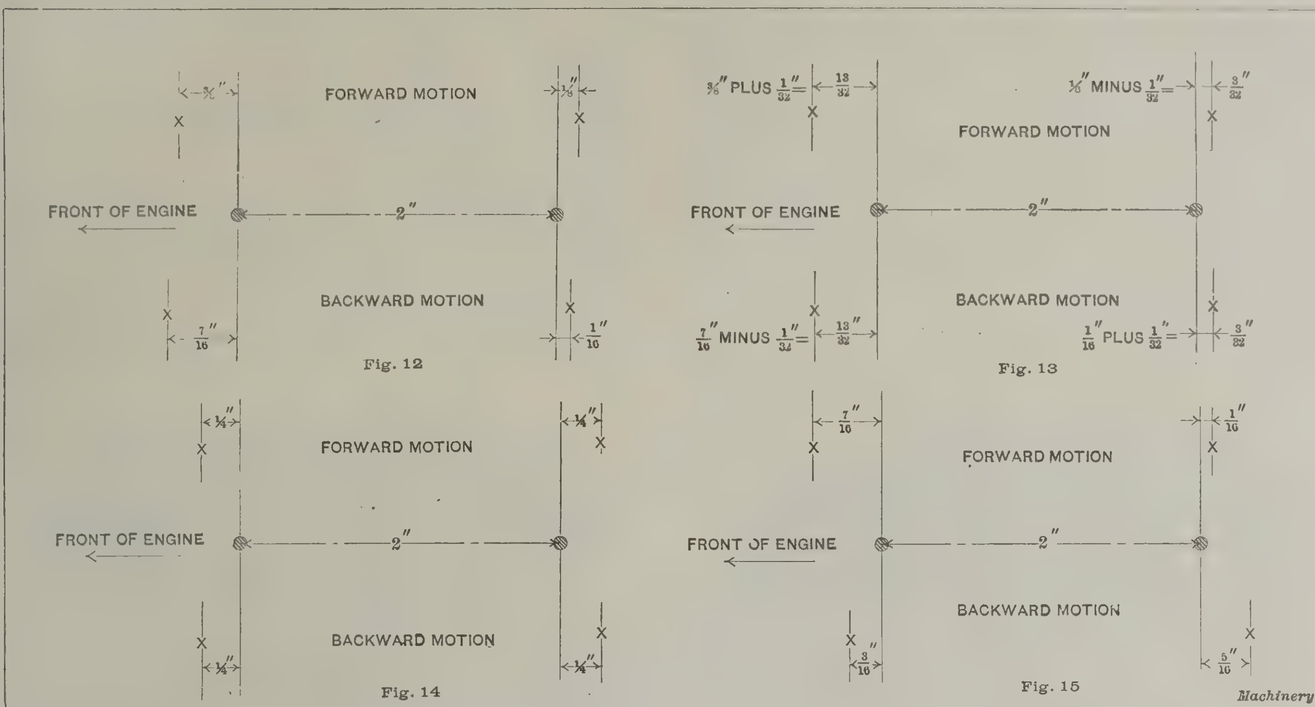
in the forward gear, the eccentric crank *leads* the main pin. On the other hand, if the block is in the upper half of the link when in the forward gear, the eccentric crank *follows* the main pin. With a valve having *inside admission*, the valve rod is connected to the combining lever at a point below the latter's connection to the radius-rod (as shown in Fig. 2), and if the block is in the lower half of the link when in the forward gear, the eccentric crank *follows* the main pin, whereas if it is in the upper half of the link when in the forward gear the eccentric crank *leads* the main pin.

Inasmuch as the position of the valve when the piston is at the end of its stroke, is dependent upon the combining lever only, it is evident that the lead is the same from all points of cut-off. This is the principal feature which distinguishes the Walschaerts gear from the Stephenson motion, as far as steam distribution is concerned. The former should be correctly laid out to give the lead most desirable for the usual running speed. After the parts have been correctly made, it is impossible to alter the lead without seriously deranging the mechanism. In this respect the Walschaerts gear is less flexible than the Stephenson, but when once set up it is less liable to derangement, and the engine is more easily kept "square."

Before setting the valves, all detail parts are checked with their respective drawings, the main rod is erected and the valve gear connected. The main driving boxes are then blocked up one-half inch above the central position to allow for settling, after which punch marks are located on the main drivers for placing the engine on the dead centers. The method of locating these marks is the one commonly

employed in valve setting. The main crank is placed approximately six or eight inches below, say, the forward dead center, and the position of the crosshead is then marked with a tram held in a punch mark on the guide. A larger tram is also used to scribe a line on the driving wheel tire, from any convenient point on the frame. The wheel is then revolved backward until the crosshead, after passing the dead center, moves back to its first position as shown by the tram. Another line is then scribed on the tire from the same point on the frame. An arc is then drawn through these two lines on the tire and a central point is laid off on the arc to get the dead center position. A dead center mark for the opposite end of the stroke is also located in a similar manner. To place the engine on the dead center, the wheel is simply turned until the tram used for scribing the tire coincides with the punch mark on the frame and the dead center mark on the tire.



Figs. 12 to 15. Examples illustrating Adjustment for Equalizing Valve Travel in Backward and Forward Motion

Setting Outside-admission Valves

The following instructions apply to the setting of valves having outside admission:

1. With the ports exposed, set the valve at the points of cut-off front and back (as illustrated in Figs. 3 and 4) and prick punch the valve stem at points F and F_1 by tramming from any convenient place. The distance between points F and F_1 will be equal to twice the lap of the valve. When the main crankpin is on either dead center, the port should be opened an amount equal to the desired lead, as shown in Fig. 5. If a line is scribed on the valve stem with the valve set for the required lead, the distance V, Fig. 5, between this line and the point of cut-off F will equal the lead. With this statement in mind, proceed as follows:

2. Hook up the gear so that the link-block is in the center of the link; then place the main crank on the forward dead center and tram to the valve stem. Next revolve the wheel to the back dead center and again tram to the valve stem. Measure the distance between the points so obtained and compare with the specifications. This distance should be equal to twice the sum of the lap and lead. Any variation from the specified figures means that an error exists in the combining lever, the upper and lower arms of which should be made, respectively, proportional in length to twice the lap and lead and to the stroke of the piston, as indicated in Figs. 9 and 10. Assuming that the distance L, as trammed on the valve stem, is correct, the procedure is then as follows:

3. Place the gear in the forward motion with the link-block at a point in the link that will give the specified maximum valve travel when the wheels are revolved in the forward direction. This position of the link-block is obtained by experiment.

4. Place the main crank on the forward dead center and again scribe a line on the valve stem, measuring the distance between the point so obtained and the mark F, (Fig. 4). This distance should be exactly equal to the specified lead.

5. Revolve the wheel in a forward direction until the main crank is on the back dead center and again scribe on the valve stem, measuring the distance to punch mark F_1. This distance should also be equal to the specified lead.

6. Place the gear in the backward motion (as instructed in paragraph 3) and test for lead at the front and back, as described in paragraphs 4 and 5, excepting that the wheel should be revolved in a backward direction.

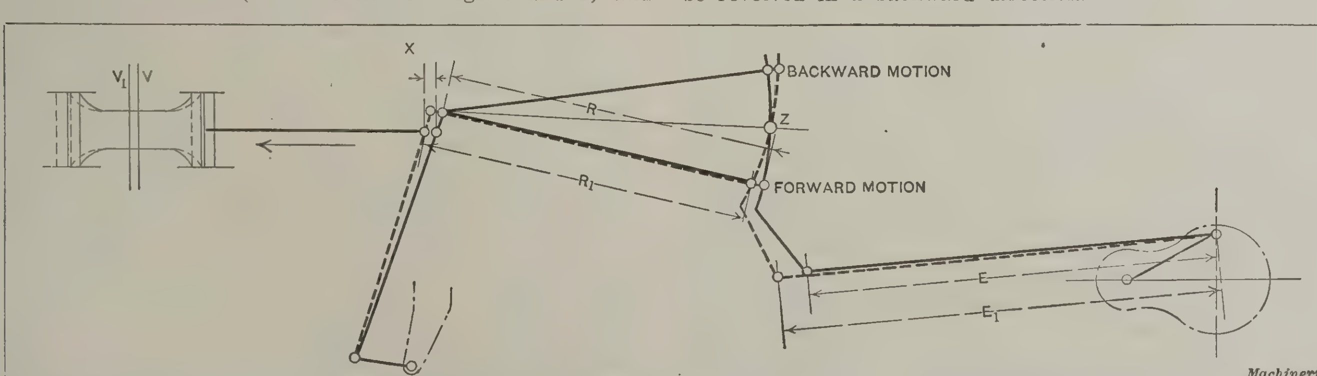


Fig. 16. Diagram of Valve Gear for Inside-admission—Note Change made by lengthening Eccentric Rod

7. If all the measurements conform to the specifications, the valves are set "square." A check should now be made by placing the piston on the forward dead center and moving the link-block through its entire travel in the link. This should in no way disturb the position of the valve. With the gear set for the full stroke forward and the full stroke backward, the maximum valve travel should also be noted when the piston is at half stroke.

In marking the forward and backward gear positions on the reverse quadrant of a "cold engine," an allowance toward the front of the quadrant must be made on each end, to correct for expansion when the engine is under steam. This al-

lowance is largely a matter of judgment, but from ¼ to ⅜ inch is sufficient for the ordinary standard gage locomotives.

If, on trial, the lead is found to be unequal, the following examples will serve to explain the corrections that should be made: Suppose the specification calls for a maximum valve travel of 5½ inches, an eccentric throw of 11 inches, a constant lead of ¼ inch, an outside lap for the valve of 1 inch, and the link-block below the center in the forward gear. It is very important that the following dimensions check exactly with the drawings:

1. Length of combining lever between the central fulcrum and the upper and lower arm centers (see dimensions *A* and *B*, Figs. 9 and 10). 2. The eccentric crank throw and length of the crank arm.

A change in the length of the eccentric rod changes the position of the valve approximately in proportion to the eccentric throw and valve travel. In this case the proportion is as 11 to 5½ or as 2 to 1; in other words, a change of ¼ inch in the length of the eccentric rod will move the valve approximately ⅛ inch when the link-block is in full gear and the main crank is on the dead center. The effect of the eccentric rod changes upon the position of the valve will be seen by referring to Fig. 11. If the eccentric rod E is lengthened to E_1, then the radius-rod R will be moved ahead to position R_1, and the valve stem will be moved a distance X in the direction of the arrow, thus displacing the valve from position V to position V_1.

The following rules can thus be formulated: If the link-block is below the link center when running ahead, then, in the *forward motion* if the eccentric rod is lengthened, the valve is moved ahead; whereas, if the eccentric rod is shortened, the valve is moved back. For the *backward motion*, if the eccentric rod is lengthened, the valve is moved back, and by shortening the eccentric rod, the valve is moved ahead. If the link-block is above the center when running ahead, then, in each case, the valve will be moved in the direction opposite to that given in the foregoing.

Changes made in the length of the link radius-rod will have approximately full effect on the movement of the valve. In other words, any variation in the radius-rod will produce about the same variation in the movement of the valve. In either forward or backward motion, the valve is moved ahead by lengthening the radius-rod the amount desired, and to move the valve back, the radius-rod is shortened. This holds good whether the link-block is above or below the link center in the forward gear. With these facts in mind, two examples will be considered:

Example No. 1: Let it be assumed that, on tramming to the valve stem with the main crank on the dead center, we find irregularities in the lead as shown by the diagram Fig. 12. The dots on the diagram represent the prick punch marks F and F_1 (Fig. 4), and the crosses represent the irregularities in the lead. First, the error between the forward and backward motion should be divided as follows:

The error in the forward motion at the front equals ⅜ — ¼ inch lead = ⅛ inch error. At the back, ¼ inch lead — ⅛ = ⅛ inch error. Therefore, to square or equalize the lead, the valve must be moved ahead ⅛ inch. The error in the backward motion at the front equals, 7/16 — ¼ inch lead = 3/16 inch error. At the back, 1/4 inch lead — 1/16 = 3/16 inch error. To equalize the lead, the valve must be moved ahead 3/16 inch.

As the errors in the two motions are in the same direction, it follows that one partially neutralizes the effect of the other, and that the combined or average error would be the difference between the two, or 3/16 — 1/8 = 1/16 inch error. To divide this error of 1/16 inch, it will be necessary to move the valve one-half of this amount, or 1/32 inch back in the forward motion. In order to do this, the eccentric rod must be shortened 1/16 inch, according to the rule previously given. When this has been done, the tram lines will be located as shown by Fig. 13. The errors at the front, in the forward and backward motions, are now 13/32 inch, and at the back, 3/32 inch, and it only remains to equalize the lead at the front and back for both motions. The position of the valve as shown by Fig. 13 is 5/32 inch too far back. Thus, 13/32 — 1/4 inch lead = 5/32 inch error front, and 1/4 inch lead — 3/32 = 5/32 inch error back.

As the effect of adjusting the radius-rod is direct, it follows that by lengthening this rod 5/32 inch, the valve travel will be equalized, thus giving a lead of 1/4 inch at the front and back for both motions, as indicated by the diagram, Fig. 14. The required changes, then, for Example No. 1, are as follows: Eccentric rod shortened 1/16 inch; link radius-rod lengthened 5/32 inch. A final trial of the valve and cut-off, etc., can now be made, as previously described.

Example No. 2: As another illustration, let it be assumed that, when tramming for lead, the results indicated by Fig. 15 are obtained. In this instance, the error in the forward motion at the front equals, 7/16 — 1/4 inch lead = 3/16 inch error; and at the back, 1/4 inch lead — 1/16 = 3/16 inch error.

To square the lead, the valve must be moved ahead 3/16 inch. The error in the backward motion at the front equals, 1/4 inch lead — 3/16 = 1/16 inch error; and at the back, 5/16 — 1/4 inch lead = 1/16 inch error. In this case the valve must be moved back 1/16 inch.

As the errors in the two motions are in opposite directions,

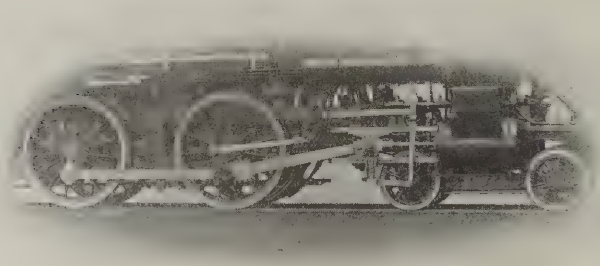

Fig. 17. Walschaerts Gear applied to American Type Locomotive

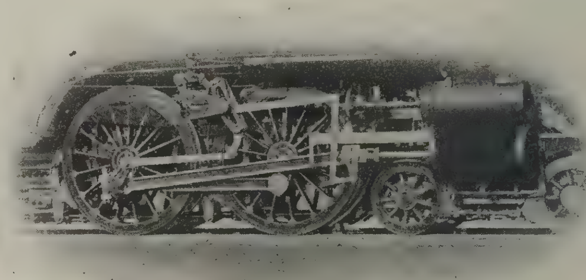

Fig. 18. Atlantic Type Equipped with Walschaerts Gear

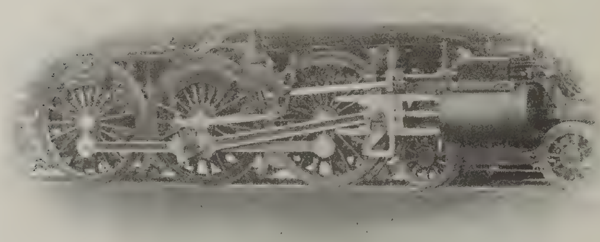

Fig. 19. Walschaerts Gear on Pacific Type Locomotive

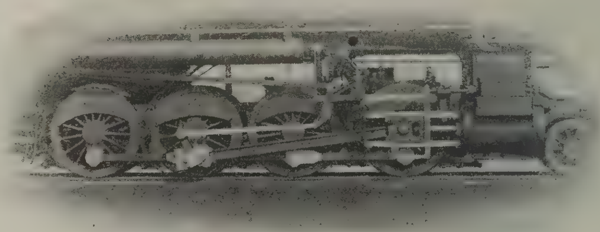

Fig. 20. Consolidation Locomotive having Walschaerts Gear

the combined or average error will be the sum of the two, or $3/16 + 1/16 = 1/4$ inch. To divide this error, it will be necessary to move the valve one-half the amount, or 1/8 inch ahead in the forward motion. To do this, the eccentric rod must be lengthened ¼ inch, which will give a lead of 5/16 inch at the front for both the forward and backward motions, and 3/16 inch at the back. The valve is now 1/16 inch too far back to equalize the lead. Therefore, the radius-rod must be lengthened 1/16 inch, which will give the results indicated by the diagram Fig. 14. The necessary adjustments, then, for Example No. 2, are, to lengthen the eccentric rod ¼ inch and the radius-rod 1/16 inch.

From the foregoing, it is evident that the errors in the forward and backward motions are made to correspond at the front and also at the back, by changing the length of the eccentric rod, after which the lead is equalized by changing the length of the radius-rod. Theoretically, the radius-rod should not be changed, but the necessary adjustment is so slight that it makes practically no difference in the movement of the valve. In special cases it may be desirable to equalize the valve travel when the gear is hooked up to give the cut-off which is most frequently used when the engine is in service. Thus, on a passenger locomotive, the most satisfactory results may be secured when the valve travel is equalized for a one-third or one-half stroke cut-off. In such a case, a slight irregularity at full stroke may be unavoidable but not detrimental.

Setting Inside-admission Piston Valves

The method of setting inside-admission piston valves is very similar to that described in the foregoing. It must be remembered, however, that to perform corresponding functions, such a valve moves in an opposite direction to that of a slide valve. When setting piston valves, the steam chest heads should be removed, for the sake of convenience, and the cut-off positions of the valve are determined by observation through peep holes provided for that purpose. In this way the points F and F_1 are located on the valve stem, as indicated in Figs. 6 and 7, by tramming from any convenient point in the back wall of the steam chest. The test for lead is made as previously described for outside-admission valves.

To illustrate the method of correcting errors with the inside-admission type, suppose we have the following specifications: Maximum valve travel, 5¾ inches; eccentric crank throw, 15½ inches; constant lead, ¼ inch; steam lap of valve, 1 inch; and link-block below the center in forward gear.

The effect of eccentric rod changes is indicated by the diagram Fig. 16. If eccentric rod E is lengthened to E_1, then radius-rod R would be moved ahead to position R_1, and the valve stem will be moved a distance X, thus displacing the valve from position V to position V_1. Therefore, the rules previously given for outside-admission valves also apply to this type. In any case, regardless of whether the gear is in the forward or backward motion, lengthen the radius-rod to move the valve ahead, and shorten it to move the valve back. It must be remembered that with an inside-admission valve, the front port opening is increased when the valve is moved ahead, and the rear port opening is increased when the valve is moved back. Bearing this in mind, an example of valve adjustment will be given.

Let us assume that, when tramming a valve, the irregularities indicated by the diagram Fig. 12 are found. First the error in the forward motion is found. As this is 1/8 inch, the valve must be moved back 1/8 inch. The error in the backward motion is 3/16 inch, so that the valve must be moved back 3/16 inch. As these errors are in the same direction, the difference between the two is found. This equals $3/16 - 1/8 = 1/16$ inch. To divide this error, it will be necessary to move the valve 1/32 inch ahead in the forward motion. As the eccentric crank throw in this instance is 15½ inches and the valve travel 5¾ inches, the ratio of the eccentric throw to valve travel is approximately 2.7 to 1. Therefore, the eccentric rod must be lengthened $2.7 \times 1/32$ inch, or approximately 5/64 inch, to move the valve ahead 1/32 inch. The valve will now tram as shown by Fig. 13. As it is 5/32 inch too far ahead, the radius-rod should be shortened this amount in order to equalize the lead. The adjustments, then, are as follows: Eccentric rod lengthened 5/64 inch; radius-rod shortened 5/32 inch.

When setting outside-admission piston valves, the method described for slide valves is followed, as the arrangement of the valve gear is the same. The cut-off position of the valve, however, must be observed through peep holes, the same as with inside-admission piston valves.

Fig. 17 shows the Walschaerts gear applied to an American type locomotive having slide valves. The link and reverse shaft bearings are bolted to a crosstie placed just ahead of the main driving wheels. A bracket bolted to the upper guide-bar supports the valve rod. As the radius-rod is down when running ahead, the eccentric crank leads the main pin. Fig. 18 shows an arrangement used on an Atlantic type locomotive. A cast-steel bearer placed between the two pairs of driving wheels, supports the link and reverse-shaft bearings. The valve is of the piston type with inside admission, and, as the radius-rod is down in the forward gear, the eccentric crank follows the main pin. Fig. 19 shows an arrangement used on a Pacific type locomotive with slide valves. A rocker is used to transmit the motion from the plane of the link to that of the valve stem, and the rocker-box is bolted to the guide yoke. Fig. 20 shows this motion applied to a consolidation type locomotive with slide valves. In this case the reach-rod of the reverse lever, is attached to an arm extending down from the reverse shaft, in order to have the block below the link center when running ahead. Fig. 21 shows a heavy consolidation locomotive of the Mallet type. The valves of the rear engine are arranged for inside admission and those of the front engine for outside admission, and the necessary arrangement of the eccentric cranks and combining levers is clearly shown. Both valve motions are controlled simultaneously by a power reverse mechanism, the reverse shafts being connected by a jointed reach-rod. The different gears referred to are typical of modern practice, but by no means represent all the modifications in successful use. The general design of the engine affects to a great extent the arrangement of the motion.

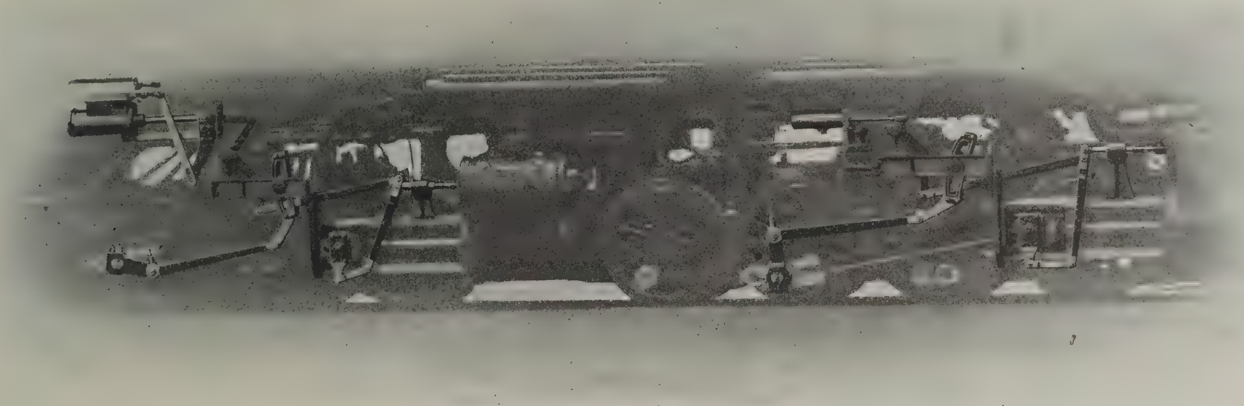

Fig. 21. Consolidation Mallet Type with Inside-admission Valves for Rear Engine and Outside-admission Valves for Front Engine

AN EXHIBITION OF SAFETY DEVICE MODELS

The illustration presented herewith shows a collection of models of different safety devices which were exhibited by the New York Central Lines at the session of the International Congress of Hygiene and Demography in Washington, D. C., from September 16 to October 5, under the general charge of Mr. George Bradshaw, general safety agent of the New York Central Lines. The following list shows the models which were on exhibition:

Lathe guard for end gears; two emery wheel guards; two water glass gage guards; shaker bar; protector for electric welder operator; two electric switch guards; four models showing exposed and correct method of applying set-screws; model of gasoline turntable motor; two models showing exposed and correct method of guarding set-screws in drill press; two models showing joiner guards; two models showing rip saw and guard; model of car bridge with spurs to prevent slipping; goggles used for emery wheel grinders; clamps and nozzle for sprinkler hose; and truck for handling driving wheel tire.

New York Central Lines Exhibit of Safety Device Models

Besides the models the exhibition included photographs of a great variety of safety devices, photographs of safe and unsafe methods of work, and samples of safety educational literature which is being distributed by the safety department of the New York Central Lines.

Experiments undertaken by the Hungarian State Railway authorities show that an alloy of 78 parts of lead, 17 parts of antimony, and 5 parts of tin constitutes an excellent journal-bearing metal. Five thousand cars were fitted with this metal in order to test its efficiency, and after a usage of three years, the results are pronounced satisfactory. This metal will now be adopted for all journal bearings on the Hungarian State Railways.

WHAT A MAN CAN DO WHEN HE GETS MAD

BY A. P. PRESS

I saw an incident the other day that showed what a man can do when he gets provoked good and proper.

It happened in the toolroom; one of the toolmakers had a fuse tip die to make. The blank was ⅞ inch thick and the fuse tip was about 1 inch long, round at one end and square at the other, with a wing-like projection on each side. The toolmaker was a good man, all right—in fact one of the very best that ever filed a die—but I guess it must have been the "morning after". He had laid out the die all right and had drilled and roughed out most of the stock when it dawned on him that he had made it left-handed, that is, he had laid the templet on the die blank wrong side up. While the die was all right, it, at the same time, was all wrong, or at least the work from it would not fold up so as to bring the burr edge of the metal together.

What did he do? He slapped that piece of work into the scrap-box, took another blank (they were all machined out ready for the templet) and in two hours and twenty minutes he had drilled out his die, roughed out the stock and finished it up ready to harden.

I have seen quick work, but never did I see the same amount of hand work performed in the same length of time as in this case. It pays to get mad once in a while.

* * *

It has been found unprofitable to use old tin cans in the process of detinning for recovering the tin. The cost of collecting, transportation and inability to dispose of the black iron plate are responsible for the cans not being utilized. This information was recently published by the United States Geological Survey which investigated the subject.—*Brass World.*

DIES FOR DROP-FORGING A CRANK-SHAFT

BY J. W. JOHNSON*

The dies for drop-forging the crankshaft shown in Fig. 1 comprise an interesting set of tools, especially to those unaccustomed to crankshaft diemaking. The principal interest of these dies lies in the fact that they were made to forge the collars, pin and adjacent parts of the crankshaft only, the remainder of the ends of the crankshaft being forged under an ordinary trip hammer. The advantages to be gained in forging the crankshaft in short dies are that on account of the

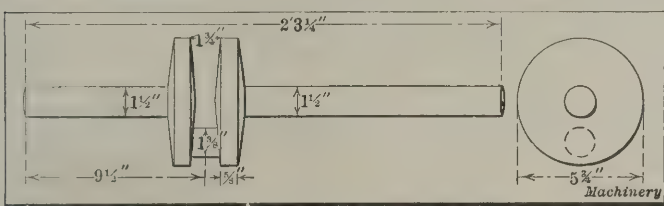

Fig. 1. The Drop-forged Crankshaft

small amount of stock being acted upon, the forging can be thus made under a lighter hammer and stock of smaller dimensions may be used, for it can be worked up by passing it back and forth from the break-down to the impression. Another important advantage in forging this job in short dies is that there is less liability of the forging sticking in the dies while being forged. If long dies were used there would

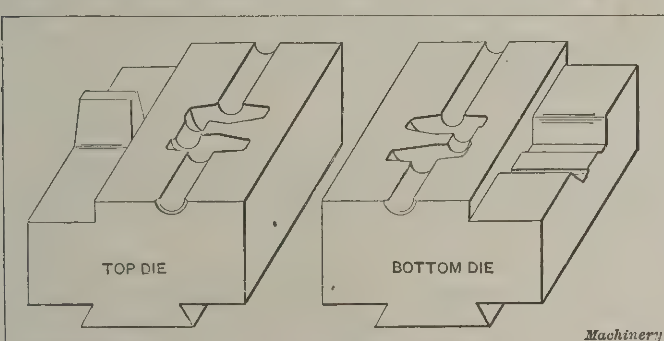

Fig. 2. Forming Dies for Forging a Crankshaft

be more or less trouble from this source. Moreover, when the forgings stick in a long die it is harder to free them than it is from short dies. Short dies are also much easier to keep lined up than long ones; in fact dies long enough to forge this entire crankshaft would give constant trouble by working out of alignment.

Fig. 2 shows the drop-forging dies for forming the forging,

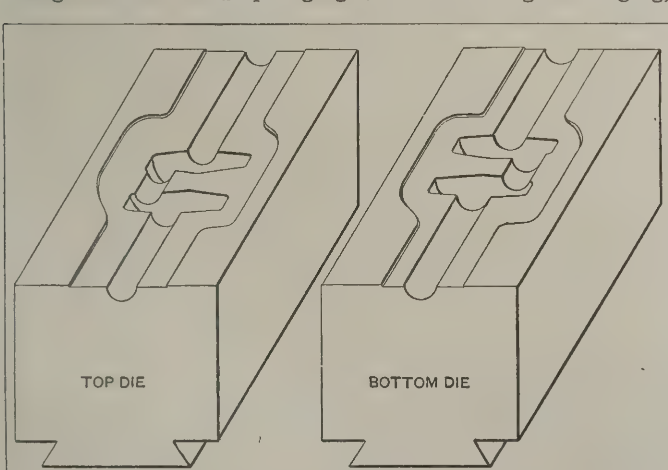

Fig. 3. Finishing Dies

the finishing being done in a separate pair of dies. It will be noticed that the break-down is of unusual width, which is necessary on account of the spreading of the stock. All corners in the forming impressions were well rounded to prevent cold shuts. In making the top die for the forming operation, the projecting piece on the break-down was made by dovetailing a separate piece into the side of the die. If this were not done, a great deal of superfluous labor would have to be done in shaping away the rest of the face of the die. The finishing dies are illustrated in Fig. 3, and, of course, the impressions are like those in the forming dies, except that the corners are not rounded as much and are flashed. It is obvious that no break-down or anvil was required on the finishing dies.

The trimming die and punch for this forging are shown in Fig. 4, and it will be noticed that the die is made in halves and left open at the front for hot-trimming. The punch was milled out to receive the forging for trimming so that it would not bend during the trimming operation.

The stock used for forging this crankshaft was nine inches long and four inches square. The first operation consisted of forging a tong-hold on one end. The piece was then put back in the fire, heated all over to a good forging heat, and

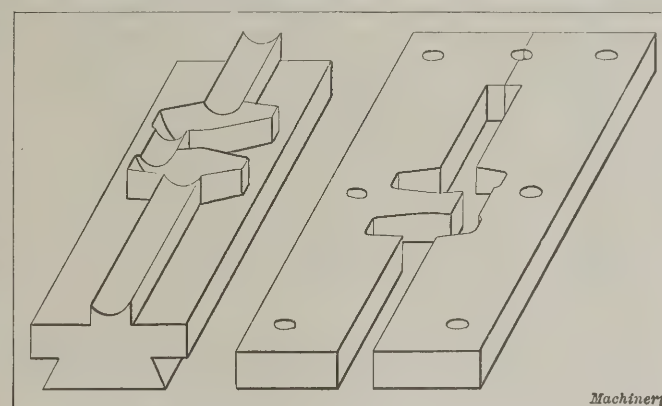

Fig. 4. Trimming Dies

the first blow of the hammer given the piece when in the break-down. Care was necessary in locating the piece in the die for the first blow, for this crankshaft is longer on one side of the collars than on the other. The stock worked up very rapidly, as it drew from the smaller sections and flowed into the collars. Quite a number of blows were necessary to draw enough stock from the ends to get the collars full.

After distributing the stock by means of the forming dies, a few blows in the finishing die brought the corners up and sized the forging, after which it was hot-trimmed in the ordinary manner in the trimming dies shown in Fig. 4.

* * *

The statistics compiled by the *Archiv für Eisenbahnwesen* give the total mileage of the world's railways in 1910 as 640,158 miles; the total increase in the last year was 14,460 miles and in the last decade, 149,092 miles. This increase in mileage had been exceeded by but one previous decade, that between 1880 and 1890, when 152,179 miles of railway were built. Of all the railways in Europe more than 50 per cent are owned by the respective governments: 60 per cent of the railways in Africa, nearly 60 per cent of those in Asia and about 95 per cent of those in Australia are owned and operated by the State. It is interesting to note that while Great Britain has no state railways, and Canada only 1718 miles out of a total of 24,731 miles, this form of administration prevails almost exclusively in the British possessions of Asia, Africa and Australia.

It is also of interest to record the growth of the world's railway system from the time of its beginning. In 1840 there were about 4800 miles of railway in the world; in 1850, 24,000; in 1860, 67,000; in 1870, 130,000; in 1880, 231,000; in 1890, 383,000; in 1900, 490,000; and in 1910, as mentioned, 640,000 miles.

* * *

At a recent meeting of the Society of German Engineers, Herr Hammer, after having reviewed the improvements in the locomotives shown at the recent Turin exposition in Italy, stated that the following lines of development are being followed: A high steam pressure; the use of steam more highly superheated; valve gear improvements; utilization of the heat of the waste gases now escaping through the smokestacks; and the purification and pre-heating of the feed water.

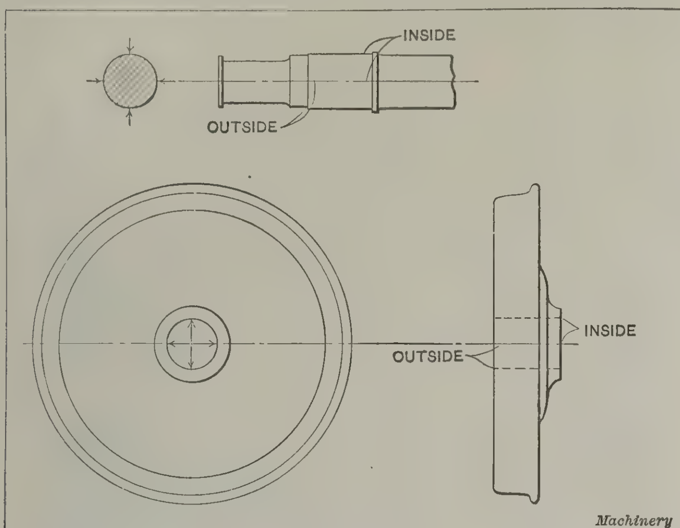
WHEEL AND AXLE PRESS FITS

The accompanying table gives data for wheel and axle press fits, as used in different railroad shops. The data given in the tables requires no further explanation, as it merely records the practice followed in various shops. The writer had the opportunity of obtaining this data during the carrying out of a systematic investigation covering the points recorded. He believes that a great deal of interest is attached to this



Illustrations showing where Dimensions given in the Accompanying Table are measured

subject, as he found that in all the railroad shops visited the men were very much interested in the methods followed in other shops. It will be seen that the practice differs considerably in the various places, both as regards the speeds and feeds used in wheel and axle turning and as regards the allowances for fits. Five shops are represented in the table, the data from each being grouped together as indicated. Two dimensions are given for each axle or bore diameter, these being measured in two directions at right angles to each other as indicated in the accompanying illustration. H.

CHECKING LIST FOR DRAWINGS

BY E. E. MINARD*

The questions are sometimes asked, "Why is it necessary to check drawings? Why cannot the draftsman be depended upon to make them right in the first place?" As a matter of fact, however, draftsmen are no more infallible than other men, although probably no less so. There are few who can make a drawing with the average amount of detail without some error or omission being found by a competent checker. The errors in design or dimensions are apt to be quite costly if not discovered before the parts are machined or assembled. It has been the experience of the writer that the most costly errors occur where they are least expected, and particularly with regard to matters which it has not been considered necessary to check. If the drawings cover simple and inexpensive parts, the checking might cost more than an occasional spoiled piece, and, in that case, it might be dispensed with, but when the drawings cover expensive parts, like tool work, careful checking is imperative.

It is often claimed that draftsmen are apt to be careless when they know that their work is to be checked afterwards. This may be true if the discipline is lax and the checker is inefficient, but if a standard checking list, such as given in this article, is handed to the draftsman with the understanding that his work must conform to its requirements, a marked increase in the efficiency of the draftsmen will, in most cases, be noted. The checking list submitted herewith is given as an example for one special class of work. Different lists should be prepared for different classes of work. In making up such a list, one should guard against the mistake of trying to make this standard checking list as complete as an instruction book. To make it efficient and useful, it must be brief in every item, and must be used simply as a supplement to other necessary instructions. The sole object should be to instantly call to the mind of the draftsman the requirements of the standard practice. The list given below is for punch and die work drawings, and will, of course, vary according to the practice and working conditions of different drafting-rooms.

* Address: 722 Saginaw St., W., Lansing, Mich.

Standard Checking List—Punches and Dies

Design Approval:
1. Authorization, requisition, memorandum, blueprint, sketch or sample.
2. Yearly requirements.
3. Grade of tool.
4. Method of operation.
5. General and specific requirements of departments.
6. Harmony in design, compared with other up-to-date tools.
7. General design.

Assembly:
1. Views and projections.
2. Work to be easily placed in die.
3. Work to be easily removed from die.
4. Same gaging points on succeeding operations.
5. Parts to be readily machined and assembled.
6. Interference of moving parts, slides, etc.
7. Burr side of blank in proper relation.
8. Provision for grinding.
9. Stripping and knockout devices to be adequate.
10. Clearance for slugs and burrs.
11. Setting pins.
12. Safety pins for unsymmetrical blanks.
13. Punch height to clear work during forming operation.
14. Size of punch shank to be standard.
15. Relation of shut height to available presses.
16. Size of dowel pins and standard screws.

Details:
1. Views and projections.
2. Views of details placed in same relative positions as assembly.
3. Detail to check with assembly.
4. Easily machined.
5. Easily assembled.
6. Easily hardened without liability to check.
7. How fastened in place.
8. Scaling and calculating of dimensions.
9. Intermediate dimensions.
10. Overall dimensions.
11. Limits.
12. Size and location of holes.
13. Finish marks.
14. Grinding marks.
15. Detail number.
16. Name.
17. Number of pieces required.
18. Material.
19. Hardened.
20. Ground.
21. Forging.

Title:
1. Class and type of punch and die.
2. Part number.
3. Model number.
4. Scale.
5. Initials.
6. Drawing number.
7. Date drawn.
8. Date traced.

General Requirements:
1. Neatness and clearness.
2. Crowding of views, details and notes.
3. Lettering.
4. Lines.
5. Section-lining.

The different men in the drafting-room use all or part of this list, as required. The designer uses the section on "Assembly." The head of the division or department uses the sections under the headings "Design Approval," and "Assembly." The detailer uses the portion under the headings "Details," "Title," and "General Requirements." The tracer need pay attention only to the section of "General Requirements," after which the checker uses the complete list with the exception of "Design Approval." It is understood that before a list of this kind can be used successfully, detailed instructions in separate form must be given to the draftsmen, covering all the parts to which attention is called in this list.

* * *

Men who are absolutely convinced of the accuracy of their opinions will never take the pains of examining the foundation on which they are based.—*Buckle.*

RELATIVE FIELDS OF THE BOARD AND STEAM DROP HAMMERS

BY H. TERHUNE*

It has been suggested that the steam drop hammer is rapidly replacing the board drop hammer. The writer wishes to state that after visiting practically all of the drop-forge plants and manufacturing plants making drop forgings, he is not of the opinion that the steam drop is replacing the board drop on the same class of work, but that the nature of the work at the present time has outgrown the limits of the board drop, which, even from a mechanical point of view, has always been placed at 3000 pounds falling weight.

In the Middle West and along the Lakes, where the bulk of heavy forging is done, drop hammers of from 2000 to 16,000 pounds falling weight are required. Here we find, perhaps, one and one-half board drop to every steam drop hammer, with a total falling weight much in favor of the steam drop; but from the western borders of Pennsylvania and New York to the Atlantic coast the conditions change almost as abruptly as does standard time, and we find about twelve and one-half board drop hammers to every one steam drop. The bulk of the board drops are from 800 to 1500 pounds and the steam drops from 2000 to 5000 pounds. Generally speaking, it is as difficult to convince people in New England of the merits of the steam drops as it is to do the same thing with relation to the board drops in the Detroit and Cleveland districts.

Each hammer has its advantages. The managers of the drop-forge shops say that a certain class of accurate work can be done more economically on a board drop than on a steam drop, provided that it does not require a hammer larger than from 1500 to 2000 pounds, and a number of plants that have been provided with all steam drop hammers have recently put in board drops to take care of this class of work. However, there are four or five drop-forge shops in the Middle West where nothing is considered except steam drop hammers for all classes of work.

Nearly everyone admits that the cost of operation and repairs is greater on the steam drop hammers, but at the same time about one-third more work can be done on these. The writer has failed, however, to obtain exact data as to the relative cost of operation and upkeep of the two types of machines. Some claim that these items are about double for the steam drop hammers, but this seems rather high.

The power required for board drop hammers varies considerably with the nature of the work. Very little power is required at the point of "pick-up" if the work is practically "die to die." A great deal more power is required when the work is very soft and there is no rebound; this is largely due to the small amount of kinetic energy in the driving pulleys, the rolls thus having to pick up a dead load from rest. When there is a good rebound, with the knock-off properly timed, the board will have practically the same upward velocity as have the rolls when they come together, and the ram is simply continued on its upward stroke by the rolls. Heavy flywheels would be an advantage, but makers of drop hammers would hardly consider them on account of the danger of the heavy overhanging weight on the end of the driving shaft. In several shops, however, they have been used for years without an accident, and in these places the manufacturers will consider no other construction.

It is rather difficult to find a better machine than the board drop hammer on certain classes of work, at least in cases, for example, where hammers of from 500 to 1500 pounds (or even up to 2000 pounds) are used, and the shop is driven by water power or natural gas at 12 cents per 1000 cubic feet, or even electric current at from one to one and one-half cents per kilowatt-hour, especially when coal is as high as in New England.

When the work is heavy and requires a great deal of breaking down, and there is considerable drawing and bosses to be forged, and even when light work is to be done having thin sections that cool quickly, such as gear blanks with thin webs, I-sections, etc., requiring quick sharp blows, the steam drop will make the best showing in nearly all cases.

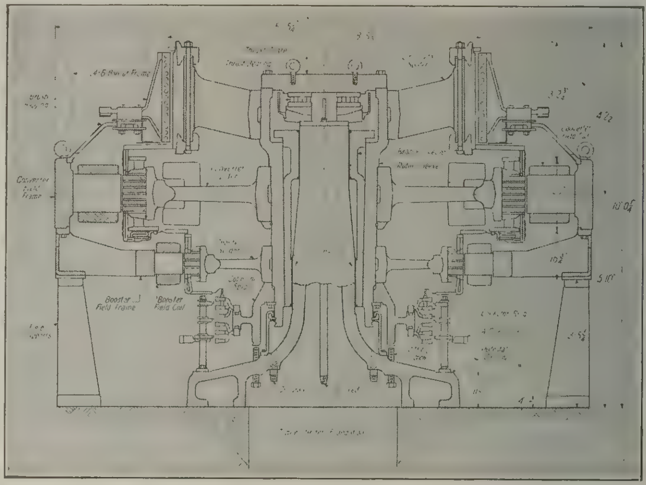
* Address: 373 N. Main St., Chambersburg, Pa.

At the present time the waste heat boiler mounted on the top of each heating furnace is receiving considerable attention. This boiler generates the steam for the hammer with little or no extra fuel other than that required for heating the work being forged. If the waste heat of each furnace were sufficient and could be utilized to generate enough steam for its own drop hammer, regardless of size, the board drop hammer would become obsolete on account of the superior economy of the steam hammer. At present, the relative advantages of each, however, depend, as we have seen, on many conditions, some of which are purely local in their character.

* * *

LARGE VERTICAL ROTARY CONVERTERS

Two 3000 K. W. vertical rotary converters have recently been built by the Westinghouse Electric & Mfg. Co. in its East Pittsburg works. These machines are of especial interest because they are the largest rotary vertical converters ever constructed. They were built for the New York Edison Co. The accompanying illustration shows a sectional drawing of these converters, some of the mechanical features of which are rather interesting and different from those hitherto used on ordinary electrical machines. The pedestal on which the armature rotates is made in one piece from a hollow steel



Section through Large Westinghouse Rotary Converters

casting. A much more rigid construction is possible in this way than with a steel pedestal provided with a flange on its lower end bolted to a cast-iron base. A roller thrust bearing is arranged at the top of the pedestal to take the weight of the revolving element. This bearing rests on the plate having a spherical seat carried on the pedestal, so that perfect alignment is possible. The roller bearing can be easily taken out by removing the top plate of the machine. When it is necessary to remove the top plate, the weight of the rotating parts is carried by six $1\frac{3}{4}$-inch bolts which pass through the flange at the base of the pedestal. When the top plate is taken off these bolts are screwed up until they raise the rotating element a trifle and assume its weight.

* * *

ARTIFICIAL RUBBER

A consular report states that a factory for producing artificial rubber has been established at Ymuiden, in Holland. It is stated that the company that has started this factory has succeeded in producing a substance having the qualities of rubber, and in addition, some advantages over genuine rubber. The principal ingredients of the product are said to be fresh sea fish with about 15 per cent of natural rubber, the resulting substance being as flexible and as elastic as rubber, but costing but one-sixth of real rubber. The low price of the product is caused partly by the use of the by-products, which can be employed as artificial fertilizers. It is stated that this artificial rubber can be vulcanized, that it is benzine-proof and that it can resist the effect of heat. The substance much resembles real rubber, but the slightly fishy smell betrays the chief ingredient. It is explained that this will be prevented by extracting the fat from the fish used. The development certainly is interesting, providing the claims, too, are not "fishy."

WATCH MOVEMENT MANUFACTURE—4

METHODS, MACHINES AND SPECIAL TOOLS USED BY THE SOUTH BEND WATCH CO., SOUTH BEND, IND.

BY DOUGLAS T. HAMILTON*

The final operations on a watch movement, such as jeweling, stem fitting, banking, dialing, balance truing, over-coiling, spring truing, finishing, timing and adjusting, are necessarily hand operations which require the attention of experienced workmen. The assembling operations are, of course, also accomplished by hand. Before the winding wheels, plates, bridges or other exposed portions of the movement are ready to be assembled, they are usually decorated by means of a tortoise shell lap charged with carborundum, held in a damaskeening machine. In addition to the operations mentioned, the methods used in making the dials will be dealt with in the following.

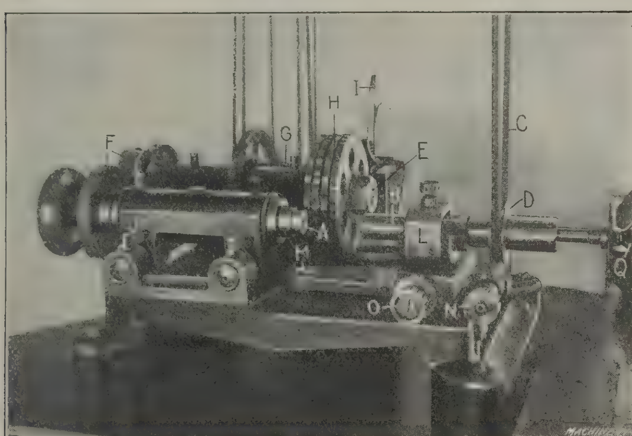


Fig. 40. Machine used in Damaskeening Winding Wheels, etc.

Decorating Watch Movement Parts

To produce the decorations on the winding wheels, etc., the parts are held in the spring chuck *A* of the damaskeening machine shown in Fig. 40. The tortoise shell lap, which for the steel parts is charged with diamond dust, is held in the spindle *B*, the latter being rotated by a belt *C* running on pulley *D*. The work is rotated by the cam-shaft *E* through change gearing *F*, the former receiving power from grooved pulleys *G*, through a worm and worm-wheel.

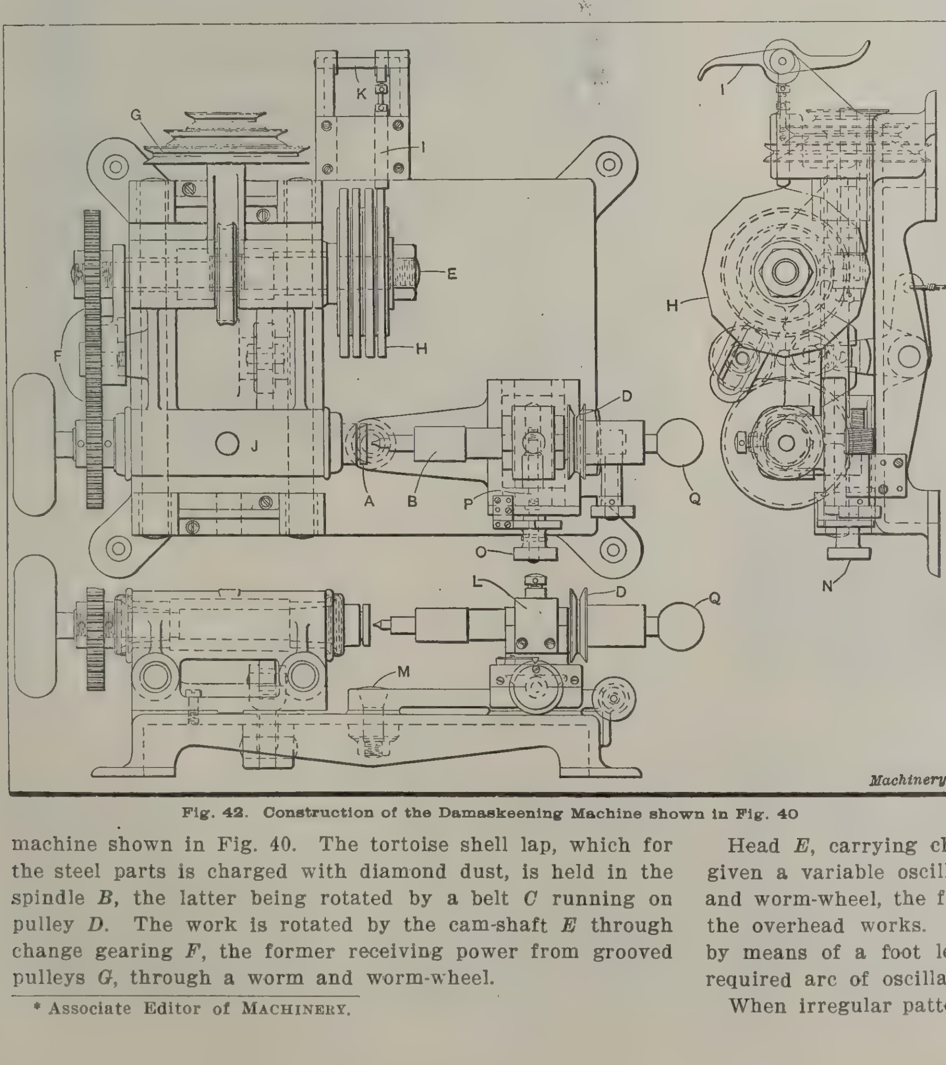

Fig. 42. Construction of the Damaskeening Machine shown in Fig. 40

The oscillating movements of the work required to produce the desired decorations are obtained from irregular faced cams *H*, which, through an adjustable pawl *I* transmit the required oscillating movement to the head *J*. As is shown in Fig. 42, this pawl can be slid back and forth on pin *K*, and thus be brought in contact with the irregular faces of the various cams. The entire head which carries the change gears and work is thus moved back and forth while the work is being rotated.

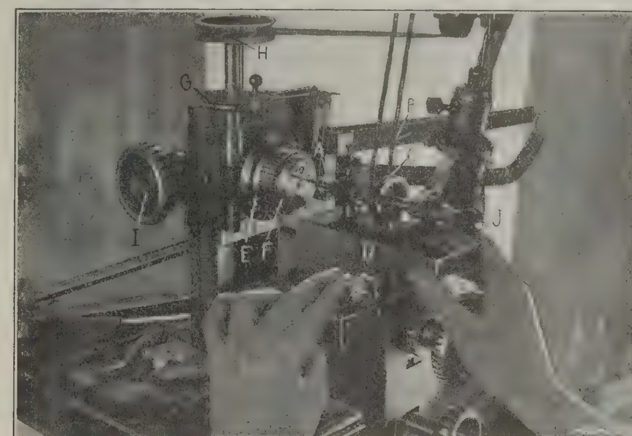

Fig. 41. Damaskeening Machine of the Upright Type for Decorating Bridges, Plates, etc.

The head *L* carrying the spindle in which the diamond-charged lap is held is pivoted at a point *M*, and is made to move through an arc by operating knob *N*, which has a worm formed on its forward end meshing in a rack cut in the base of the holder. This adjustment of the spindle is necessary to change the angular position of the face of the lap in reference to the work, so that fine or wide "wavy" decorations can be produced. The head carrying the lap can also be adjusted laterally to conform to the diameter of the required circle by means of a knob *O* and screw *P*. The lap is kept in contact with the work by the operator pressing on knob *Q*.

Damaskeening Bridges and Plates

The bridges and plates are decorated in a machine which differs in construction to a considerable extent from that shown in Figs. 40 and 42. This machine is shown in Fig. 41 at work on the rear watch plate. As before, the decorating is accomplished with a tortoise shell lap, which in this case, however, is charged with carborundum. The lap is held in a spindle *A*, which is rotated at a high rate of speed by means of a belt *B* and pulley *C*. The table *D* on which the lap spindle is held can be tilted to an angular position, so as to change the width of the decoration. For large work, the table can be moved back and forth, and is provided with an index, so that all lines can be spaced the same distance apart.

Head *E*, carrying chuck *F*, which holds the work, can be given a variable oscillating movement by means of a worm and worm-wheel, the former being driven by a pulley *G* from the overhead works. The belt driving the worm is shifted by means of a foot lever, stops being provided to give the required arc of oscillation.

When irregular patterns are desired, irregularly-faced cam-

* Associate Editor of MACHINERY.

strips retained on the rear of the machine are brought into play. These cams, through the medium of a follower, impart a forward and backward movement to the head, the latter being raised and lowered automatically by means of pulley *H*. This pulley is driven by a round belt from the overhead works, and by means of stops which shift the driving belt, its direction of rotation is changed to raise and lower the head. The head can also be moved back and forth by means of knob *I*.

The variety of patterns which can be produced on this simple machine is very great. By using any one of the irregularly-faced cams, the outline of the pattern is altered, and by using the same cam, but changing the angle of inclination of the lap spindle, an entirely different pattern is produced. Various combinations of patterns can in this way be produced without special attachments. The lap, of course, is kept in

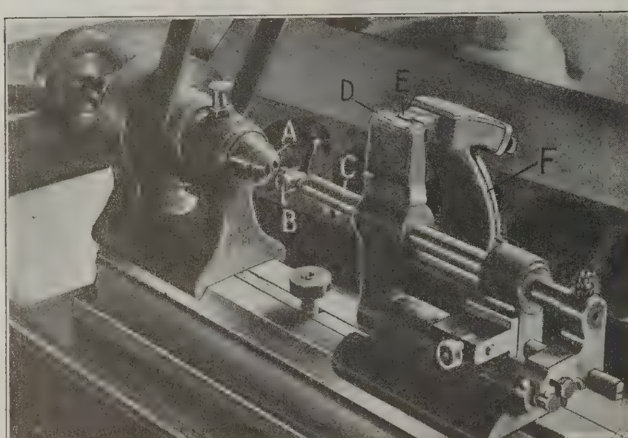

Fig. 43. Jewel "Letting-in" Machine and Caliper Rest for governing Diameter of Hole for Jewel

contact with the work by the operator, who presses on the knob *J* with the palm of her hand.

Fitting Jewel Settings and Jewels

The jewels, which act as bearings for the staffs, are not in all cases set directly in the plates and bridges, but are located in settings, the latter being retained in the plates and bridges. The machine used for producing the holes in the settings for the jewels is shown in Fig. 43. The setting is held in a spring collet *A*, and the boring tool in a holder *B*, provided with a shank fitting in spindle *C*.

A device called a "caliper rest" is used in connection with this machine for determining the diameter of the hole for the

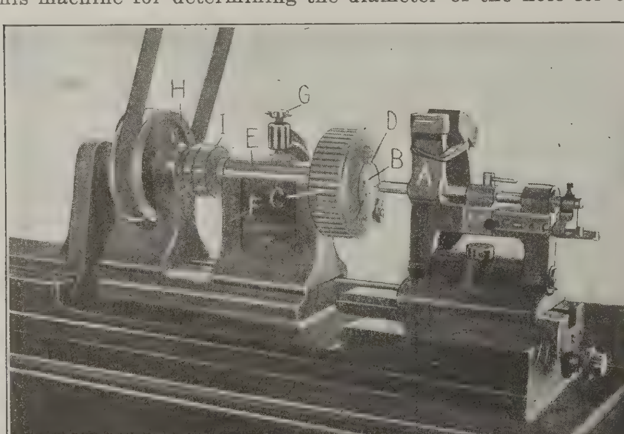

Fig. 44. "Cutting-in" Machine for Jewel Settings

jewel. This caliper rest is shown in detail in Fig. 45. The jewel is placed between the two jaws *D* and *E*, and as arm *F* is cast rigid with the base, it follows that (when the jaws are together) arm *H*, which is pivoted at a point *G*, must be deflected when the jewel is placed between the jaws. As radius *R* is twice *r*, the spindle *C* of the machine which fits in the bushings *I* is moved out a distance equal to the radius of the jewel. Then, as the cutter is set directly on the center line or axis of the machine spindle, it will produce a hole (when cutting on one side only) equal to the diameter of the jewel.

The plate or bridge in which the setting is retained is bored out in the "cutting-in" machine shown in Fig. 44. This machine is also provided with a caliper rest *A* similar in construction to that shown in Fig. 45. The work is held in the quill chuck *B*, which is tightened onto the work by turning the corrugated ring *C*. This ring, in turn, operates a ring having cam grooves which draw in the dogs *D* to grip the

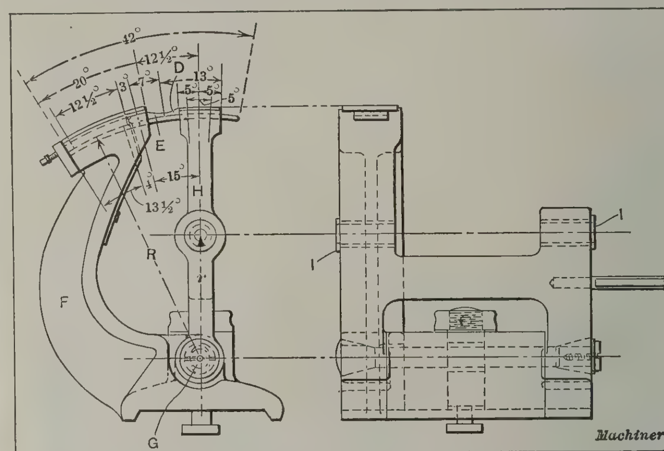

Fig. 45. Construction of the Caliper Rest shown in Figs. 43 and 44

work. This chuck is provided with a quill in which the spindle of the chuck rotates. The quill *E* is held by a clamp screw *G* in a U-shaped groove cut in the rest *F*. The spindle of the chuck is driven from pulley *H* by means of a clutch *I*. This method of holding and driving the chuck is conducive to greater accuracy, because vibration and wear are practically

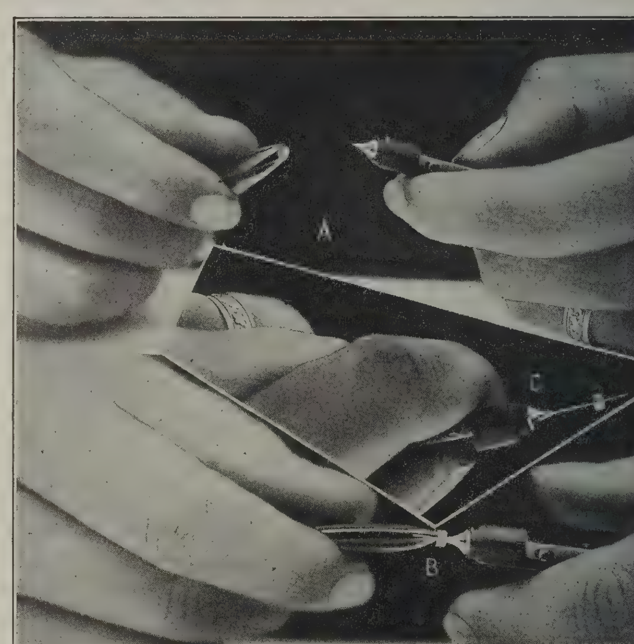

Fig. 46. Gaging the Holes in Jewels by Means of a Needle Gage

eliminated. The pull of the belt does not affect the alignment of the spindle, and the latter is free to rotate in the quill which is clamped rigidly in the rest.

Another good feature of the quill chuck is that it can be removed from the machine and replaced with the assurance that it will always run true and be in perfect alignment. A chuck is also made for every different part, and is used only for that part, thus insuring interchangeability—one of the chief objects sought in modern manufacturing.

Polishing and Gaging Jewels

The jewels used for bearings in watches are obtained from Switzerland already drilled. It is necessary, however, to lap the holes and round the corners (making what is called an "olive" hole), so the staff will rotate in it with as little friction as possible. The jewel is held in a small speed lathe, the spindle of which is rotated at about 150,000 R. P. M. The polishing is accomplished by a lap made from peg wood—the same class of wood as is used for pegging shoes—charged with No. 6 diamond powder.

After lapping, the holes are gaged by means of a "needle" gage in the manner illustrated in Fig. 46. At *A* the gage is shown in position for inserting it into the jewel; at *B* the operator has forced the needle into the jewel, and is obtaining the correct reading on the scale; and at *C* the needle is forced out to the limit. The needle is slightly tapered and is set in a holder, and its position with reference to the scale gives the diameter of the hole in the jewel. It is absolutely necessary that the jewel be placed on the needle in the manner illustrated at *A* in Fig. 46, because of the slenderness of the needle. If it were attempted to put the jewel on the needle when the latter was in the position shown at *B* or *C*, a broken needle would be the result.

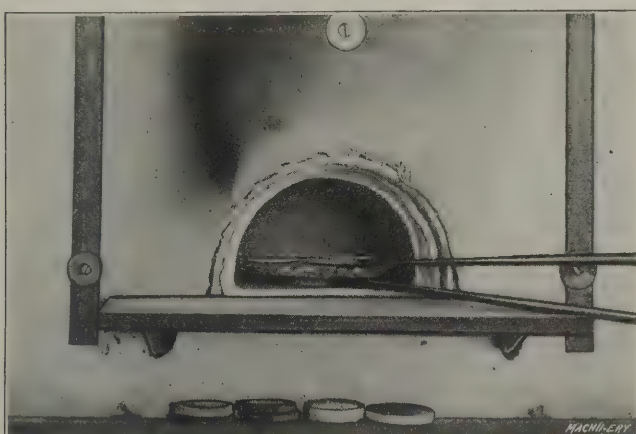

Fig. 47. Furnace for "Baking" the Enamel on the Watch Dials

Making Watch Dials

A watch dial consists of a copper disk or base upon which three or more layers of enamel are deposited. The first coat —known as the grip coat—is much harder than the top or last coat. The enamel used for watch dials comes from Germany. It is received in the form of lumps, which are broken up and put in a grinding barrel provided with a wedgewood lining. The grinding is accomplished by porcelain balls, which are put in the barrel with the lumps of enamel. After the enamel is ground it is sifted through bolting cloth—the same as that used in flour mills—two meshes of this cloth being used. The finely powdered enamel is used on the back of the dial—it being absolutely necessary that the enamel used on the front of the dial be of a uniform size of grain.

After the copper bases have been blanked out in the punch press, the dial feet are riveted in. Small rings are then soldered around the base of these dial feet so that they will be held securely. In soldering the dial feet into the copper blank, the latter is bent out of shape, so it is necessary to flatten it on an ordinary flat die.

When the dials or bases have been prepared in the manner described, the copper bases are laid flat in a sieve tray, after they have been cleaned in acid, washed and dried. The tray containing the copper blanks is then taken to a sifting device which holds the ground enamel, the latter being sifted over the dials by means of a knocker, producing a slight vibratory movement of the container, thus spraying the enamel evenly over the copper blanks. After an even deposit of enamel has been sprayed on the copper disks, they are dried over a gas fire. Both the back and front of the copper disks are treated in this way. Then the front of the dial receives a second coat of a uniform thickness. After applying this coat, the enamel is fused in the gas furnace shown in Fig. 47, where the dials remain for about one minute. They are then taken out and allowed to cool off gradually.

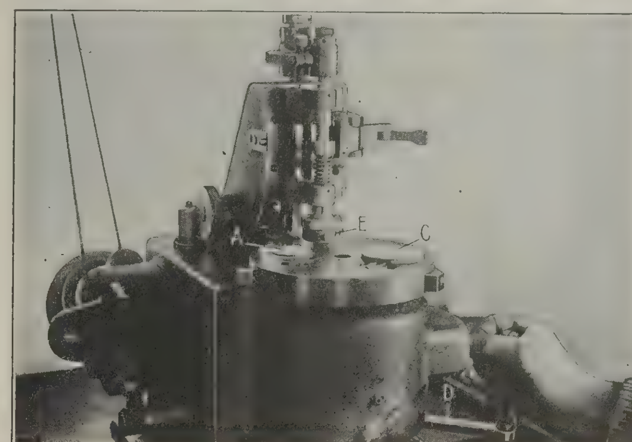

Fig. 48. Dial Printing Machine

The dials used on expensive watches are as a rule double sunk, that is, they are composed of various sized disks soldered together, that portion of the dial around the second hand usually being depressed. In such a case the enamel-coated disk is taken to a small grinding machine where that portion of the dial to be sunk is removed by means of a copper arbor coated with flour of emery, and located by means of a pilot fitting a punched hole in the dial. This emery charged arbor grinds away the enamel down to the copper on each side of the dial. The dials are now coated with paraffine wax, and an aluminum cup is placed around the ground ring in the enamel; then this is luted in place with wax. This aluminum cup is now filled with pure nitric acid, which eats or burns through the copper in about ten minutes.

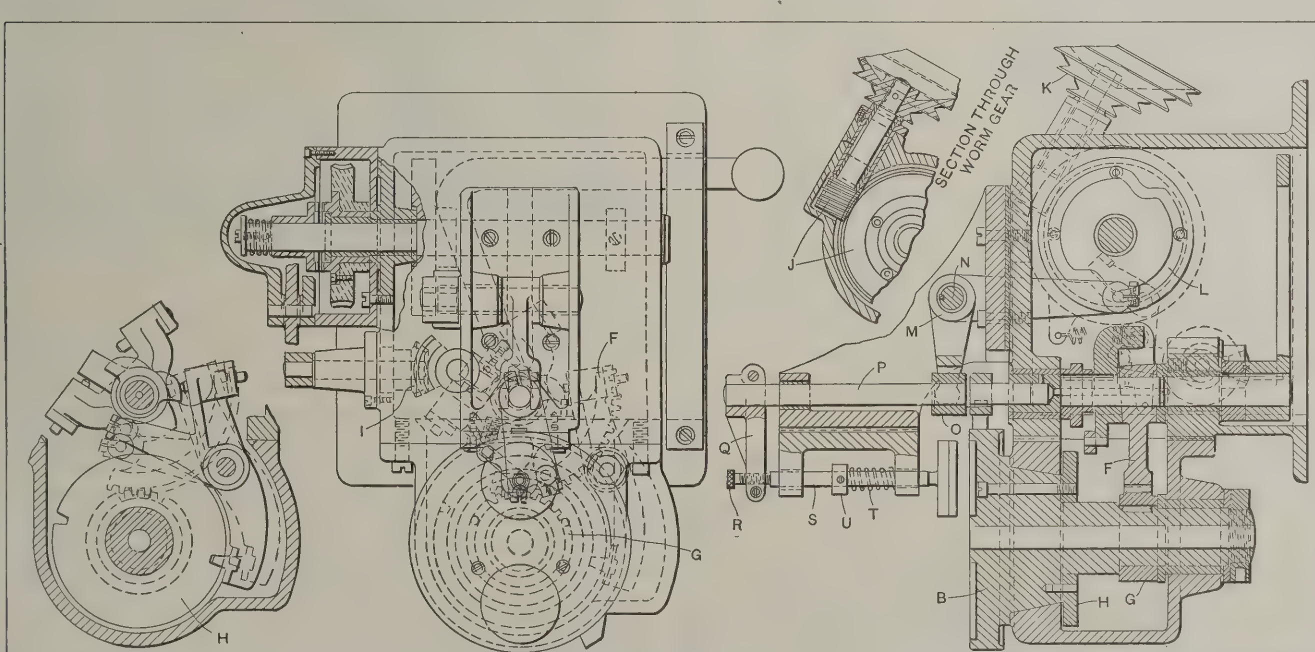

Fig. 49. Construction of the Dial Printing Machine shown in Fig. 48

While eating out the small copper disks with nitric acid, the dials are placed in a box-shaped container, provided with a rather ingenious arrangement to carry away the fumes of the acid. As is well known, nitric acid fumes, if in the vicinity of steel parts, will soon cause oxidation. Now, as the dial house is in close proximity to the factory in which the steel parts are made, the fumes of the acid would be carried to the other manufacturing departments and cause an endless amount of trouble. The device about to be described,

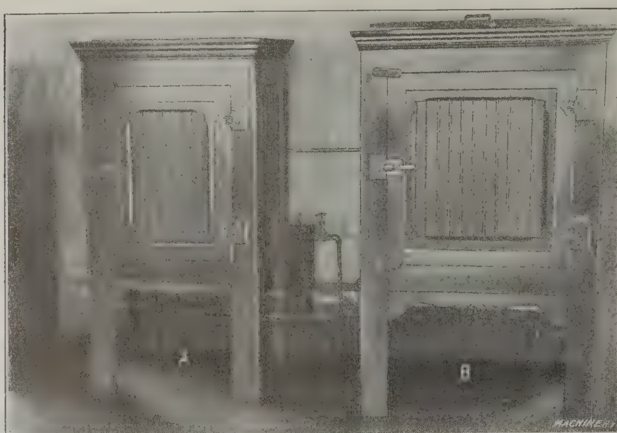

Fig. 50. Temperature Adjusting Cabinets

which was devised by Mr. Charles T. Higginbotham, consulting superintendent, takes care of these acid fumes in a satisfactory manner.

The arrangement consists of a funnel-shaped box through which the acid fumes are blown by means of an electric fan. This funnel-shaped box terminates in another box, where the fumes meet with a fine spray of water which descends in the

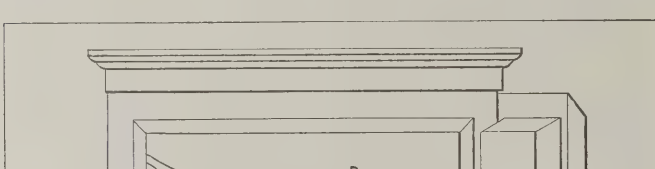

Fig. 51. Interior Arrangement of the Temperature Adjusting Cabinet shown at A in Fig. 50. Fig. 52. Temperature Regulator

shape of a fog, absorbing the nitric acid fumes and carrying them to the sewer.

After burning out a portion of the copper disk, the hole is lapped with a copper lap coated with a putty powder made from oxide of tin. The sunken portion of the dial is then cemented in place with gum arabic and the parts are soldered together. The dials are next coated with shellac varnish to obviate scratching. There are a number of other minor operations on the dials before they are ready to have the characters stamped onto them, such as beveling the edge, drilling cross holes through the dial-foot pins, etc.

Printing the Characters on Watch Dials

The characters which were formerly painted on watch dials by artists are now put on by means of a transfer method, using a steel stamp in a dial printing machine. This machine is shown in Fig. 48, and in detail in Fig. 49. The dial to be printed is placed in a nest *A* held in the table of the machine. The steel stamp *C* fastened to the table has the characters cut in it (not in relief). This stamp is coated with fondant and the excess material removed, leaving the characters filled with the "paint." The operator, by means of handle *D*, now throws in the clutch, indexing the table to bring the steel stamp under the rubber transfer pad *E*, the latter being brought in contact with the stamp by means of a cam. The table is again indexed, bringing the dial under the rubber transfer pad, and the characters are stamped on.

The mixture used as a paint for printing the characters on the dial is composed of black enamel, which has been ground extremely fine and then mixed with oil of thyme. After the dials have been stamped they are coated with "under-glacé" and the dials black-fired. Before this latter operation, however, the dial has received two impressions in the dial print-

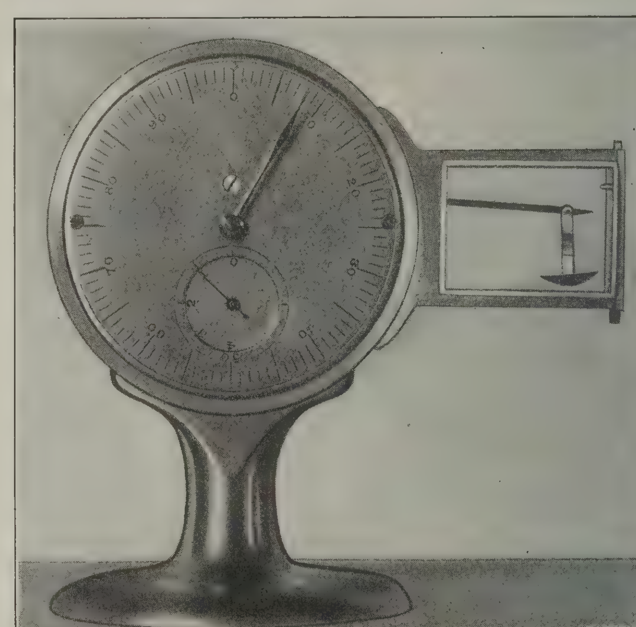

Fig. 53. Scales for Weighing Balance Screws

ing machine, the first impression being allowed to dry before th second one is applied. The black-firing takes place in the gas furnace shown in Fig. 47.

The machine used for printing the characters on the dial has some interesting mechanical features. It consists essentially of a table *B* on which the work and stamp are held. (See Fig. 49). This table is indexed or rotated by means of a sector gear *F* meshing with a pinion *G* keyed to the spindle of the table. An indexing dial *H*, provided with two notches in which an indexing finger fits, locates the table in the two positions. The sector gear receives its motion through bevel gears *I* and a worm and worm-wheel *J*, the latter being driven by pulley *K* belted to the overhead works.

The rubber transfer pad is operated by means of a cam *L* and bell-crank lever *M*, the latter being fulcrumed at *N*. The upper arm of this lever straddles a sleeve *O* which butts against a shoulder on spindle *P*. This spindle has an arm *Q* fastened to its top end carrying an adjustable screw *R* which comes in contact with the upper end of the spindle carrying the rubber pad. Spindle *S* is returned to the "up position" by means of a spring *T* working against collar *U* which is fastened by a set-screw to the spindle.

Assembling and Finishing Operations on Watch Movements

Upon completion, all of the small parts are turned into the stock-room from which they are sent out when needed. When

the jewels have been burnished into their settings, the settings are put into the plates and bridges, and the latter are ready to be assembled with the various parts of the movement. Following this, the hair spring is trued, over-coiled and vibrated for strength. The balance is also trued up and fitted to the staff. Probably one of the most interesting operations performed on a watch movement in its final stages of completion, however, is that of temperature adjustment. After the watch movement has been completely assembled and tested, it is placed in the oven shown at *A* in Fig. 50. This is provided with a water jacket having a capacity of 40 gallons, and is heated by two 4-candlepower bulbs, which keep the water at a temperature of 90 degrees. The water jacket is used as a precautionary measure so that in case the electric current is turned off for a short time there will be no difference in the temperature.

The device used for heating this cabinet and keeping it at a uniform temperature is shown in Figs. 51 and 52. The door is made to fit closely and is provided with a door jamb set at an angle. The electric bulb *B* is wired to the electric circuit and also to the temperature controlling mechanism. This, as shown in Fig. 52, consists of a wooden base *C*, to which a block *D* is fastened to hold the lamp socket. Two bi-metallic bars *E* and *F* are let into a wooden block *G*. These bars are made from a strip of brass ½ inch wide by 0.060 inch thick by 12 inches long, to which a strip of steel 0.040 inch thick is soldered. The wires *L* and *M* lead from the switch of the electric wiring, while wire *O* connects the bar *E* with the lamp. The brass strips on these bars face each other. Contact is made by a platinum tipped adjusting screw *P* that comes in contact with the platinum facing *R* on bar *E*.

This device works on the same principle as a compensated balance. Heat expands the brass strips to a greater extent than it does the steel strips, thus bending the bars outward and breaking the electric circuit by separating the platinum faces. Screw *P* is used to adjust the contact at the proper point, so as to regulate the temperature. A thermometer *Q* is suspended with its bulb near the watches to be tested, so that a true temperature will be recorded. The watch movements are kept in this cabinet at a temperature of 90 degrees F. for 24 hours.

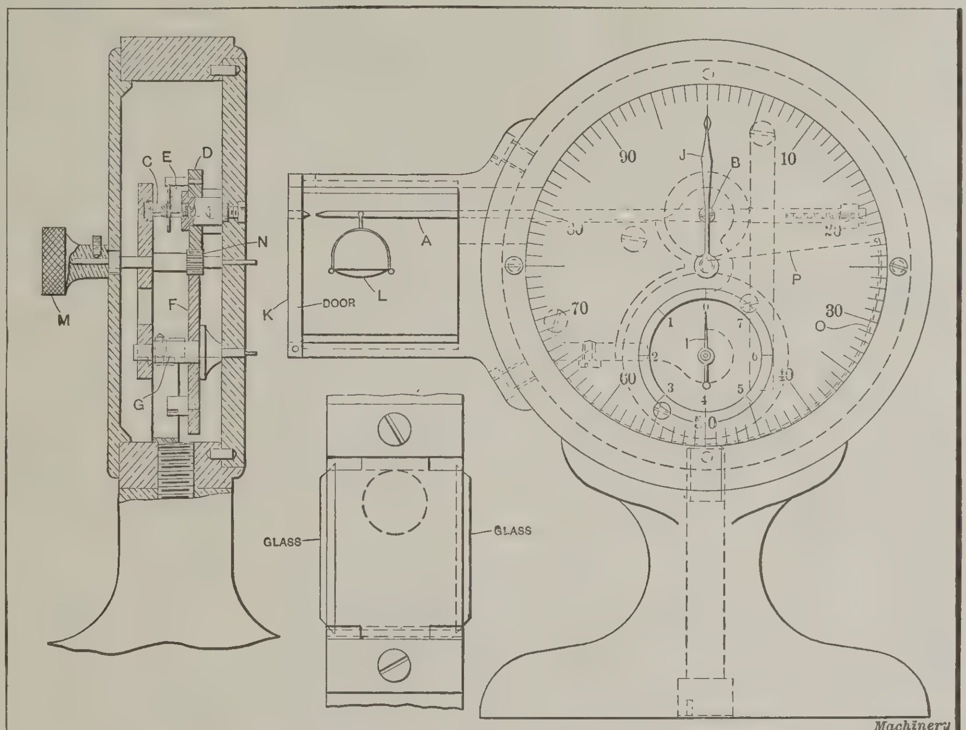

Fig. 54. Construction of the Balance-screw Scale shown in Fig. 53

After the movements have been removed from cabinet *A*, Fig. 50, they are placed in the ice box shown at *B*. Here they are left for 24 hours at a temperature of 45 degrees F. They are taken out and the change in time noted. The adjustment for temperature is accomplished by changing the weight of the balance screws, and also their location in the rim, so as to equalize the expansion and contraction of the balance.

Weighing Balance Screws

The scales used for weighing the balance screws are shown in Fig. 53 and in detail in Fig. 54. The dial is provided with 100 graduations, each graduation equaling one ten-millionth of a pound avoirdupois. The lower dial hand registers 1 when the larger hand makes one complete revolution of the dial.

Referring to Fig. 54, it will be seen that this scale consists of a beam *A* pivoted at point *B* on a balance staff *C*, the pivots of which run in jewels. Attached to the staff *C* and to a pin in wheel *D* is a watch hair spring *E*. The main wheel *F* held on arbor *G* rotates the small needle *I*, which makes one complete revolution to every eight revolutions of the large hand *J*.

To weigh a balance screw, the glass door *K* is swung back and the screw deposited in pan *L*. Then the door is closed and the hair spring *E* wound up by means of knurled thumbscrew *M* and pinion *N*, until the tension of the hair spring overcomes the weight of the screw. The screw is then removed from the pan and the door closed, when the hands register the weight of the screw on the dial in ten-millionths of a pound avoirdupois. Flat spring *O* and thread *P* take up the back-lash in the gearing. So sensitive is this scale that the amount of lead deposited on a piece of paper when writing a name with a lead pencil is clearly registered on the dial.

A difference in weight in a pair of screws, located in the rim of the balance, of one ten-millionth of a pound equals a variation of one second an hour in a watch.

Final Inspection

In the making of the South Bend watch movement parts, over twelve thousand separate and distinct operations are required. Over one hundred operations are performed on the dial alone, while the completed watch has passed through four hundred and eleven inspections. After the watch movements have been accurately adjusted and timed they are, as a final test, run for six days in order to insure uniformity of rate. Even after a watch movement has passed through all of these inspections and has been packed ready for shipment it goes to a final inspector, who unpacks the movements and puts them through a final examination for the purpose of reducing to a minimum the chance of any defect.

* * *

A bill framed as a committee measure by the Patents Committee of Congress, and which covers the features of all the different bills that have been brought in during the present session of Congress relating to patent monopolies, contains the following features of special importance: It provides for compulsory licenses, which, however, will not apply to the original inventor, but only to those persons or corporations who acquire patents by purchase, and who in the past have often done so for the purpose of suppressing competition. It also provides that no purchaser, licensee or lessee of a patented article shall be liable for action for infringement of the patent because of breach of any contract of sale or license. The bill does not propose to take away any right of action, so far as the contract is concerned, but it does take away the rights that may now exist to bring an infringement suit growing out of a contract with regard to the use or sale of a patented article. It also proposes to so amend the Sherman anti-trust law as to make it clearly applicable to combinations and trusts in restraint of trade where patents are involved in the monopoly.

THE REVIVAL OF BUSINESS

The fall season has opened with a heavy increase of business in iron and steel products, machine tools, accessories and kindred lines required in manufacturing, which makes the outlook bright; but the tendency to mark up prices higher than conditions warrant is a mistaken policy that will inevitably result in a setback.

The crops are large and the railroads have more freight than they can move, and there is already a car shortage which is likely to increase to serious proportions. So marked a revival of trade in a presidential election year is a phenomenon almost unequaled. The common notion that business must be dull every four years apparently has been exploded, and we sincerely hope that the quadrennial scare incident to the presidential election has been dispelled.

America's resources are too great and its business is based on too solid a foundation to be seriously disturbed by possible or impending changes in the political complexion of the government. Changes in economic policy are inevitable, and whatever the coming readjustment of the tariff schedule may be—for readjustment there will be, in some respects, whoever is elected—these changes will be made conservatively and with due regard to the welfare of the great industries that have developed during the past fifty years under a protective tariff.

THE TESTING OF MATERIALS

When speaking of the testing of materials for construction, one generally understands merely the testing, by suitable machines or other means, of the various qualities of a material. The scope of the work of the International Association for Testing Materials, however, is much greater than implied by this narrow definition of the testing of materials. It is recognized that it would be of little or no use, though we were ever so expert in the mere testing of materials, if we did not at the same time know exactly what was required of certain materials for certain service. We may, for example, be able to test the tensile strength, elastic limit, hardness, elongation etc., of the material entering into steel rails, but the information thus obtained would be of comparatively little value did we not at the same time know, with certainty, the requirements necessary for steel rails that have to stand the pounding of heavy engines on a sharp curve at high speeds. It is the object of the men interested in the testing of materials not only to devise means for carrying out the required tests, but also to settle upon the necessary specifications for materials to be used for different purposes and to aid the makers of these materials, if possible, in obtaining the required qualities in them. The scope of the International Association for Testing Materials, therefore, is a very wide one. It embraces in its final analysis not only that part of the engineering science which deals directly with the study of materials, but also that which enters into the fields of design and manufacture. The work of the association is highly important to the engineering world, and the sixth congress of the association, held in New York City during the early part of September, tended to emphasize this fact. The great number of papers presented indicated the activity of the members, and the engineering world, in general, is to be congratulated upon the effective work being done.

* * *

MECHANICAL EFFICIENCY

The theory of the efficiency of machines is one of the simplest in applied mechanics, but it nevertheless seems to be one very often misunderstood and misapplied. The hundreds of inventors of perpetual motion machines are notorious examples of those who misunderstand it and the great principle of conservation of energy, but they may be classed as impractical men of little or no importance in the machine building world. There is another large class, however, whose ideas are embodied in machines built, sold and used with various degrees of satisfaction who are more or less hazy on certain fundamental principles. It is important that this class thoroughly understand the general principles which conserve power, reduce wear, and tend generally to promote the life and efficiency of machines.

A machine may be effective without being mechanically efficient, and again it may be mechanically efficient without being effective. This is an apparent paradox generally understood and appreciated. A worm-gear, as ordinarily made, is effective but not efficient, and on the other hand if highly efficient it fails to be effective as a brake—a most important consideration in some machines. In the case of machine tools, mechanical efficiency is ordinarily regarded as a minor matter, while accuracy, convenience of operation, adaptability, safety and pleasing lines are of paramount importance. But mechanical efficiency, aside from power saving, is important, nevertheless, as a mechanically inefficient machine wears rapidly and requires more lubrication to do its work than the efficient machine.

The efficiency of a machine is measured by the percentage of useful work available after transformation in the machine. The percentage of useful work is always less than one-hundred, is rarely over ninety-five in the simplest mechanisms, and is often less than ten. Efficiency is expressed by the formula: $E = \frac{W - w}{W}$, in which E is efficiency; W, the work put in; and w, the work delivered.

A stiff machine in which the train of mechanism is well supported is more efficient, other things being equal, than one having a weak and flexible train. Work is lost in bending the parts, especially when the action is intermittent. A reciprocating motion may be transmitted, for example, through a lever so weak and flexible that all the work put into the machine is lost in deflecting this member, thus producing molecular distortion and heat. Take, for example, a compressed air riveting machine of the alligator type. The stiffness of the levers is an important factor in its efficiency. A riveter having ample cylinder capacity might, nevertheless, be so weak in the levers that the toggle action would fail to produce the squeeze necessary to upset the rivets. The work that should be expended on the rivets is lost in friction of the pivots and in springing the levers which yield at the critical position so much that the necessary force to upset them is not developed. This machine would use as much compressed air as another of the same size but with stiffer mechanism which would effectively set the rivets. One is efficient and the other is totally inefficient.

Hence mechanical efficiency, while meaning the percentage of power available in terms of the power expended on a machine, should also mean that the machine is so designed that its parts are subjected to minimum wear, that a minimum amount of oil is required for lubrication and that no part is subjected to such high bending stresses at any point that it bends appreciably when transmitting the load required to do its work effectively.

* * *

SQUARE AND HEXAGON SOCKETS

The analysis of the stresses acting in square and hexagon socket safety set-screws by Mr. Myers in another part of this number, is an excellent example of practical application of mathematics to design. This is a case in which the strength of two members should be equal, if possible, but the proportions necessary for equal strength cannot be determined by simply adding here and taking off there. While the analysis is not rigid, it is sufficiently complete to answer practical requirements. It shows how the wrench socket may be so proportioned as to secure the maximum strength for both the wrench and the screw. Of paramount importance is the matter of durability when the hollow screw is employed for lathe chucks and other parts requiring constant manipulation. While it is shown that for pulley hubs and other machine parts the hexagon socket set-screw is best, as it can be so proportioned as to have greater strength than square socket set-screws of the same size, it is also shown that the square socket is better adapted for those situations in which it is subjected to daily use. Hence for lathe chucks, drill chucks, lathe dogs, etc., the square socket is preferable.

The superiority of this method of determining proportions of machine parts over mere guesswork and numerous tests is obvious. Tests, of course, are necessary to verify conclusions and make certain that the minor factors neglected in calculations are not of greater importance than assumed, but a comparatively small number of tests will suffice to verify a rational design; whereas, with rule-of-thumb or guesswork design those proportions necessary for maximum strength and efficiency are usually found only by a slow and costly process.

* * *

TABLES AND DIAGRAMS

There is considerable difference of opinion among mechanical men regarding the relative advantages and uses of tables and diagrams for recording data. Some engineers seem to prefer to tabulate all data coming under their observation, which may be useful in their practice, regardless of the fact that much of this information could be more conveniently shown in diagrams. Others have what might be called the diagram hobby, and apparently believe that all mechanical data that can possibly be given in diagram form should be put in that shape.

Both of these extreme types show a lack of appreciation of the true uses of tables and diagrams. There is, in general, a fairly well-defined field for each, and engineering data should be recorded partly by tables and partly by diagrams, according to which form best meets the requirements of the practical man. Whenever the matter dealt with has to do with parts, devices and objects made in certain specified sizes, once standardized, a table is most convenient. As an example, may be mentioned data relating to tap drills and other dimensions required in the use of pipe taps. Here a diagram is of little or no value, as there are but comparatively few standard pipe tap sizes, and all the dimensions relating to each of these sizes can be easily and conveniently tabulated with much greater exactitude than they could be put in diagram form; at the same time the chance of error in using a table is far less than in reading off a dimension from a diagram. The diagram, again, is most useful in cases where an indefinite number of combinations of values may exist, and where curves may be used to indicate the values to be found for any combination. An example of this kind is a horsepower diagram from which the horsepower that may be transmitted by gearing of different pitches and velocities may be found. In this case, tables would be entirely too voluminous, and could hardly contain all the possible combinations covered by a diagram of comparatively simple construction.

In a general way, therefore, the proper place for a table is where certain definite data are known and fixed and the values to be found corresponding to them can be conveniently put in plain figures. The diagram should be used instead in all cases where a great number of different combinations of two or more initial values are given, and where a tabulation would be entirely too voluminous to be practicable, both because of the time required for compilation and the inconvenience incident to its use. The diagram has in some cases another advantage—a curve may show the trend of certain functions, indicating the rising or falling values under certain conditions, etc. In this case, the diagram is especially useful in investigating work, when making tests, or when comparing the relative efficiency of mechanisms.

THE ONE HE GOT FROM HOME

BY A. P. PRESS

Bill was a first-class toolmaker, one of the very best we had in the shop, and the only fault we had to find with him was that nothing he ever did or saw us do—in fact, nothing in the shop or even in the whole country was so good as what they did "back home." What they did "back home" according to Bill's tell was certainly a wonder.

One day he got to talking to the boss patternmaker about extension bits.

"I tell you what, the extension bits we have 'back home' are way ahead of anything that you can get in this country, and the next time any of the boys go 'home' I am going to send and get one for you. I'm willing to pay for the bit, just to show you what they make over there."

Two weeks after that one of the boys in the shop made up his mind to take a trip to the old country, and when he came into the shop, after he got his ticket, Bill put it up to him to get him (Bill) an extension bit.

"Buy me the very best extension bit you can find, no matter what you pay for it, or who makes it, and bring it back when you come, and I will make it right with you."

"All right," and off he went.

Two months passed by, and one day he came in and asked for his old job, and as he was a "crackerjack" good man, we were glad to get him, and told him to come in in the morning.

When he came in the next day he brought in Bill's extension bit. It was in a box the same as they make "back home," and what it said on the label we are unable to tell as we only read and speak one language.

"There," said Bill, as he proudly took it out of the case, "there's a bit that is a bit. Look at that finish, and look at the way the blade is held in on the end."

"Say, but that is pretty good," said the boss patternmaker, "but at the same time it looks kind of familiar. What name is that on the shank? Hold on a minute. I can read that. Why that was made by the S. S. & S. Co., right up here in the next town."

"Well, Bill," said the boss patternmaker, "I want to thank you for that bit. Never mind if it was made only ten miles away, it has been to the old country and back again, and that is more than I ever expect to do, and I shall treasure it all the more for that."

This was the last of anything that we ever heard about "back home."

* * *

According to *The Foundry*, experiments have been made by the Crane Co., Chicago, Ill., which have shown that if iron borings are used in place of a portion of the gravel mixed in concrete, floors of this material can be successfully used in certain portions of foundries. Many foundrymen are interested in the use of concrete floors, but have generally found them unsatisfactory because molten iron will not lie on concrete on account of its porous and, therefore, generally moist condition. The mixture recommended consists of one part cement, three parts sand, four parts gravel, and one part of iron borings. It is stated that floors made from this mixture are perfectly safe.

CASEHARDENING AND CASEHARDENING PRACTICE*

A REVIEW OF METHODS IN THE BICYCLE, AUTOMOBILE BUILDING AND ALLIED TRADES

BY ROBERT H. GRANT†

A great improvement has been made in casehardening processes during the last few years. The advance was begun with the development of the bicycle industry, and the necessity for casehardened parts of the highest quality in automobile manufacture has been the cause of still further improvements in this field.

As an example of what can be accomplished by proper methods, consider the transmission gearing of an automobile. Who would think of throwing in the back-gears of a lathe or any other machine tool without first stopping the machine? In an automobile, however, this very thing is actually done, perhaps a hundred times a day, by a person who gives little thought to what he is really doing. Yet the gears stand up under this treatment because of being manufactured from special steels developed during comparatively recent years, and because of being heat-treated and casehardened by improved methods.

Principles of Casehardening

Casehardening is actually only an improvement on the old cementation process used in times past for making steel from wrought-iron. This process consisted of rolling the wrought-iron into thin strips and then placing it in boxes with some material containing a fair portion of carbon. These boxes were then heated to a very high temperature and the carbon was gradually absorbed by the iron.

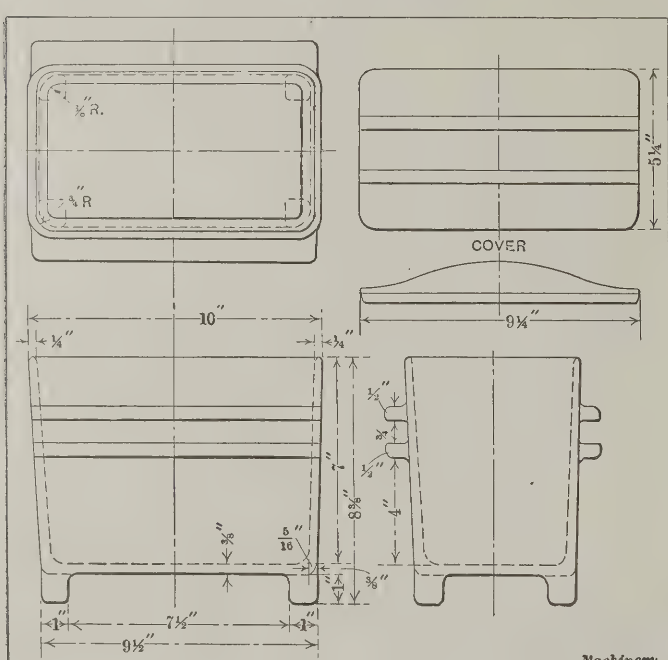

Fig. 1. Box for Casehardening, of Approved Design

In modern casehardening there are a number of different questions that must be taken into consideration. In the first place, the steel or material to be used must be considered. Another most essential thing is the casehardening furnace which must give a uniform heat. As oil has almost wholly superseded coal for heating casehardening furnaces, the changes in furnace construction have, of late, been considerable. The box constitutes another item which must be considered, as well as the material used in packing the parts to be casehardened. The methods used for hardening the parts after they have been carbonized is another question that must be dealt with.

Steel to be used for Casehardened Parts

As the casehardening process consists in adding carbon to the steel, it is necessary to use a material which will absorb the carbon without necessitating overheating or burning. The effect of carbon on steel is, in general, it may be said, to make it dense, and the denser the steel, the higher the heat necessary to open the pores through which it must absorb the carbon. A low carbon steel containing say from 0.15 to 0.20 per cent of carbon is, therefore, most suitable for casehardening. It should also be borne in mind when selecting the material that the casehardening process does not eliminate any of the impurities ordinarily found in iron, such as sulphur, phosphorus, etc., and hence a material as free as possible from these impurities should be selected.

Furnaces for Casehardening

In building or constructing a furnace for casehardening, the size of the work to be hardened should be the first consideration. It is far better to use a small furnace with a small box whenever possible. If the work varies in size, different sizes of furnaces may be used. Small furnaces require less fuel, and small work must be placed in small boxes as otherwise the pieces packed near the sides will be overheated while those in the center will not reach the required temperature. The furnaces should be made right- and left-hand so that they can be placed close together. Thick walls should be used to retain the heat. These walls should be supported by a substantial concrete foundation, so that they will retain their position and shape, even when subjected to a high heat. Large flues should be provided to carry away the smoke and gases.

The furnace should also be so constructed that as much as possible of the heat of the combustion gases may be extracted before they are discharged. The flues and all parts of the furnace should be easily accessible, and a door, the full width of the oven, should be provided so that the tiles can be taken out and the flues cleaned. A pressure blower with a light oil should be used with all the pipes accessible and placed, preferably, above the furnace. If, however, they are placed below ground, they should be arranged in compartments which can be easily reached if repairs are required.

The blower pipes should be run through the furnace so as to preheat the air used; if cold air is used directly it will reduce the heat in the furnace. The furnace fronts should be made in several parts to prevent cracking, with the door properly balanced and lined. A shelf should be provided, projecting at the front, for holding the boxes when they are taken out or put into the furnace. The smokestack should be made of sufficient height to produce a good draft.

Burners should be placed both at the front and rear of the oven and should be arranged in separate compartments, so that the heat will be uniform in the oven. The hot gases will then pass over the top of the compartment wall and strike the boxes on the top, after which they pass out through small openings in the corner of the furnace. They then take a zigzag course under the tiles and pass from there through a flue to the rear of the furnace. A large conduit should be provided just below the ground which will catch all the soot. This conduit should be provided with iron covers which can easily be taken off to remove the accumulation of soot.

The furnace should not be heated too quickly, as this is apt to crack the brickwork. The cooling should also be done gradually. After the work has been taken out and the heat shut off for the day, all the dampers should be closed to hold the heat. In this way the furnace will cool slowly and cracking or bulging out of shape will be prevented. In addition, it will be easier to heat the furnace the next morning, as it will have retained some of the heat.

When work is to be annealed, it should be placed in the furnace after the work to be hardened has been removed, and then the furnace brought to the proper heat. The ma-

† Address: 912 Oakland Ave., Ann Arbor, Mich.

terial to be annealed can then remain in the furnace until the next morning with the furnace closed up and the burners turned off.

A light oil should be used. It should have a high heating value and be comparatively free from carbon deposits, etc.

Boxes for Casehardening

The boxes for casehardening should not be made larger than necessary for the class of work being handled. They should be made from a malleable iron, as ordinary cast-iron boxes are not suitable on account of the fact that they are very porous and absorb the carbon of the carbonizing material. The boxes should also be provided with feet, as shown in Fig. 1, so that the heat can circulate all around them. The covers should be provided with ribs on the top to prevent excessive warping, and the sides should be ribbed so that a

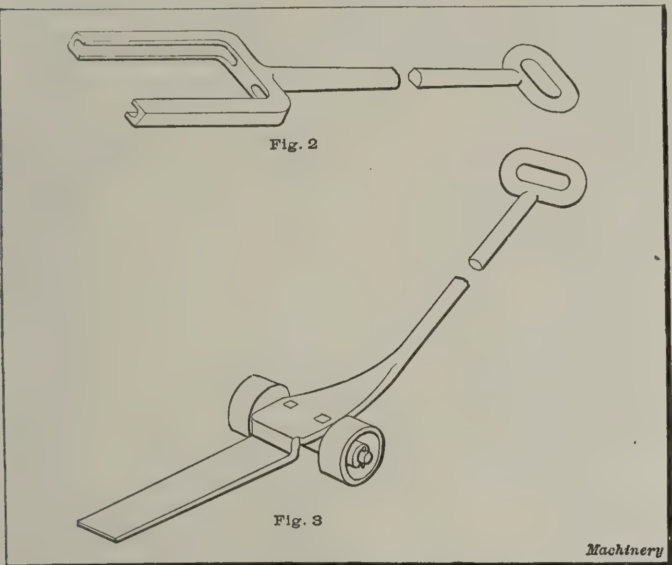

Fig. 2. Grapple Iron or Fork used for Handling Casehardening Boxes. Fig. 3. Truck for Handling Heavy Boxes

fork or grapple iron, as shown in Fig. 2, can be used for handling the boxes. The sides of the boxes should taper slightly towards the bottom so that the contents can be easily dumped out of them; they are also easier to cast when made in that way.

When very large boxes are required, they should, if possible, be provided with a hole through the center so that the heat can reach the contents from the inside, as well as from the outside. A box of this kind is shown in Fig. 4. For long work, such as shafts, tubing, etc., a wrought-iron pipe with a cap on each end provides an ideal box.

Local Hardening

In many cases it is essential that the piece of work be hardened at a certain place and that other parts be left soft. There are three ways in which this can be accomplished: First, by copper-plating and enameling; second, by covering the part which is not to be hardened by fire clay; and third, by using a bushing or collar to cover the part to be left soft.

In the first case the article should be painted with enamel where it is to be hardened, the enamel being baked after having been applied. The remainder of the piece that is to be left soft is copper-plated. In the second case, if the article to be hardened has a recess, such as a hole, slot, etc., this may be filled with clay. The third method is used when a shaft, for example, is only to be left soft for a short distance. A collar is then placed on the shaft, and this provides the easiest and least expensive means for accomplishing the purpose.

In the case where enamel and copper-plating is used, the enamel will burn away and allow the surface covered by it to absorb carbon and, hence, to be hardened, whereas the copper will stand a very high heat and prevent hardening of those portions that are covered by it. If the copper is burned off, it is an indication that the work has been overheated. The clay prevents the hardening of a portion of the work in the same way as does the copper. It is also of advantage when dipping the work, as it prevents the formation of steam pockets which are apt to warp or distort the piece. When a sleeve or collar is used, this should be made about one-half inch longer than the part which is to be left soft, so as to prevent carbonization near the ends of the collar.

Packing for Hardening

The packing room should, if possible, be separate from the room containing the furnaces, so that the packing can be done without the discomfort of the heat and dust. Tables on wheels, or trucks, provided with shelves of the same height as the shelf in front of the furnace and large enough to hold the required number of boxes for one furnace, should be provided, so that the packed boxes can be easily moved to the furnace and quickly placed in it. The work to be hardened should be classified according to its size and the percentage of carbon required, as it will take a higher heat for larger work, as well as for pieces which are required to absorb a higher percentage of carbon.

There are a great many different kinds of hardening materials, but the old-fashioned method of using ground bone can always be relied upon to give satisfactory results. During the last few years, however, the use of bone in various manufactures has increased so that the price of ground bone for casehardening purposes is almost prohibitive. Leather has become very extensively used for this purpose, it being first burned and then ground and graded.

A mixing bin is a great advantage in connection with the handling of the casehardening material. Some partly used bone and some new is then used to make a mixture suitable for the size of the pieces to be hardened. Large pieces require a richer material than smaller ones, as during the higher heat required for the larger pieces and the longer application of the heat, more of the carbonizing material will burn away.

When packing a box, first put a layer of the casehardening material on the bottom, the thickness of this layer depend-

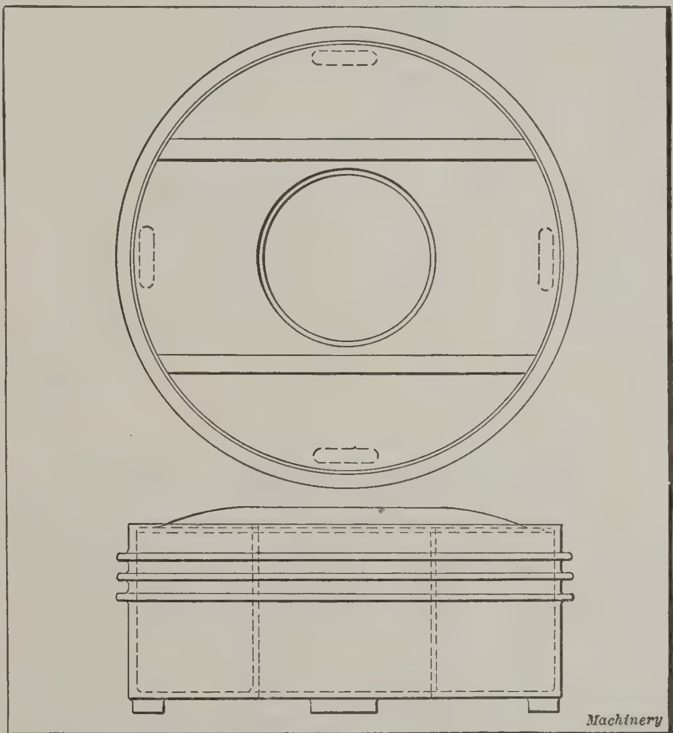

Fig. 4. Large Circular Box with Hole in Center for the Circulation of the Gases of Combustion

ing upon the size of the pieces to be hardened. If the articles are heavy, they do not require such great care in packing, but if they are thin or long, or have a peculiar shape, greater care is required. It has frequently been stated that one piece should never be permitted to touch another when packing, but it has been found that this precaution is not necessary. If a box is properly sealed, the parts can touch each other without injury. Thin long pieces should, if possible, be placed in an upright position to prevent their sagging out of shape. Between each layer of pieces, casehardening material is packed according to the size of the pieces to be hardened. It has been found from experience that if there is not enough

of the carbonizing material in the box, the work is liable to have soft spots.

About two inches from the top of the box, sheet steel strips about 1/16 inch thick should be laid and these should be covered with a layer of about one inch or more of powdered charcoal. Then the cover is placed on the box and the edges are sealed with fire clay. If there is any doubt about the length of time required for heating the pieces to obtain a certain depth of case, wire a couple of pieces together, allowing the wire to project out of the box. These pieces can then be taken out quickly and hardened, and, in this way, it can be ascertained whether the parts have been sufficiently carbonized. In casehardening very small work, it is advisable to wire the pieces together so that they can be taken out of the box at once; otherwise, they would have to be picked out with small tongs, as it is impossible to sift very small work in a screen because the mesh would have to be so fine that it would take a long time to do the sifting and the work would become too cold for hardening. If it is desirable to color the work, from one-third to one-half of the carbonizing material should be burnt leather.

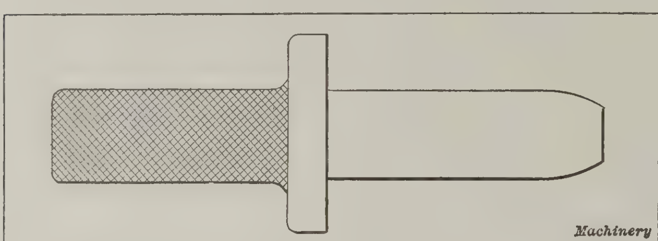

Fig. 5. Mandrel used when Hardening Collars, etc., on the Outside

The boxes should never be put into the furnace under a high heat, but should be placed in it when its temperature is from 800 to 900 degrees F. Then the heat should be slowly brought up to from 1500 to 1800 degrees F. In placing the boxes in the furnace, great care should be taken that the hot gases have an opportunity to circulate all around them. A pyrometer should be put in some convenient place and properly wired so that the heat in the furnace can be readily ascertained at any time. If there is a great deal of night work to be done, a recording pyrometer should be used as it gives the man in charge a record of the heats during the night.

By the aid of the pyrometer it has been found that it is necessary to have an expansion tank in order to get a constant air pressure, otherwise the pulsation from the blower will affect the heat in the furnace. This expansion tank should be situated so that the blower is connected directly with one end while the discharge pipe is connected at the opposite end. This will then act as a reservoir, producing a constant pressure. When oil is used for the heating, it is preferable to pump it from the storage tank in the ground to a stand pipe, which will insure a constant flow of the oil. The intermittent action of the pump, should the oil be used directly as it comes from it, is objectionable. There is also another advantage, in case the pump should have to be shut down on account of break-down. In that case, the furnaces could still continue to operate, as the stand pipe should hold a supply of oil sufficient for several hours. At night and on holidays the oil should be drained back into the storage tank in order to minimize the danger incident to its use.

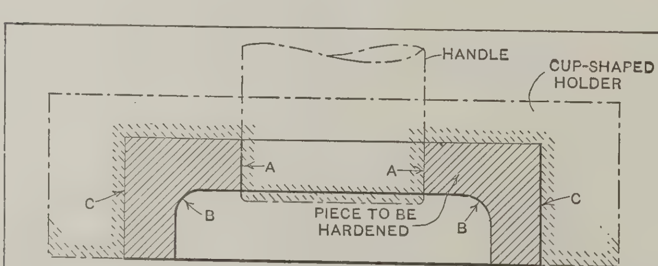

Fig. 6. Holder for Parts which are to be hardened locally

The supply pipe for the air should come from the outside and should be so arranged that the air passes through a fine wire netting, so as to prevent foreign substances from entering the blower.

On the outside of each furnace a card should be placed telling the kind of work that is in the furnace, when the work was put in, the heat required for it, and when it is to be removed. These cards can be kept as a record which will be of value when comparison is made with the depth of case obtained under any specific conditions.

Carbonizing, Reheating and Hardening

The heat required for casehardening is a great deal higher than that required for ordinary hardening. If, for example, the material to be casehardened was heated only to 1375 degrees F., which would be sufficient for the hardening of ordinary tool steel, the result would be very unsatisfactory. In fact, there would be no result at all. Small parts must be heated to at least 1575 degrees F., in which case sufficient depth of carbonized surface will be obtained in from six to eight hours. The time recorded as the correct one for casehardening should be taken from the time the boxes are heated clear through.

The correct way in which to caseharden is first to carbonize the material and then to allow the boxes to cool down with the work in them, after which they are reheated and hardened in water. The reheating refines the grain of the steel and prevents the formation of a distinct line between the outer hardened case and the soft core. If there is a distinct line between these two sections, the case is liable to flake off when the hardened part is subjected to severe stresses.

A still more refined method of casehardening is to repack the work, after it has been carbonized, in old bone, and after heating for two or three hours take it out and dip the pieces in the hardening tank directly as they come from the boxes. This will produce a very fine grain and in many cases prevent warping. If the work is large and it is required to toughen the inner core, it should be reheated to a higher heat than otherwise; then, after dipping, reheat again to 1500 or 1600 degrees F. according to the size of the work, and redip.

However, if the work to be hardened consists of bolts, nuts, screws, etc., it is satisfactory to dump them into water directly from the furnaces, without any reheating. A regular iron wheelbarrow with two pieces of flat iron placed across it lengthwise should be provided. On top of these bars is placed a sieve made from 1/8-inch wire with 1/4-inch mesh, about 18 inches square by 6 inches deep. This sieve should have a handle 6 feet long and 5/8 inch in diameter. The boxes are emptied into this sieve, and after sifting, the heated material is dumped into a tank of cold water which should be of sufficient size to prevent the water from heating too quickly. Care should also be taken in emptying the contents of the boxes into the water that they are not all dumped in one place, but scattered about in the tank. A constant flow of water should be available while the work is being hardened. The work should under no circumstances be removed from the furnace until the heat has been lowered, as the steel should be treated as tool steel after it is carbonized, and it would be injurious to the steel to harden it at the high carbonizing heat.

Gears and other parts which should be tough, but not glass hard, should preferably be hardened in an oil bath. There is then less liability of warping the work, and the hardened product will stand shocks and severe stresses without breakage. Cotton-seed oil is the best hardening medium to be used in this case.

After the work has been properly carbonized, the next operation in the case of all parts, except those mentioned as exceptions above, is to reheat. This may be done either as already explained, or it may be done in a regular muffle gas furnace in which the work can be put in rows on the tile. In this way the work can be heated very slowly, a new piece being put into the furnace to take the place of each piece as it is removed. Collars, etc., which are required to be hardened on the outside, but ought to be left soft on the inside, should be hardened on a mandrel, such as shown in Fig. 5, the diameter of the mandrel being from 0.001 to 0.003 inch smaller than the hole in the piece to be hardened. If the

inside of the piece only needs to be hardened and the outside should be left soft, a cup-shaped holder, such as shown by the dash-dotted lines in Fig. 6, may be used. In this case the work will harden at B while it is left soft at A and C.

The hardening tank should be about 30 inches in diameter and 36 inches deep and have a constant flow of water from a pipe in the center about 6 inches below the surface.

Straightening the Work after Hardening

On account of the manner in which steel is rolled, drawn or forged, the density varies in different parts of the steel, and no matter whether the material is heat-treated or not, it will warp more or less when hardened. It is, therefore, necessary to provide apparatus for straightening the work. In straightening, it is necessary to bend the work about twice as much as would be required to merely keep it straight while the pressure is applied, as, on account of its elasticity, it will have a tendency to work back to its original form. Small rollers and shafts can best be straightened in a vise by having a three-point contact on the jaws. For large diameters a special straightener will be required. A surface plate placed to the height of a man's eye, and at a slight angle towards the light, provides the easiest means for testing work of this character while being straightened.

When there is a large quantity of rings to be straightened or trued up, a surface plate can be readily rigged up in the following manner: A solid strap is provided on one side and a compound lever on the other, adjustable to any place along the plate by means of a slot in the latter. By a slight movement of the lever the ring can be trued up. An indicator should be placed at the front of the plate so that the operator can try a ring to see at which points the ring is out, and also the amount necessary for making it round. In straightening washers or flat pieces of any kind, the hydraulic press provides the best possible means. It might be well to mention that washers or flat pieces should be ground by taking a small amount off each side alternately, as, otherwise, they will return to their original warped shape. Another precaution, relating to the grinding of cylindrical surfaces, is to use a copious supply of water, as otherwise the heat of the grinding operation will draw the surface, producing soft spots. These will appear to have been caused by improper casehardening, but as a matter of fact, they are wholly produced during the grinding operation.

ITALIAN NATIONAL AERO LEAGUE

A national "Aero League" has been formed in Italy and the raising of funds by public voluntary subscriptions has been started to build an aerial fleet of one hundred aeroplanes for the Italian government. A similar movement for collecting, by voluntary subscriptions, funds for the building of military airships has also been started in France; and the extent to which the military craze carries some of the European countries is further exemplified by the fact that in Sweden voluntary subscriptions are now being solicited for the building of battleships. A curious thing is that these movements meet with enthusiastic response, and that in Sweden, for example, millions of dollars have been collected within the space of a few months.

LIMITS ON GEARING

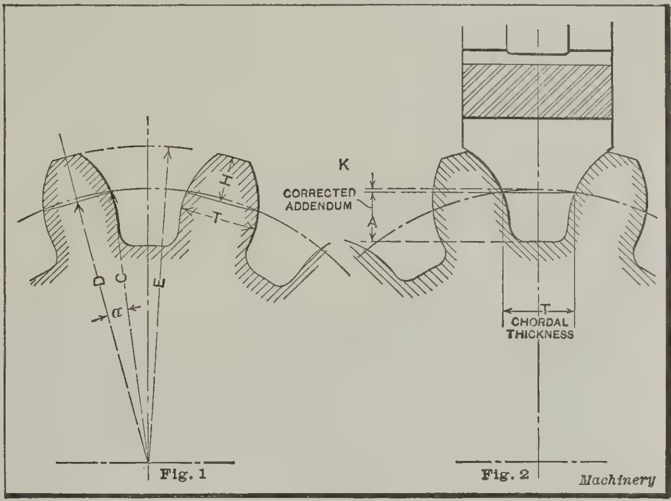
In an article in the *Machine Tool Engineer*, a supplement to the *Practical Engineer* (London, England), Mr. Francis W. Shaw gives the following table for allowable limits for spur gearing, the limits being based on the pitch of the gears:

Pitch	Center Distance	Pitch Diameter	Blanks, Outside Diameter
16	±0.002	−0.003 to −0.005	0.000 to −0.005
14	±0.003	−0.004 to −0.006	0.000 to −0.005
12	±0.0035	−0.0045 to −0.007	0.000 to −0.006
10	±0.004	−0.005 to −0.008	0.000 to −0.006
8	±0.005	−0.006 to −0.009	0.000 to −0.007
6	±0.006	−0.007 to −0.010	0.000 to −0.008
5	±0.007	−0.008 to −0.011	0.000 to −0.010
4	±0.008	−0.009 to −0.012	0.000 to −0.015

CHORDAL THICKNESSES AND ADDENDA FOR GEAR TEETH AND GEAR CUTTERS*

In measuring the thickness of gear teeth and gear cutters, it is necessary to make allowance for the curve of the pitch circle of the gear. In the ordinary 14½-degree involute system, eight cutters to a set are used, the cutters being laid out as follows: No. 1, for 135 teeth; No. 2, for 55 teeth; No. 3, for 35 teeth; No. 4, for 26 teeth; No. 5, for 21 teeth; No. 6, for 17 teeth; No. 7, for 14 teeth, and No. 8, for 12 teeth.

In the following article will be given formulas for finding the chordal thicknesses and what is called the "corrected" addenda, that is, the perpendicular distance from the chord at the pitch circle to the outside diameter of the gear as indicated at H, in Fig. 1. In the accompanying Data Sheet



Figs. 1 and 2. Notation used in Formulas for Chordal Thicknesses and Addenda of Gear Teeth and Cutters

Supplement, tables are given for the chordal thicknesses and the corrected addenda for gear teeth and gear cutters. Let,

a = half the angle subtended from the center of the gear by one gear tooth (see Fig. 1),
N = number of teeth in gear,
T = chordal thickness of tooth at pitch line,
D = perpendicular distance from chord T to center of gear,
H = perpendicular distance from chord to outside circumference of gear,
C = radius of gear at pitch line,
E = outside radius of gear.

The formulas are as follows:

$$a = \frac{90^\circ}{N};\quad T = 2\,C \times \sin a;$$

$$D = \sqrt{C^2 - (\tfrac{1}{2}\,T)^2};\quad H = E - D.$$

In the case of the gear cutter (see Fig. 2), the chordal thickness is the same as that for the gear, but the corrected addendum of the gear cutter is different from the corrected addendum of the gear. The two dimensions, however, added together must equal the total depth of the gear tooth. To obtain the corrected addendum A of the gear cutter, we can, therefore, either subtract the dimension H, as found by the previous formulas, from the dimension for the total depth of the tooth, or we can take the dedendum for the particular pitch required from any standard table of gear tooth parts and subtract the dimension K, Fig. 2, which is found by the formula:

$$K = C\ (1 - \cos a).$$

The values thus found are given in the tables entitled "Chordal Thicknesses and Addenda for Gear Cutters" in the accompanying Data Sheet Supplement. As these tables are calculated for both diametral and circular pitch and for all commonly occurring pitches in either system, they should prove of considerable value to persons engaged in gear cutting or in the making of gear cutters.

* * *

Rivets should never be used in direct tension, but bolts and nuts should be used instead.

* With Data Sheet Supplement.

PRE-HEATING METALS TO BE WELDED BY OXY-ACETYLENE PROCESS*†

OBJECT OF PRE-HEATING, AND METHODS AND APPLIANCES USED IN THIS WORK

BY J. F. SPRINGER‡

The use of the oxy-acetylene torch for heating the work from the ordinary open-air or room temperature to that of, say, red heat, is a rather wasteful method. It is frequently more economical to do this pre-heating by some cheaper method and then to complete the heating with the torch. Various methods are used for pre-heating; as a rule these methods are comparatively simple. A number of examples will be described in the following.

In pre-heating a large cast-iron kettle, a charcoal fire was employed. The kettle weighed about 18,000 pounds and the metal around the crack, which was about two feet long, was several inches thick. The crack was in the bottom and so the kettle was overturned in order to make the crack more easily accessible. The pre-heating was then done from within the kettle, and, in this case, was not only economical but probably essential, as it would have been difficult to obtain the required amount of heat by the torch flame alone. Asbestos sheeting was employed to protect the operator from the heat radiation.

In repairing a break in a locomotive cylinder, Fig. 1, the pre-heating was also done with charcoal, a temporary oven having been built up of loosely laid bricks, as shown in Fig. 2. The fire was kept going for two and one-half hours, at which time a dull red heat was secured. This condition was maintained for six hours longer during the welding operation. It is often possible to use an ordinary blacksmith's forge for the pre-heating, and if a great many similar parts are to be handled, a special forge and bellows may be found of advantage. In addition to the use of charcoal, torches using illuminating, producer, or natural gas, oil, or gasoline, may be employed; in fact, any method for obtaining a large amount of heat, but not necessarily a high temperature, can be employed. In one case, in welding a break in a locomotive engine frame, a gasoline torch was employed for the pre-heating, the torch being applied throughout the welding operation. In cases of repetition work, special pipes and burners may be used.

In one plant in Europe, where tubing is manufactured with the aid of power-driven gas-welding machines, provision is made for the rolled but unwelded tube to pass through a muffle just before reaching the torch, so that the tube is bright red when passing under the torch. Sometimes the outer flame of the torch itself may be used for pre-heating. Thus the Edison Storage Battery Co. employs a machine (see MACHINERY, September, 1911, engineering edition, "Oxy-acetylene Welding and the Edison Storage Battery Can") in welding a straight seam on the containing cans of their batteries. The torch, the work, and the clamping devices are so arranged that the outer flame of the oxy-acetylene jet is divided into two long streamers. One of these impinges upon the seam several inches ahead of the place where it is reached by the working flame. It is possible that this arrangement was not provided with a view to pre-heating, but that is the effect, and a consequent economy in gas consumption is the result.

The use of the outer flame for pre-heating may come to be quite an important factor. A large quantity of heat is generated by this flame. In the machine referred to, the clamps arranged along the sides of the seam are beveled to afford access to the torch, the bevels being quite steep—about 60 degrees. The writer would suggest that similar clamping bars be formed in connection with regular hand-welding work, so as to provide a canyon-like working groove. In hand-welding larger sizes of tubing, it would also be practicable to provide a series of gas jets on a single supply pipe beneath the joint. In this way the edges could be pre-heated with cheap gas.

Pre-heating is often resorted to for reasons other than those of economy of gas consumption. It is used where the effects of expansion and contraction are objectionable. The rise of 2000 degrees in the temperature of a metallic body occasions considerable expansion in every direction. For example, a 12-inch steel bar will lengthen about 5/32 inch. It is easily seen that the sudden swelling and resultant shrinking of only a small part of the work may, at times, have disastrous results. Take as an example the spoke of a fly-wheel with a piece broken out. This piece just fits into its place. If we repair this by making the required grooves and then filling them with new metal, thus producing an apparently good weld, we will find that, upon cooling, a break will frequently occur in the weld or at some other point, due to the contraction. A similar case is met with in a crack in a casting. It is chipped out in order to obtain beveled edges for the flame, the faces are heated, and new molten material filled in. When the weld cools off, however, the new material is likely to shrink away from the walls of the crack.

Now what can be done to meet this condition? If we could uniformly heat the whole work within as well as without, we should probably have an ideal solution, but one of the great objects in oxy-acetylene welding is to localize the heating. We can, however, pre-heat a larger portion of the whole body than is required for the welding alone, and in this way distribute the stresses. In the case of the flywheel, the broken spoke, the adjacent spokes, and the intervening rim may be heated

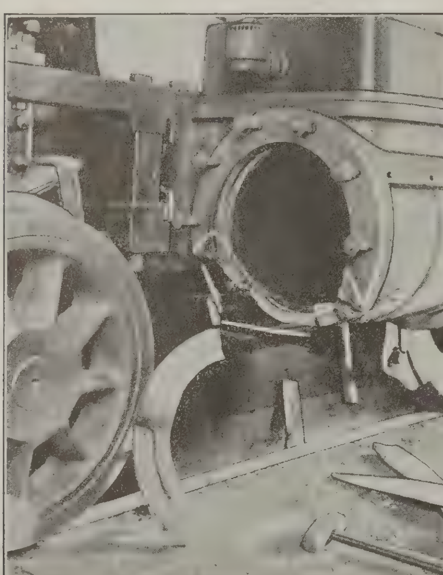


Fig. 1. The Broken Cylinder

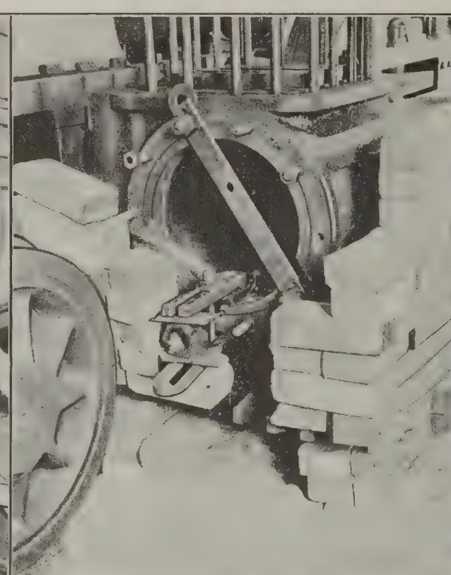

Fig. 2. Arrangement for Pre-heating

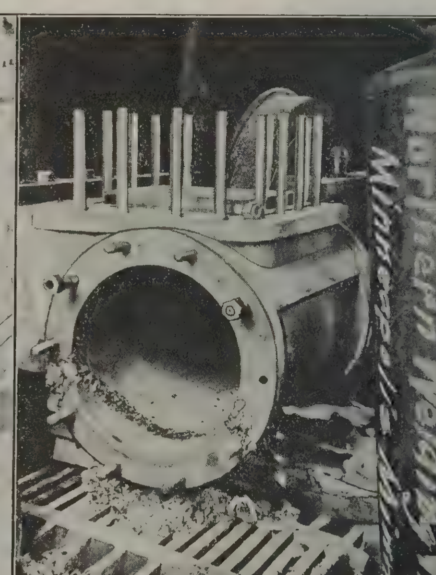

Fig. 3. After Welding, before Cleaning Weld

* For further information on autogenous welding, see "Modern Welding Methods," MACHINERY, December, 1911, and the previously published articles there referred to.

† This article has been prepared with the cooperation of the Davis-Bournonville Co., New York, and is a chapter from a forthcoming book: "Oxy-acetylene Torch Practice."

‡ Address: 608 West 140th St., New York.

to a red heat, gradually diminishing toward the other parts of the wheel, so that the pre-heating itself does not introduce new stresses. When the new material for making the joints is filled in, the spoke is naturally longer than it will be at ordinary temperatures, and while there is a local contraction of the weld, there is also a general contraction of the whole spoke and those adjacent, which diminishes the effect. In the case of a cracked cylinder casting, the pre-heating of the metal beyond each end of the crack, if properly done, will ordinarily open up the crack so that when it is filled with new metal, the amount which is used will be sufficient, when the cylinder

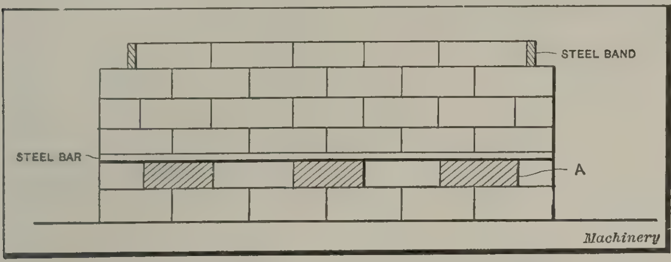

Fig. 4. Arrangement of Temporary Brick Furnace

cools off, to fill the original space. Ordinarily, the walls of the crack should be held apart until the weld is completed, so that the width of the crack and the new metal will contract together. If the crack runs from a point within the periphery all the way to the edge it may be opened up by heating at a point a little further in than the beginning of the crack. The welding is begun at the inner end of the crack, working toward the edge.

The pre-heating should ordinarily be done rather slowly so as not to introduce sudden temperature changes and stresses. Slow heating is especially to be advised when there is a combination of thin and heavy parts. Similar remarks apply to the cooling, which should be slow to be safe; the cooling may be retarded by the use of asbestos sheeting or by packing the object in heated ashes or heated slacked lime.

When it is possible to pre-heat the entire casting, this seems to be the best way of taking care of expansions and contractions. Castings the size of which makes necessary special arrangements may be placed on a bed of fire-brick ar-

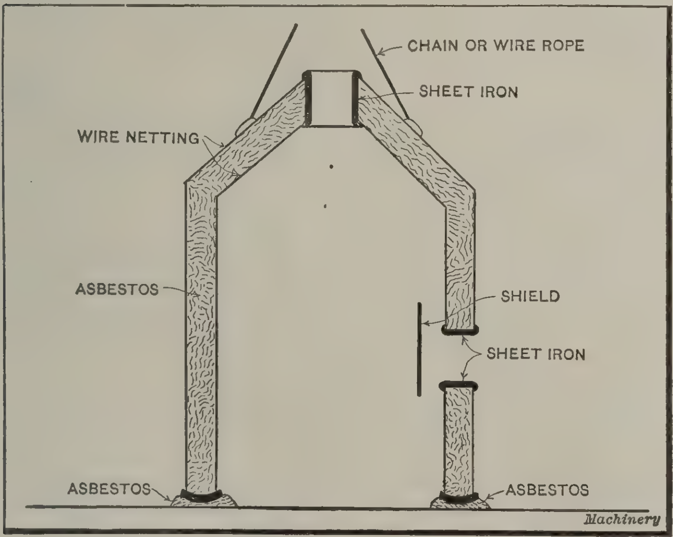

Fig. 5. Hood used for the Pre-heating Operation

ranged with spaces between them. A temporary wall or furnace is then built around the whole, fire-brick being used for this also. These are arranged, of course, without the use of mortar, with very narrow openings between them, one method of constructing such a wall being shown in Fig. 4.

Flat steel bars may be employed just above the separated course of bricks *A*. The top course may be held in place by a steel band. The object of the open spaces is to provide a draft. Charcoal is now filled in between the casting and the wall and the fire started. A sheet of asbestos is used as a cover. This cover should contain a number of holes so as to provide an exit for the gases.

Another method is to make a hood of a material that is a poor conductor of heat. Such a hood is shown in vertical section in Fig. 5. The walls consist of two sheets of wire netting with an intervening space filled with asbestos. A hole, the wall of which is made of sheet iron, is provided at the top. Another aperture also lined with sheet iron is provided on one side of the vertical cylindrical wall. The bottom of the hood is furnished with an annular base ring of sheet iron, the netting and sheet iron being joined by welding. Provision should be made for lifting and lowering the hood, so that it can be let down over the casting which is to be pre-heated. To make a tight joint with the floor, some loose asbestos may be used as a foundation for the hood. A kerosene or other torch may now be inserted through the aperture in the side. Some kind of shield may be used just inside of the side opening to divide the flame, so that, as far as possible, the casting will be encircled by it. Sometimes it is advisable to use auxiliary fires on shelves above the main fire at the bottom. This is especially to be recommended for tall castings, so that there will be no severe concentration of heat at one point. As already mentioned, the heating should be done slowly, the fires being started in a moderate way and gradually increasing in intensity. During the welding the hood must, of course, be raised, and when the welding is completed the hood may again be lowered into position in order to retard the cooling. The oil torch should be brought into service again for a short period. It may then be shut off and the openings of the hood covered. In this way, slow and even cooling is assured.

In general, after a welding operation, the casting should be reheated as soon as the welding is completed, and then covered with asbestos wool or scrap asbestos. The casting may also be buried in any of the materials ordinarily used for retarding the cooling of steel which is to be annealed. If the casting is of such a shape that it is not likely to crack, it may be cooled in the bed of charcoal in which it has been heated.

Cast iron may be pre-heated to about 700 or 1000 degrees F. Generally speaking, the higher the temperature of pre-heating, the less the danger of cracking when cooling. Aluminum castings should be pre-heated to about 600 or 700 degrees F., the heat if possible being maintained during the entire time of welding. To accomplish this, it is often advisable to cover the casting with asbestos and to leave only the working area exposed. Asbestos sheeting will be found satisfactory for keeping any class of work hot during the welding.

It may be of interest to refer to a specific case of welding performed by the Pullman Co. of Chicago. The bed of a hydraulic press was cracked; the casting weighed about 10 tons, and the crack was about 10 inches long and 26 inches deep. The material of the bed was cast steel. The casting was placed on supports of brick about 14 inches high and a fire of wood and charcoal was maintained during the night, with the result that when the welding was begun the metal was at a red heat. A No. 10 Davis-Bournonville tip was used with a soft steel welding rod, two workmen carrying out the work. The time consumed for the welding operation was about five hours. The necessary enlargement of the crack was made by the oxy-acetylene flame. The expense was estimated at $19.16, and the result of the welding was very satisfactory. As the gas cost of the Pullman Co. is extraordinarily low, for ordinary conditions the expense would, perhaps, be as follows:

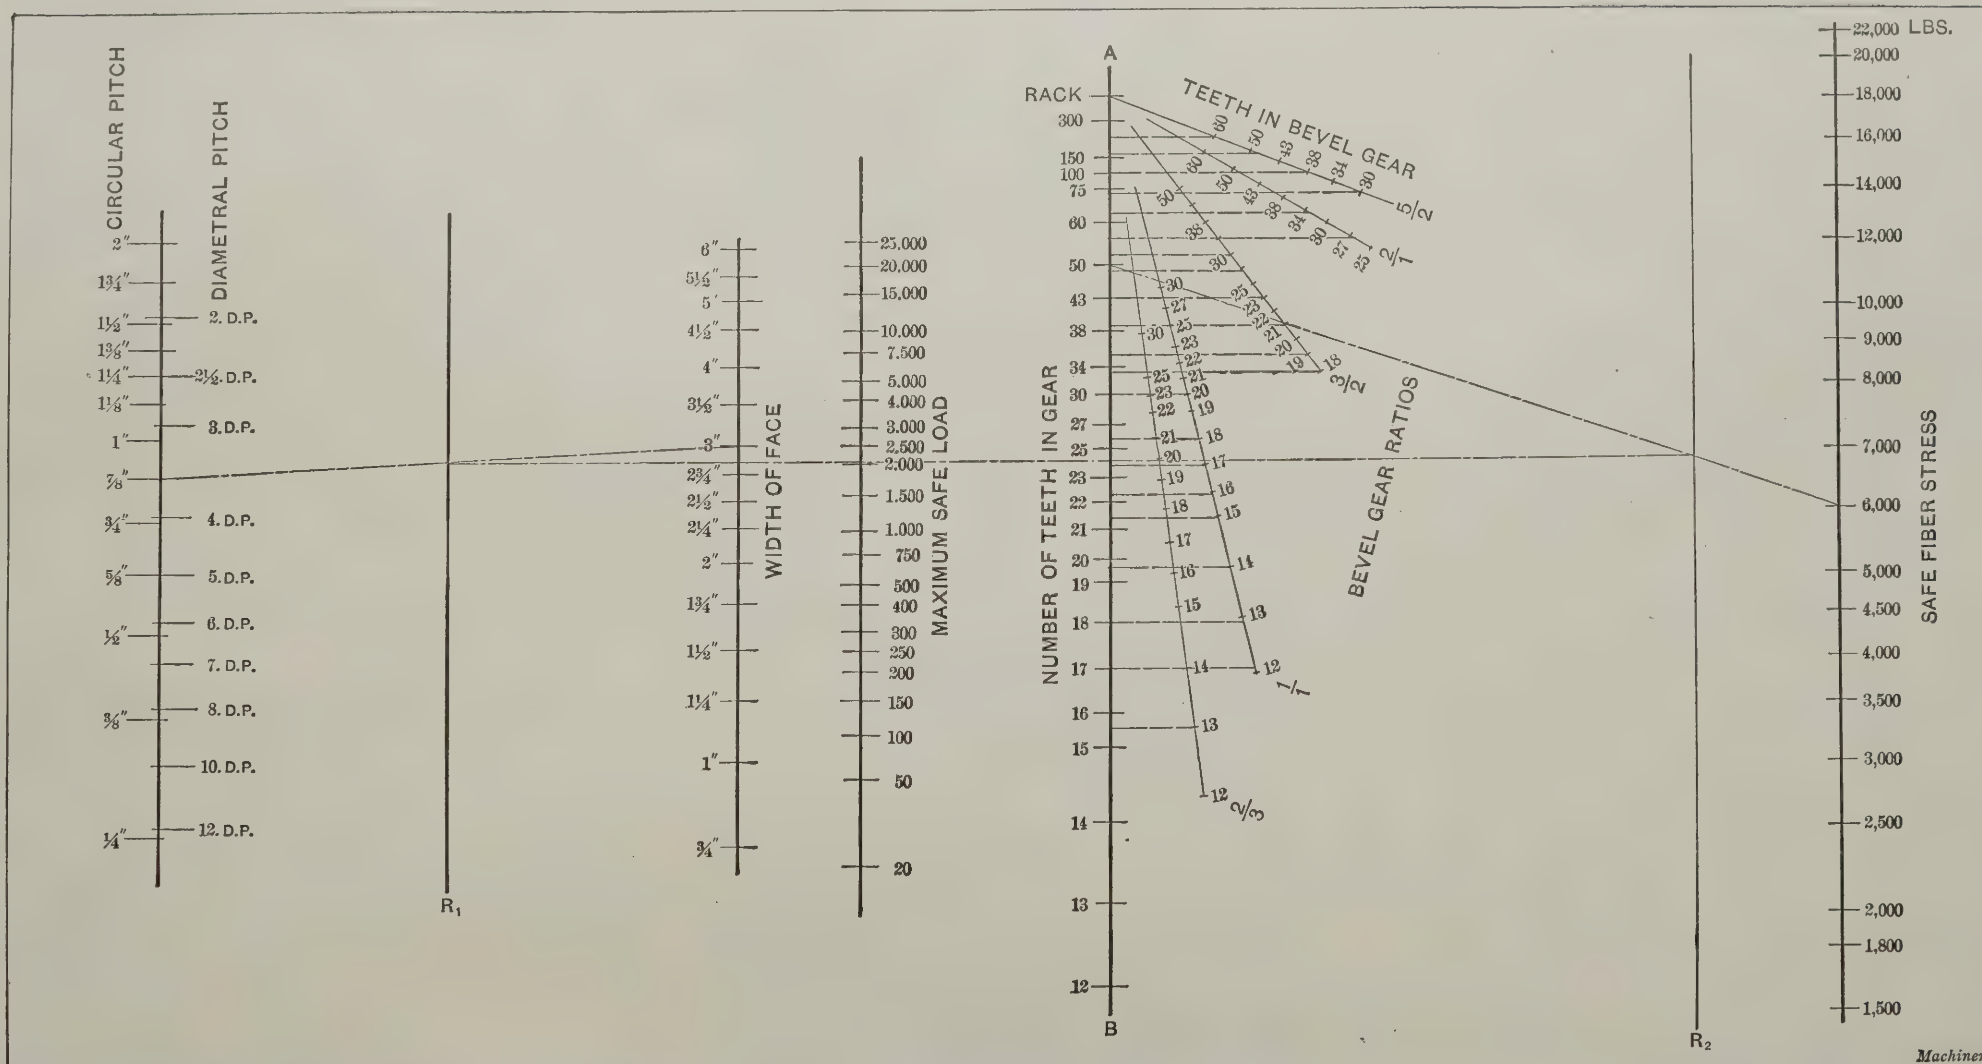
357 cubic feet of oxygen at 3 cents per cubic foot...	$10.71
143 cubic feet of acetylene at 1 cent per cubic foot..	1.43
Labor	7.40
Fuel for pre-heating and annealing..................	4.00
	$23.54

The expense of replacing the casting by a new one would have been about $600.

* * *

An investigation of the melting points of tungsten and tantalum has been carried out at the University of Wisconsin, the measurements having been taken with especial care, using the optical pyrometer and a direct vision prism transmitting monochromatic light. The melting point of tungsten was found to be 3002 degrees C. (5435 degrees F.), and of tantalum, 2798 degrees C. (4982 degrees F.). These values are somewhat different from those generally accepted.

CHART FOR FINDING THE STRENGTH OF GEAR TEETH



Conditions of Drive	Pitch Line Velocity, Feet per Minute	Approximate Safe Fiber Stress, Pounds per Square Inch					
		Spur and Bevel Gears				Helical Gears	
		Cast Iron	Steel	Phosphor-bronze	Rawhide	Cast Iron	Steel
Without shock	Any	5000–8000	18,000–20,000	14,000–16,000	2500–3500	5000–8000	18,000–20,000
With shock	200– 800	3000–6000	14,000–18,000	9000–12,000	2500–3500	5000–8000	18,000–20,000
	800–1600	2000–4500	10,000–14,000	6000–10,000	2500–3500	3000–6000	14,000–18,000
	1600–2400	1500–3000	7000–12,000	4000– 7000	2500–3500	2000–4500	10,000–16,000

HOW TO USE THE CHART

Required to find the safe load for a cast-iron gear having 50 teeth, ⅞ inch circular pitch, and 3-inch face; assume the fiber stress to be 6000 pounds per square inch. Join the graduation for ⅞ inch circular pitch with that for 3 inches width of face; also join the graduation for 50 teeth with that for 6000 pounds fiber stress. Then join the points where these two lines intersect lines R_1 and R_2, respectively. The intersection of this joining line with the maximum safe load scale gives the safe load, which for this gear is about 2050 pounds.

LOGARITHMIC CHART FOR FINDING THE STRENGTH OF GEAR TEETH*

BY H. T. MILLAR†

The accompanying illustration shows a logarithmic chart for the strength of cut gearing. The chart is based on the well-known Lewis formula. The method of using it is explained by the example shown in dash-dotted lines. Assume that it is required to find the safe load for a cast-iron gear having 50 teeth, the gear being of ⅞ inch circular pitch and having a 3-inch face. The fiber stress is assumed at 6000 pounds per square inch. To use the chart, join the graduation for ⅞ inch circular pitch with that for 3-inch width of face; also join the graduation for 50 teeth with that for 6000 pounds fiber stress. Join the points where these two lines intersect lines R_1 and R_2, respectively. The intersection of this joining line with the scale for the maximum safe load indicates that the safe load for this gear is about 2050 pounds.

The tooth form of a bevel gear is stronger than that of a spur gear of an equal number of teeth. The chart can also be used for bevel gears, as indicated. The increase in strength due to various cone angles is taken care of by the diverging lines marked with the ratio of the bevel gears. To use the diagram for bevel gears, follow the horizontal line from the actual number of teeth in the bevel gear to the scale *AB;* then use the number of teeth thus found on this scale for determining the strength, as already explained in the previous example. In using the chart for bevel gears the pitch selected must be the mean or average pitch and not the nominal pitch.

Some notes on helical gearing may be of interest, and may be found useful on account of the increased use of this class of gearing. The increased strength of helical gearing comes from two causes. The meshing action is more continuous, and, therefore, a high velocity is not so likely to induce shock. The contact between two helical teeth in mesh is very different. The line of contact is inclined across the face, beginning at the root and passing through the pitch line to the point. Considering, therefore, the tooth as a cantilever, the mean leverage of the load is less than with a straight cut tooth, where the load may have a leverage almost as great as the tooth depth. The angle of the tooth helix is usually so arranged that with a minimum width there is always contact at the pitch line of one of the teeth in mesh. In practice, it has been found that most double helical gears, especially pinions, fail through wear rather than through breakage, since in the usual case of helical gear reductions the circumferential speed of the gears is high. It is not wise to have a bearing pressure per inch of width very much higher than that given in the Lewis formula, unless the teeth are lubricated. It is also customary to select a fine pitch and a relatively wide face, say about six times the circular pitch, or 20 divided by the diametral pitch. When using the chart for helical gearing, the maximum safe load may be obtained by selecting a somewhat larger pitch than the actual one, and this pitch should be used for the graphical work.

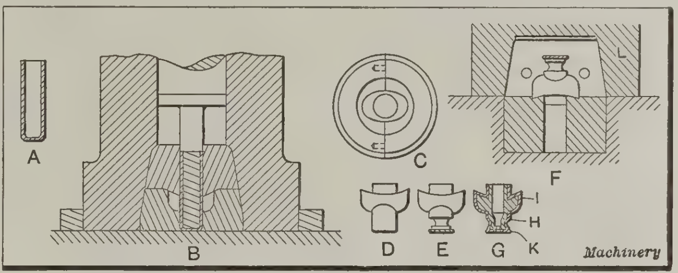
METHOD OF MAKING WATCH CASE PENDANTS

In the August, 1912, number of MACHINERY an article appeared entitled "Watch Case Manufacture," in which the making of a number of parts of watch cases is described. Little attention is given in this article, however, to the making of watch case pendants. It may, therefore, be of interest to show, in general outline, a method for making one-piece pendants as invented by Charles W. Butts of Sag Harbor, N. Y., and described in U. S. Patent No. 865,759, from which the accompanying description has been obtained. The principal object of this invention is to form a watch case pendant wholly of one piece from what is commonly known as "filled" metal or "gold-filled"; that is, gold covering a base metal, which latter must not be exposed after the pendant is formed.

The principle employed for accomplishing this result is to use dies of such a shape that when a straight tubular blank containing a core of a soft plastic metal is placed within the dies and pressure is brought to bear upon the blank and the core, the metal of the blank and core will flow into the cavities of the die and thus form a pendant of the desired shape. The pendant is then removed from the die, which is made in halves for this purpose, a central hole is drilled in it, and by means of rolls the lower part of the body of the pendant is depressed and a foot and bead are formed on it. The final over form of the foot of the pendant is obtained by placing the pendant, after the foot and bead have been formed, within a die made in halves and exerting pressure upon it. In this way it is possible to produce a pendant in one piece.

In the past, watch case pendants have generally been made in two pieces, the body and foot of the pendant having formed one piece, while the oval cap has been made in a separate part, these parts afterward being soldered together. Pendants made in this manner are not satisfactory, for the reason that, in forming the cap separate from the body of the pendant, the filling metal is necessarily exposed in some places; nor is an absolute uniformity in product possible when the pendants are made in two parts and afterward fastened together.

The accompanying illustration shows, in a general way, the methods for making the pendants in the manner described. At



A Method for Making One-piece Watch Case Pendants

A is shown the blank from which the pendant is made. This blank has a tubular section and is closed at one end. It is made of a base metal covered with a precious metal. This blank is filled with a core of base metal and then inserted in the hole in the dies at *B*, which shows a vertical section through the dies used for forming the cap. The tube with its core of soft plastic metal is shown in the center of this illustration. By filling the blank with a core of base metal, the tubular blank is caused to flow more quickly and evenly into the cavities of the die, and, at the same time, the strain on the precious metal covering is relieved while the cap on the pendant is being formed. When the plunger descends upon the blank the core of metal of the latter is upset and forced to flow outward, thus preventing the wall of the blank from collapsing inward. When the plunger has reached the limit of its downward stroke, the walls of the metal blank will have been forced tight against the walls of the cavity in the die. A plan view of the lower die is shown at *C*. The die is made in two parts in order to make possible the removal of the formed pendant after the operation is completed.

At *D* is shown the appearance of the pendant after the blanks have been operated upon by the dies shown at *B*. The core, after this operation, of course, completely fills the blank, and a hole is then drilled through it, this hole being shown in the section at *G*. The blank is then placed between rollers or other suitable tools and the cylindrical part is spun and the foot and bead formed so as to give it the shape indicated at *E*. After the foot and bead have been formed on the lower portion of the body, the blank is inverted and placed so that the oval cap will rest within the depressions of the dies shown in section at *F*. The upper die is made in halves which, when placed together, give the foot and bead their final oval shape. This is accomplished by having the two halves of the die slightly apart at the beginning of the operation, but forcing them together by the block *L* as the operation proceeds, the outside of the die and the inside of blank *L* being conical in shape as indicated. A section of the pendant after this operation is completed is shown at *G*. The part *H* is cylindrical, while the cap *I* and foot *K* are oval in shape. The hole through the pendant is made, of course, in any suitable manner to fit the winding-stem of the watch.

* See MACHINERY, January, 1908, engineering edition: "Variation of the Strength of Gear Teeth with the Velocity." See also MACHINERY's Reference Book No. 15, "Spur Gearing," Chapter VI.
† Address: 150 Waterloo Road, Manchester, England.

It will be seen that the process briefly consists in the making of a one-piece watch pendant by first upsetting a cylindrical blank to form a non-cylindrical cap and a cylindrical base, using a core of soft plastic metal within the tubular blank to accomplish this, and then drilling the hole through the soft metal core. The base is then spun to form a cylindrical foot and bead, and finally the foot and bead are compressed into a non-cylindrical shape.

ALLOWANCES ON PARTS TO BE ASSEMBLED BY PRESSURE*

BY S. M. HOWELL†

The following article gives some data on the allowances for parts to be assembled by pressure. The subject is one of much importance in machine construction, and the data given has been secured by observation and personal experience in a large number of cases.

In making a press fit, the pressure at which the parts are assembled is estimated from the size and character of the job and the degree of tightness desired. In the case of very large work, the pressure may be limited by the capacity of the press. When the tonnage of pressure has been decided, the next step is to determine the allowance on the parts for the fit, that is, how much larger the fitted part should be than the hole into which it is forced, in order to enter at the required pressure. In plants where a special line of machinery is regularly manufactured, and the same parts are continually made, work to be assembled in this way is machined to dimensions which are known to be right from previous experience, and is usually fitted to gages; but in repair shops and other places where the work is of a more diversified character, the allowance must be determined in each individual case.

The "feel" of the calipers is, of course, a ready way of judging small variations of size, and is sufficiently reliable for many purposes, but when more definite results are desirable, a predetermined allowance, accurately measured, should be made. For this purpose an inside micrometer gage and a pair of outside calipers constitute a practical device.

In determining the allowance to be made in a given case, the governing conditions are the diameter and the length of the bearing, and to a greater or less degree also the character of the material and the smoothness of the surfaces of the fit. It is obviously impossible to accurately calculate the effect of varying degrees of hardness and other irregular conditions by means of mathematical formulas. In the majority of cases, however, the shaft or pin to be forced into place is of soft steel, and the receiving part is either of cast iron, or is a steel casting. The material is of average quality and the machined surfaces are slightly rough, the finishing cut having been taken with a moderate feed and without filing. Assuming these to be the conditions, the allowance to be made for the fit will, in a general way, depend upon the diameter and length of the bearing and the required tonnage. For finding the allowance, the following rule is applied:

Multiply the pressure in tons by 4.4, and divide the product by the product of the length and diameter in inches. The quotient is the allowance in thousandths of an inch. This rule may be given as a formula, as follows:

$$A = \frac{4.4P}{LD}$$

In this formula

A = allowance in thousandths of an inch,

D = diameter of hole in inches,

L = length of fit in inches,

P = pressure in tons.

As an example, assume that a pin is to be forced into a hole 4 inches in diameter, 6 inches long, the pressure being 40 tons. From our formula we find:

$$A = \frac{4.4 \times 40}{4 \times 6} = 7.3$$

Hence the proper allowance is 0.0073 inch.

As another example, assume that a shaft is to be forced into a hole 5 inches in diameter with a pressure of 60 tons; the length of the bearing is 8 inches. Then:

$$A = \frac{4.4 \times 60}{5 \times 8} = 6.6$$

Hence the allowance is 0.0066 inch.

The rule can be transposed so that we can find the required pressure when the allowance and the length of the bearing are known. In this case the rule will be:

Multiply the length by the diameter in inches, and multiply this product by the allowance in thousandths of an inch; divide this final product by 4.4.

The quotient will be the required pressure in tons. As a formula this rule becomes:

$$P = \frac{LDA}{4.4}$$

As an example, assume that a pin 2 inches in diameter is to be forced into a bearing 4 inches long, the allowance being 0.004 inch. What will be the required pressure in tons?

$$P = \frac{4 \times 2 \times 4}{4.4} = 7.3 \text{ tons.}$$

When forcing shafts into large rollers there is usually a short bearing at each end. In this case the shaft must be driven into both bearings at once, and the pressure required will be double that of a single bearing of the same length, or, in other words, in calculating the allowance, the length used in the formula must be equal to the sum of the length of the two bearings.

In small work where the parts are strong and it is required that they be tightly driven, an allowance of 0.002 inch per inch of diameter may be made, but care must be taken that the required pressure is not so great as to strain the material beyond its elastic limit; otherwise there is danger of damage to the work even if there is no visible distortion at the time of making the fit. In work of moderate size, an allowance of 0.001 inch per inch of diameter is usually made, but this is excessive for large diameters. In making a shrink fit, where the maximum tightness is required, a shrinkage allowance of 0.003 inch per inch of diameter may be used, provided the parts are strong enough to stand it.

A driving fit may be based upon an estimate of 10 tons pressure at the most, but the allowance should never exceed 0.001 inch per inch of diameter, and frequently must be much less. As a matter of fact, the allowance for light driving fits is often so small that it is best estimated by the "feel" of the calipers alone. If a hole is not true, but oblong, or tapers slightly, it should be calipered near the small end. In these cases, the parts will go together at a somewhat lower tonnage than if the hole were true.

The outside calipers used in this and other work requiring accuracy should have parallel chisel points about 1/16 inch wide, slightly rounded or dulled on the extreme edges. These points should be casehardened and smoothly finished. The inside pair may have one chisel point and the other point rounded or spherical. With calipers of this kind, a size may be transferred from one caliper to the other more easily and with greater certainty than if all the points were round or of an irregular shape which they might have acquired from use.

One of the Middle Western railroads—the Illinois Central—has appointed an official whose duties are practically that of a "courtesy expert." The official title is: "Inspector of Passenger Train and Station Service." His duties will be to see that passengers are enabled to make use of every convenience which the system affords, to suggest improvements for the comfort of the passengers, and to travel on passenger trains so as to ascertain in person the conditions of the service as far as it pertains to the comfort and convenience of the passengers.

THE MANUFACTURE OF BLUEPRINT PAPER

CHARACTERISTICS OF PAPER, SENSITIZING AND SENSITIZING SOLUTIONS

BY F. B. HAYS*

The constantly increasing use of blueprints has caused the manufacture of blueprint paper to become an industry of considerable magnitude. The majority of people connected with engineering work have a fairly clear idea of the methods employed in making blueprints, and a few draftsmen and engineers understand the principles of coating the paper, but only a very small number have any conception of the methods and processes employed in producing large quantities of blueprint paper. The following article briefly describes the most general methods used. The machinery illustrated in the accompanying halftones is installed in the plant of the Indianapolis Blueprint and Supply Co., and is said to be the most modern and efficient type in use.

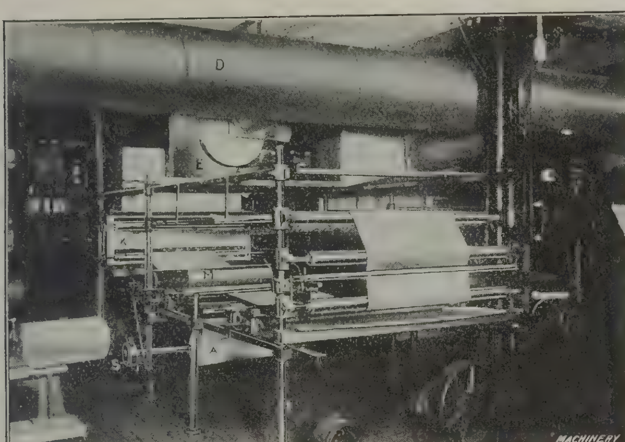

Fig. 1. Front View of Coating Machine and Dryer for Blueprint Paper

A special kind of paper is used in making blueprint paper. The principal requisites of this paper are: first, that it be free from wood pulp and the chemical impurities that are found in cheap papers such as newspaper stock, wrapping paper, etc.; second, that it be sufficiently tough to withstand frequent washing and rough handling; third, that it possess a fairly hard, and not too absorbent or coarse grained surface; and fourth, that it be properly sized on that surface which is to receive the coating. The size which gives the best results is a mixture of arrowroot flour and water. The flour is first mixed with a sufficient quantity of cold water to produce a thick paste, and then from forty to fifty parts of warm water is added.

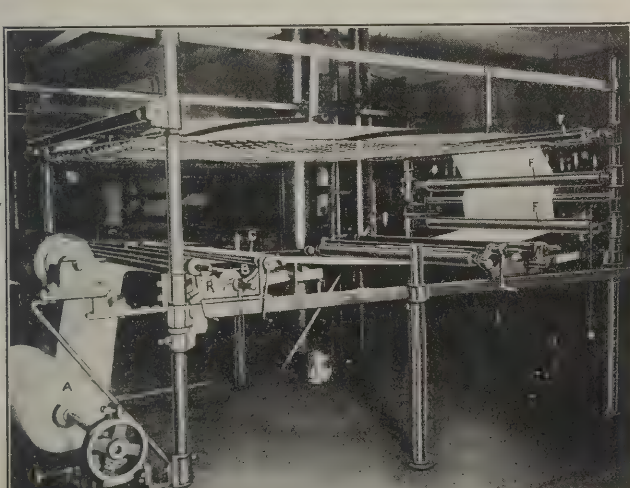

Fig. 2. Side View of Machine shown in Fig. 1

Sensitizing Solutions

The process of coating paper for blueprinting is termed "sensitizing," and it consists of coating the paper on one side with a solution that undergoes marked chemical changes when brought into contact with certain kinds of light and water. This process, although more or less complicated from a chemical standpoint, is very simple mechanically, provided only small quantities of paper are to be sensitized, but when done on a large scale special machinery and very skillful handling are required.

One of the oldest and most popular formulas for sensitizing paper that will print white lines on a blue background is: (A) Ammonia-citrate of iron, 20 parts; water, 100 parts. (B) Potassium ferricyanide, 16 parts; water, 100 parts. The sensitizing solution is made by mixing equal parts of (A) and (B) together, and filtering just before using. Another solution which gives good results, and which may be kept on hand for several months without deteriorating, is the following: (A) Ammonia-citrate of iron, 12 parts; water, 16 parts. (B) Potassium ferricyanide, 9 parts; water, 16 ounces. Mix together and filter one part each of (A) and (B), and add two parts of water just before using.

For coarse-grained, rough-surfaced papers, and silk and linen cloth, an excellent solution is obtained by the use of gum arabic. (A) Pulverized gum arabic, 1 part, dissolved in 20 parts water, and strained through muslin, combined with ammonia-citrate of iron, 5 parts. (B) Potassium ferricyanide, 4 parts, water, 20 parts. Equal parts of (A) and (B) are mixed before using. Fabrics must be washed and then sized in gelatine (hard gelatine dissolved in twenty parts water) before sensitizing.

Positive paper, or that which gives a blue line on a white background is produced in the same manner as negative paper, except that it is sensitized with different solutions. A number of mixtures may be used, but the two following are probably the most popular:

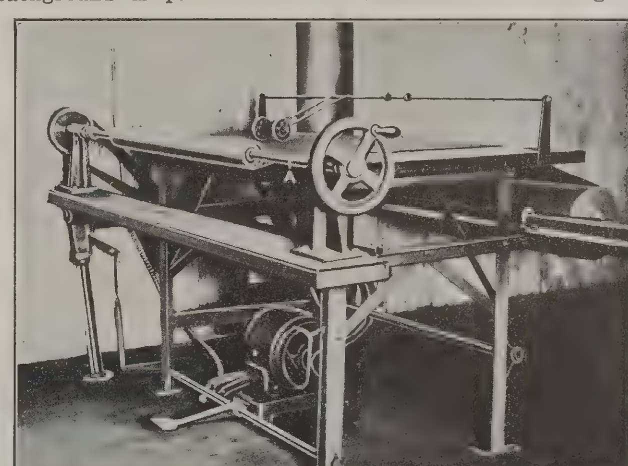

Fig. 3. Measuring Machine for Blueprint Paper

1. Oxalic acid, 1 part; iron perchloride, 2 parts; water, 20 parts.
2. (A) Powdered gum arabic, 2 parts; water, 10 parts. (B) Ammonia-citrate of iron, 2 parts; water 4 parts. (C) Chloride of iron, 1 part; water, 2 parts. First dissolve the gum and strain the solution (A) through muslin; add solution (B) to solution (A), stirring well; finally add solution (C) to the mixture of (A) and (B). This solution must be kept for twenty-four hours in the dark and must be frequently agitated before using.

Paper which produces positive black lines on a white background is sensitized and then developed. The sensitizing is a solution consisting of ferrous sulphate, 20 parts; ferric chloride, 45 parts; tartaric acid, 40 parts; water, 190 parts. The developing solution is a mixture of gallic acid, 15 parts; oxalic acid, 2 parts; water, 1700 parts. After developing, the prints are washed in running water.

In mixing any of the foregoing solutions, only distilled water should be used, and all operations should be carried out in a red or orange light.

Sensitizing the Paper

The coating of the paper with the sensitizing solutions and the subsequent drying and rolling is now done entirely by

* Address: 107 W. Walnut St., Indianapolis, Ind.

machinery. Fig. 1 shows a general view of a machine for this purpose. The coating machine is shown towards the front and the drier in the background. The driving mechanism is shown on the floor in front of the machine. The air for the drier is received from a purifier and forced through pipe *D* and heater *E* into the drying oven. The general operation of the machine is as follows: The sized paper starts from the roll *A*, Figs. 1 and 2, and passes between two pulling rollers and over the celluloid coating roller *B*, Fig. 2. This roller is partially submerged in the coating solution placed in tank *R*, and as it revolves it carries a small film of the solution, which is absorbed by the lower surface of the paper. A glass bar runs along the edge of the tank, and a roller *C* presses the paper against this bar so that all excess solution is wiped from its surface and returns to the tank. This latter roller also regulates the pressure between the paper and the coating roller *B*. The bearings for roller *C* are placed in a rocker arm, so that it may be raised or lowered by means of a crank, thus decreasing or increasing the tension on the paper. Another retaining tank and a similar series of rollers is shown at the other end of the machine, and serve to administer the second coat of the solution. The rollers *F* are simply guide rollers, and the tubes above the machine prevent the paper from sagging and becoming strained between the guide rollers. All of the rollers are made of brass, except the coating roller which is made of celluloid, and are mounted upon ball bearings. They are driven from the main shaft by gears proportioned to impart the same lineal speed to each roll.

At *S*, Fig. 2, is shown a band brake which regulates the tension of the paper and also prevents it from unrolling from the spools when the machine is stopped. Upon leaving the coating machine the paper immediately enters the drier, where it runs upon rollers along the upper part of the drier to the extreme end, and returns upon rollers on the lower side, leaving at *K* and being wound upon the spool *M*, Fig. 1. Both the top and bottom of the drier are covered with steam coils, and the hot air forced into it thoroughly dries the sensitized paper before it is wound upon the spool *M*. The moist air is removed from the drier by a pipe at the back, which terminates at an exhaust fan on the outside of the building.

As it is necessary to keep the colored windows of this department closed because of the injurious effects of daylight upon the finished paper and the sensitizing solutions, air is artificially supplied by blowers and exhaust fans.

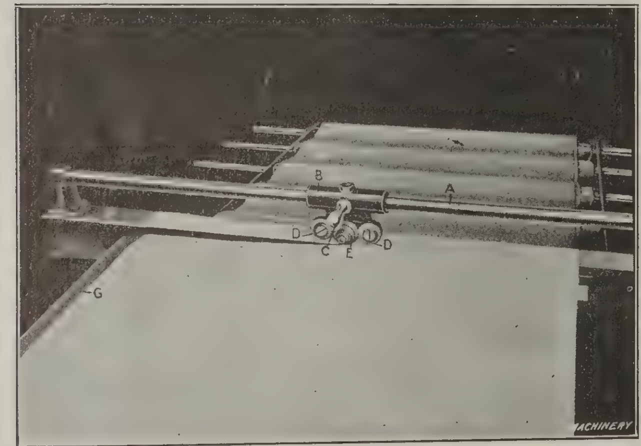

Fig. 4. A "Cutting-off" Machine

When the rolls of sensitized paper are removed from the coating and drying machines (each of which has a capacity of 1500 yards an hour), they are taken to the rerolling and measuring machine shown in Fig. 3, where they are rerolled into packages of desired length for the market. This machine consists of a "rolling" shaft *A* having a universal joint and driven through a friction clutch at the left from the motor beneath the machine; the clutch is controlled by a foot pedal. The operation of the machine is as follows: The operator places one of the large rolls of paper from the drier on the shaft at the back of the machine and starts it upon the "rolling" shaft *A* by means of the handwheel. This wheel has a jaw clutch connection with the shaft, so that it can be slipped out of connection with the shaft as soon as the paper is started, and the shaft driven by power through the clutch. As the paper passes over the table of the machine the registering device shown records the number of yards rerolled, so that the operator simply has to throw out the clutch and cut off the paper when the package has reached the proper size. The shaft *A* is then swung out on its universal joint and the roll slid off and sent to the packing department, where it is wrapped in light-proof paper and sealed up ready for the market.

Frequently orders for large quantities of short lengths of paper are received, and are handled by means of the mechanism shown in Fig. 4. This consists of four shafts, each

Fig. 5. Section of Department for Sensitizing Solutions. Note that all Solutions are kept in Light-proof Receptacles

inserted into a roll of paper, and supported by a steel plate on each end; a polished steel guide *A*; a steel I-beam support *F*, which is finished on the top and upper edges; two ball bearings *D*; a hardened tool steel cutter *E*; a handle *C*; and a body casting *B*. The paper is pulled from the rolls in four layers (one from each roll) and measured by means of a steel scale *G* on the edge of the table. The operator then pushes the cutter across the paper by means of the handle *C*, the ball bearings holding the paper rigidly in place while the cutter shears it off. The top of the beam *F* acts as a cutting table, and the finished edge serves as a sharpener for the circular cutter. Five hundred and eighty yard lengths of paper an hour are cut by this device. It is especially successful in handling tracing cloth and drawing paper.

The principles involved in the chemistry of sensitizing paper for blueprinting were first discovered about 1725, but were not practically applied until 1835 when an English scientist, Sir John Herschel, developed the ferro-prussiate process, which is still used at the present day and which serves as a basis for all other blueprinting methods. Many new branches of industry have arisen since 1835, and practically all the methods of the old industries have been greatly changed and improved, but the principal chemical processes of making blueprints are virtually the same now as they were twenty-seven years ago. Great strides have been made in the mechanical methods of making, coating, and printing blueprint paper, but no improved simple and efficient chemical process has been developed for producing sensitizing solutions, or for incorporating them with the fabrics. What we need at the present time is a cheap, reliable, quick printing paper that will require neither developing nor washing after printing, and that will withstand rough usage and not fade a short time after printing. It seems reasonable to believe that such a paper could be produced at the paper mills by incorporating the sensitizer with the primer, provided a suitable sensitizing solution were discovered. Far more wonderful developments than this have been made in the chemistry of photography, but for some reason chemists seem to have entirely overlooked its sister subject, blueprinting. Let us hope that in the near future chemists will turn their attention to this matter, and that the chemical side of blueprinting will be greatly simplified and improved.

WIRE ROPES FOR LIFTING APPLIANCES*†

AN INVESTIGATION INTO SOME OF THE MOST IMPORTANT CONDITIONS THAT AFFECT THEIR DURABILITY

The question of the durability of the parts of mechanical structures seems to be strangely neglected by all authorities. A designer has generally the choice of several formulas for calculating the mere strength of a given member, but usually he has to depend upon his own experience for the correctness of the proportions that will insure for it a reasonable length of life. The durability of wire ropes, in particular, is of great importance to all engineers, whether engaged in the design and manufacture of lifting appliances, or in their care and management.

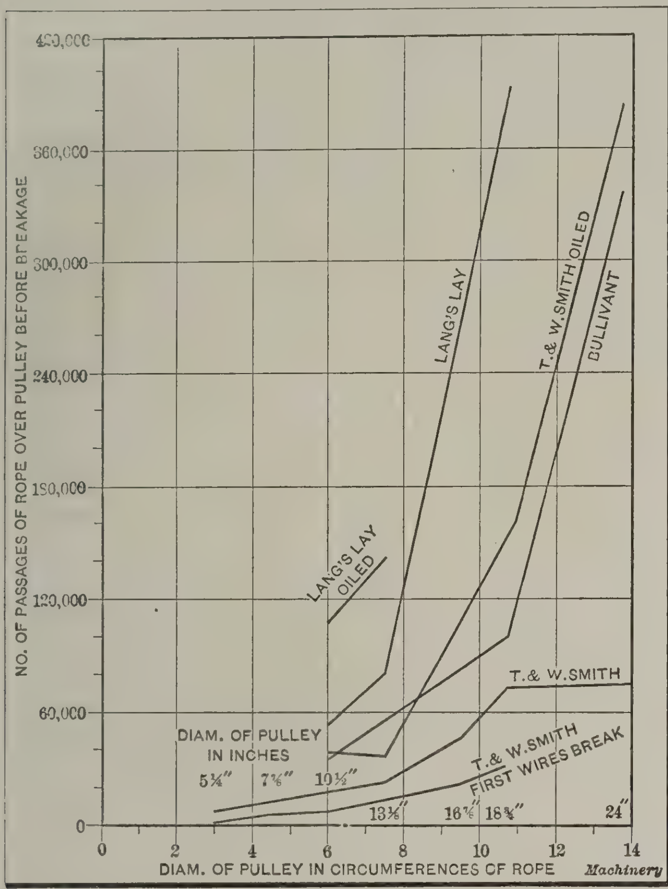

Fig. 1. Results of Experiments on the Durability of Wire Ropes

The two most important conditions appertaining to the manufacture and use of steel wire ropes that affect their durability are the quality of the material and the size of wire, and the diameter of the pulleys and arrangement of the ropes.

Quality of Material and Size of Wire

The wire used for lifting ropes is of crucible steel having a tensile strength varying from 80 to 130 tons per square inch. Although ropes made from material having a high tensile strength are of smaller diameter for a given load and a given factor of safety, this is not of great advantage to the crane designer. The stiffer character of the wire makes larger drums desirable, if the durability of the rope is to be considered, notwithstanding the fact that some rope-makers claim as an advantage for the stronger material that it does enable smaller pulleys to be used with a consequently lower cost of the working parts of the crane.

The ratio of the diameter of the individual wires to the diameter of the completed rope is an important factor. If the wires are too large, they are stressed considerably when passing over the pulleys, and accordingly the material is quickly fatigued and the wires break. Smaller wires, on the other hand, are more quickly worn through by rubbing against the pulleys and against their neighbors in the body of the rope. The stress in a wire due to bending round a pulley is directly proportional to the modulus of elasticity and to the diameter of the wire, and inversely proportional to the radius of the pulley; therefore, the radius of the pulley should be increased with an increase in the modulus of elasticity, if the same number of bends is to be endured by a stronger wire of the same diameter. Unfortunately, a theoretical calculation of the stresses induced in the wires of a rope by being bent over a pulley does not alone afford a reliable guide to the length of life to be expected from the rope, for consideration must also be given to the mutual wear that takes place among the wires.

Assuming, for the purpose of comparison, that two ropes are constructed of equal size, one from wires half the diameter of those in the other, then, for equal strength, the one rope will have four times the number of wires, and each of the wires will have one-quarter the cross-sectional area. According to the usual formula, the stress due to bending will be half as severe in the smaller as in the larger wires, when the ropes are bent over pulleys of the same diameter. If it be allowed that a reasonable figure for the estimated stress due to bending an ordinary rope over a pulley of a size usually adopted in crane design be, say, 30 tons per square inch, and that the stress due to the suspended load be 10 tons per square inch, then there will be a stress of 40 tons per square inch in the material each time the maximum load is lifted and released. The corresponding stresses in the rope of finer wires will be 15 tons per square inch due to bending, and, as before, 10 tons per square inch due to the suspended load, or a total of 25 tons per square inch.

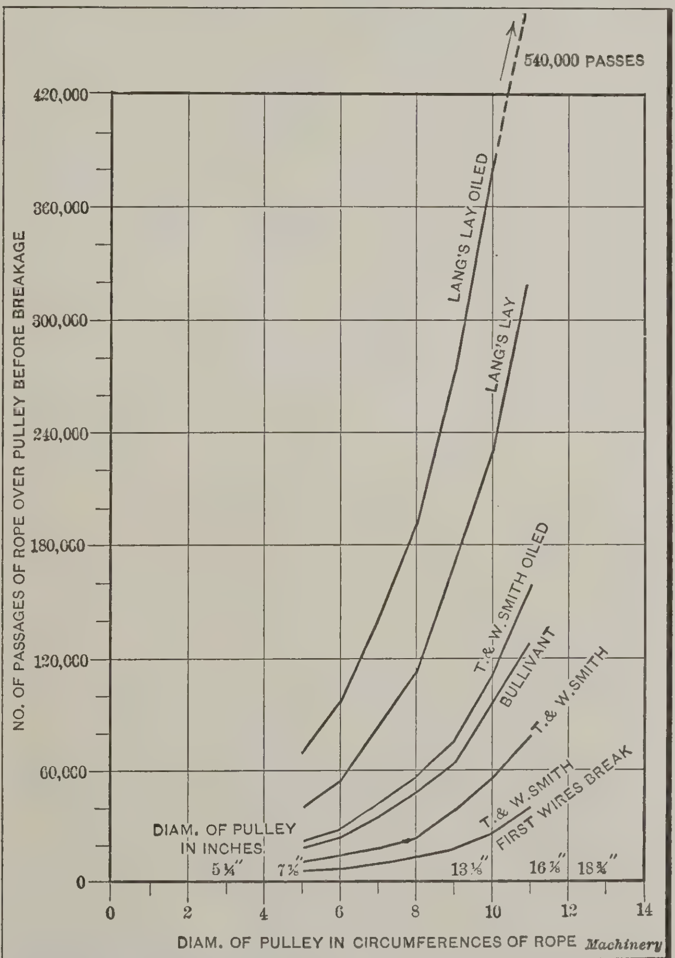

Fig. 2. Curves based on the Data in Fig. 1, covering the Conditions of General Overhead Crane Practice

There is, as yet, no agreement as to the exact effect upon endurance, of variations in the working stresses. It seems, however, to be reasonable to assume that a reduction in range of stress from 40 tons per square inch to 25 tons per square inch would increase the life of material such as ropes are

* Abstract of a paper by Mr. Daniel Adamson, read before the Belfast meeting of the Institution of Mechanical Engineers, Great Britain, July, 1912.

See also MACHINERY'S Reference Book No. 24, Chapter III, "Bending Stresses in Wire Rope."

composed of about 500 times. As no such improvement in the life of a rope has ever been experienced, or is to be reasonably expected, it must be taken for granted that abrasion is the principal factor in limiting the life of wire ropes, and, therefore, the effect of abrasion upon the suggested rope of finer wires must be considered.

When the rope of finer wires is passing over the pulley, there being four times as many wires in it, the pressure at each point of contact between the rope and the pulley and between the individual wires of the rope may be assumed to be one-quarter of what it is in the rope of larger wires. The wires being of half the diameter, the damage done to them by contact, even under this lower pressure, will be at least half that done to the coarser wires in the other rope, and this half damage done to a wire of one-quarter the sectional area will result in the cutting through of the wire in half the time, so

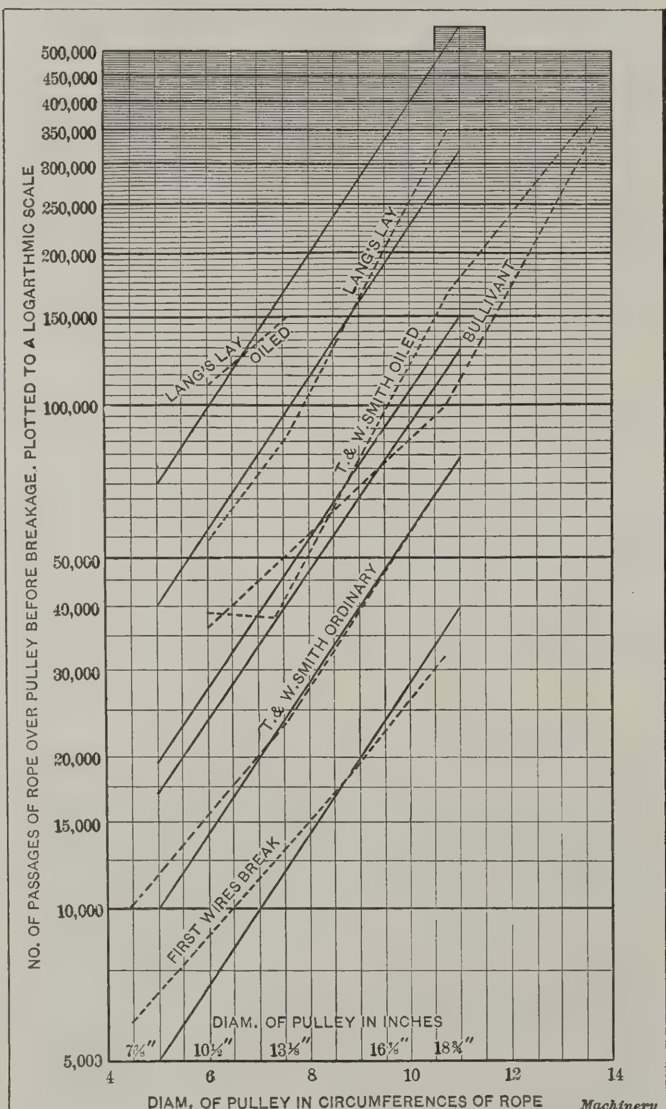

Fig. 3. Durability as affected by Diameters of Rope and Pulley

that the effect of abrasion upon the rope of finer wires will be twice as great. If a smaller pulley be used for the rope of finer wires, as suggested by some authorities, the pressure at the points of contact and the stress due to bending will be proportionately increased, so that it may reasonably be expected that with a pulley-diameter bearing in each case the same proportion to the diameter of the wires, the life of the rope with fine wires will be one-quarter of that of the rope of coarser wires working over a pulley of correspondingly increased diameter.

A German investigator (Ernst Heckel) refers to the very great surface pressures on the wires at the place of contact with the pulley (amounting in his opinion to as much as twelve tons per square inch) as a vital point in connection with the wear of wire ropes. This high pressure, accompanied as it must be by relative movement, even if quite small, readily accounts for the wear which takes place on the surface of the wires where they touch the pulleys or the other wires in the rope.

Diameter of Pulleys and Arrangement of Ropes

The lists issued by makers of wire ropes contain recommendations as to minimum sizes to be adopted, but no information is given as to the effect of using pulleys of different diameters. The author has felt for many years past the want of such information, but the experience of users afforded no reliable guidance, on account of the great difference in the conditions under which ropes work in different shops. In a paper read before the Manchester Association of Engineers by Mr. Matthews in 1902, he states that from 400 to 1700 lifts per crane per annum was the amount of duty required from certain cranes under his control, while the present author, in the discussion on Mr. Matthews' paper, mentioned from 32,400 to 43,200 lifts per crane per annum as representing his own experience in another class of work. Other important features that will affect the life of a crane rope are the average weight lifted and the average height of lift; cranes are generally occupied with loads much below their nominal capacity, but this will vary in different workshops, as will the proportion between the maximum height of lift available and the height most frequently attained by the hook.

Inquiries addressed to the users of cranes elicited varied replies; ropes working upon cranes of the same general design were found to last for periods of from two years to ten years and upwards, and one correspondent suggested that twenty years might be expected from ropes on cranes (of from five to twenty tons capacity) if damage from accidental causes could be eliminated. As might be expected, the ropes on foundry cranes have not so long a life as in erecting shops, the relative difference being perhaps as three is to five.

The most reliable and consistent information that the author has been able to discover is contained in a paper by Mr. A. S. Biggart, published in 1890 in the *Proceedings* of the Institute of Civil Engineers, Vol. CI, page 231. The experiments to which this paper refers were undertaken with the object of selecting the best form of rope to be employed in the construction of the Forth Bridge. The apparatus used by Mr. Biggart contained two pulleys, round which the rope under trial was passed, the lower pulley being weighted to give the required tension on the rope. The experiments consisted in passing the ropes, under a normal working load, to and fro over the pulleys until breakage ensued. Experiments were repeated with different diameters of pulleys and different makes of rope, and the accompanying diagram, Fig. 1, shows the life of different classes of rope as affected by the diameter of the pulleys.

The effect of oiling the ropes is shown by the diagram to be very beneficial, increasing the life of a given rope by two or three times. This is obviously due to the reduction of the cutting action of the wires upon each other. Experiments were also made to ascertain the effect on the life of a rope of running it over pulleys so arranged that the rope was subjected to reverse stresses, as shown in Fig. 4. The results obtained from this series of experiments showed that generally the life of a rope working under such conditions was only one-half that of a similar rope bent in one direction only.

Fig. 1 is based upon the actual figures tabulated in Mr. Biggart's paper, while Fig. 2 shows the present author's approximations as obtained by the simple method of drawing fair and regular curves through or near the points representing the results of Mr. Biggart's experiments over such a range of pulley diameters (measured in terms of the circumference of the ropes) as obtain in general overhead crane practice. Several interesting deductions may be drawn from a study of these figures. The time of breakage of the first wires of a rope in the lowest curve is only recorded for one make of rope, but comparing it with the second curve, which shows the time of breakage of whole ropes of the same make, it will be seen that when the first wire breaks, the rope may be assumed to have passed through one-half of its life, and as no one knowingly works a rope until it breaks entirely, the breakage of even a few wires is a sign that a rope should be carefully watched and replaced by a new one at an early opportunity.

The effect of varying the proportions of diameter of pulley to diameter of rope is one of the most important features to be

noticed. Speaking generally, Mr. Biggart's experiments show that increasing the diameter of the pulleys by an amount equal to two circumferences of the rope will double the life of the rope. This is approximately correct for all the varieties of rope and conditions experimented with, and may therefore be taken as equally correct for all the varying conditions under which cranes are worked. It is very remarkable that so simple a rule should evolve from such numerous and varied experiments, and the author hopes that its statement in this form will be of some value to designers. That it is sufficiently correct for all practical purposes may be readily seen by referring to Fig. 3 where the ratios of pulley diameters to ropes are plotted as abscissas to a linear scale, while the durability of the ropes is represented by ordinates drawn to a logarithmic scale.

These conclusions enable one to express a definite value for the effect upon the durability of ropes, of the various arrangements of pulleys that are commonly adopted in overhead cranes, some of which are illustrated in Figs. 5 to 11. Assuming that Fig. 6 (in which the ropes make three bends in working, namely, one at the upper drum and one on each side of the lower pulley, *i. e.*, at entering and leaving) is the arrangement most frequently adopted in practice, and representing the anticipated life of the rope under these conditions by 100, then the relative lives of the ropes in each of the other arrangements indicated are as shown in Table I.

TABLE I. COMPARISON OF ANTICIPATED LENGTH OF LIFE OF ROPES ARRANGED AS SHOWN IN FIGS. 5 TO 11

Fig. No.	No. of Bends	Relative Life of Rope
5	1	300
6	3	100
7	3*	75
8	7	43
9	11	27
10	7*	37½
11	11*	25

* Including one reverse bend which is twice as effective in wearing out the rope.

If it be desired to design each of the above arrangements of pulleys so that the ropes shall have equal durability, then the ratio of the drum diameters to rope circumference (if the law indicated by Figs. 2 and 3 is to be relied upon) must be increased as shown in Table II.

TABLE II. REQUIRED INCREASE IN DIAMETERS OF ROPE DRUMS (MEASURED IN TERMS OF CIRCUMFERENCE OF ROPE) REQUIRED TO GIVE EQUAL DURABILITY

Fig. No.	Increase over Diameter called for by Fig. 6
7	1 Circumference of Rope.
8	2½ Circumferences of Rope.
9	4 " "
10	3 " "
11	4 " "

It is quite usual for purchasers to specify in their inquiries that the diameters of the pulleys and drums must bear a certain relation to the diameter of the rope, but the author wishes now to emphasize the point that this stipulation is not sufficient in itself without some consideration being also given to the arrangement of the rope and pulleys.

If the generally accepted ratio of seven circumferences, or twenty-two diameters, of the rope for the diameter of the barrel be assumed as suitable for the drum and pulleys arranged as in Fig. 6, then the diameters for the other figures, to give equal durability, should be as shown in Table III.

TABLE III. RATIO OF DIAMETER OF PULLEYS AND DRUMS TO CIRCUMFERENCE OF ROPE TO GIVE EQUAL DURABILITY

Fig. No.	Ratio of Pulley and Drum Diameter to Rope Circumference
5	4 to 1
6	7 to 1
7	8 to 1
8	9.5 to 1
9	11 to 1
10	10 to 1
11	11 to 1

To make the comparisons quite fair between the different arrangements, it must now be pointed out that owing to the increased number of falls of rope adopted in Figs. 8 and 9, the size of the rope may be reduced as shown in Table IV, while retaining the same factor of safety.

TABLE IV. RELATIVE ROPE CIRCUMFERENCE ALLOWING FOR SMALLER ROPES DUE TO INCREASED NUMBER OF FALLS

Fig. No.	Number of Falls	Relative Rope Circumference
5	2	140
6	4	100
7	4	100
8	8	70
9	12	57
10	8	70
11	12	57

Combining the figures given in Tables III and IV will give drum and pulley diameters as shown in Table V.

TABLE V. DRUM AND PULLEY DIAMETERS RESULTING FROM A COMBINATION OF TABLES II AND IV, AND STILL ASSUMING THAT 100 REPRESENTS THE CONDITION IN FIG. 6

Fig. No.	Ratio of Pulley and Drum Diameter to Rope Circumference according to Table III	Relative Circumference of Rope as per Table IV	Resultant Pulley and Drum Diameter assuming Fig. 6 = 100
5	4	140	80
6	7	100	100
7	8	100	114
8	9½	70	95
9	11	57	90
10	10	70	100
11	11	57	90

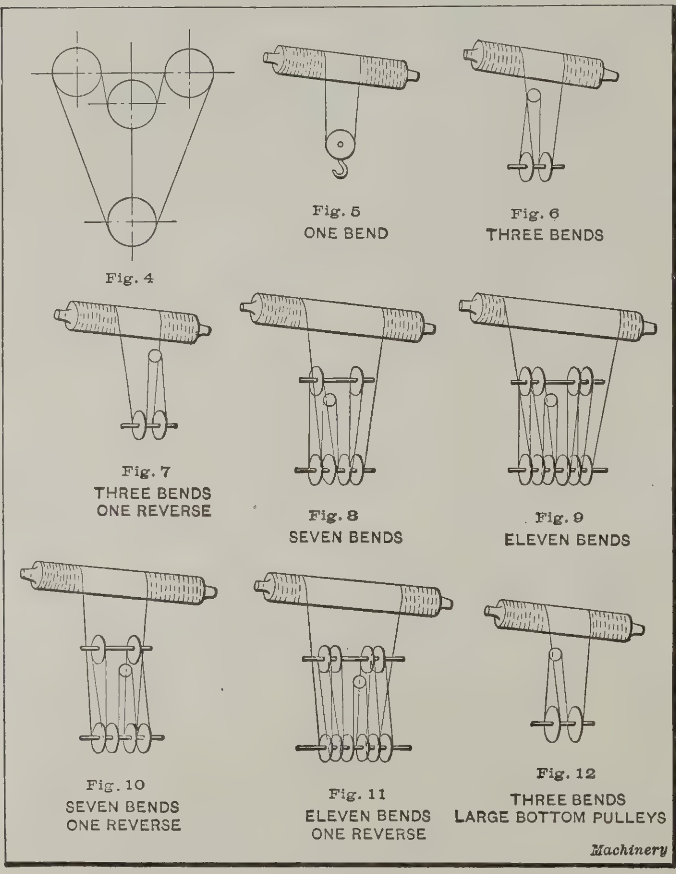
The noticeable feature in the last table is that whether two, four, or six falls are adopted, the diameter of the drum and pulleys should remain about the same, if the ropes are to have equal durability. A recent text-book upon the subject of crane design states (as an advantage of a large number of falls of rope) that the proportionately larger pulleys and barrel will insure *long* life for the ropes, but the author hopes that he has made it clear that very large proportions are necessary to insure a *reasonable* life for ropes on cranes with many falls of rope. Reference to Table V shows also the increase that should be made in the diameter of the drum and pulleys if a reverse bend occurs in the run of the rope.

Another important detail in crane design may now be referred to. In Fig. 6, as already mentioned, the ropes make two bends at the lower pulleys to one at the drum, and therefore, if the lower pulleys are made of the same diameter as the drum they will be responsible for two-thirds of the wear and tear of the rope. Now it is usually difficult to increase the diameter of the working barrel or drum of a crane, because to do so affects the ratio of the gearing and also requires a much larger framework with a corresponding increase in the cost of manufacture; but, if it is agreed, as a result of Mr. Biggart's experiments, that increasing the diameter of the pulley over which a loaded rope passes, by an amount equal to twice the circumference of the rope, reduces the evil effects of bending the rope round it to one-half, then a simple means of improving the durability of crane ropes is immediately at the disposal of the designer, namely, to increase the diameter of the pulleys in the blocks, leaving the drums of the original size, as indicated in Fig. 12. This change can usually be effected without serious alteration of the design, and may even be carried out on existing cranes. The result of increasing the diameter of the pulleys by an amount equal to two circumferences of the rope will be that the effect of the double bend round the lower pulley is halved, the resultant effect of the three bends will be equal to two only, and the relative life of the rope will be increased by 50 per cent; or the drum diameter might be reduced by an amount equal to 1.2 times the circumference of the rope with a corresponding reduction in the size of the framework of the crab or winch, while still retaining a relative life for the rope equal to that in Fig. 6. In this case the diameter of the lower pulleys would only require to be about one circumference of the rope larger than the original size of Fig. 6.

In making the foregoing comparisons of diameters of drum and pulleys with different arrangements of rope it has been assumed that the hook is raised to the full height available at each lift. This, however, is not the case in actual practice, the majority of loads not being raised one-half this height. This consideration brings to light another great advantage of the design in Fig. 12 as compared with any of the others.

Where, as is usually the case, the average height of lift in a shop does not reach half the maximum available, then that portion of the rope which passes under the lower pulley does not reach the upper drum, and accordingly is only subject to the wearing action of the two bends at the lower pulley. If, therefore, the effect of the bends at the lower pulley is reduced to one-half, by the proposed increase in diameter of the pulley, then the actual life of the rope will be doubled, instead of only being increased by 50 per cent, as was first assumed.

Where there are more than two falls of rope, as in Figs. 8 and 9, the effect of increasing the diameter of the pulleys by an amount equal to two circumferences of the rope is also very marked, reducing the effect of the seven bends in Fig. 8 to that of four and a half, with corresponding increase in the lift of the ropes. This shows up the fault of those designers



Figs. 4 to 12. Various Arrangements of Drums and Pulleys in Lifting Appliances

who adopt large drums (in order to obtain the great length of rope entailed by high lifts) and are yet content to make the pulleys of small sizes, when they could enormously increase the durability of the rope by the adoption of larger pulleys at little extra cost.

When the rope makes a reverse bend at the barrel as in Figs. 7, 10, and 11, the barrel ought to be increased in diameter to counteract the effect of the reverse bend. Thus, if in each of these cases the diameters of the drums were made larger by an amount equal to two circumferences of the rope, the durability of the rope would be equal to that in Figs. 6, 8, and 10, respectively.

Some Continental makers point out, very rightly, the desirability of making the compensating pulleys of reasonable size. The motion over such pulleys is apparently considered as negligible by some designers (judging by the forms of construction adopted), but this point of view overlooks the movement of the rope due to the swinging of the load, and the repeated bending of the rope at the same place over a small radius has an appreciable effect upon the durability of the rope.

Although the deductions laid down here appear too simple to need elaboration, a glance at the designs of many modern cranes shows that neither the designers, nor the purchasers, are aware of the importance of the principles involved; otherwise we should not see modern cranes with reverse bends in the ropes, and as many as eight plies of rope to carry the load on cranes of only 15 tons capacity.

The qualities of wire used vary considerably, and this, together with the heat-treatment in manufacture and the care taken by the makers in testing and examination, are questions that makers of ropes are in a better position to discuss than users. The "lay" of the strands and the lubrication of the rope when in use have each a considerable effect upon durability, and some guidance on these points may be obtained from Fig. 3, where "Lang's lay" is shown to have more than double the life of ropes of ordinary "lay," and ropes that are oiled last more than twice as long as when this precaution is neglected, as already mentioned. The superiority shown by "Lang's lay" naturally gives rise to the question as to why it is not exclusively used, and the answer the author has obtained from rope-makers is that such ropes must be very carefully handled to avoid "kinks," and they are also found to be more liable to "spin."

STATE TRADE SCHOOL OF BRIDGEPORT

The State of Connecticut maintains two trade schools, one of which is located in Bridgeport. The purpose of the Bridgeport school is to teach the methods of machine making, cabinet making, pattern making, drafting, machine shop practice, toolmaking, printing and plumbing.

Several plans of instruction are followed, such as day school, continuation school, and half-time school. In addition, there are vacation and evening schools. The day school course extends over two years, comprising 104 weeks of 49 hours each. The continuation school gives four hours instruction per week to apprentices employed in local factories. Each student is paid his regular wage scale by the factory while in school, and the time is employed in educational work to supplement the training he is receiving in the factory. The half-time school takes care of apprentices who alternate between the shop and the school, being employed at the factory one week and sent to the school the next. The school time is applied on their apprenticeship and the apprentice time is applied on school hours.

Each day of instruction received on the machine shop course is made up of 6½ hours shop work, one hour drafting, ¾ hour applied mathematics, ¾ hour applied science and mechanics. Shop lectures and inspection trips are given at times. In the continuation school the four hours are divided into drafting, 2½ hours, and trade mathematics, 1½ hour. In addition, the teacher occasionally visits the factories so as to keep in touch with the specific needs of each pupil. The students in the half-time school spend half of their time at their trades and the other half in school. They are rated as regular day students and receive the same instruction. Each student must finish one year of regular school training before being entered in this school. There is no charge made to students from any part of the State of Connecticut, nor are there any entrance requirements, save that the students must be fourteen years of age. The school is under the direction of Superintendent Frank L. Glynn.

HORSEPOWER AND KILOWATT

The British Association for the Advancement of Science adopted, as early as 1873, 746 watts as the equivalent of the British and American horsepower, and 736 watts as the equivalent of the metric or Continental horsepower. In a circular recently issued by the United States Bureau of Standards, it is stated that in all future publications of this bureau the former value, 746 watts, or 0.746 kilowatt, will be used as the exact equivalent of the English and American horsepower. For scientific work, it is quite important to have the horsepower thus standardized by being expressed in the so-called "absolute" system of measurement, because the common definition of 550 foot-pounds per second is scientifically correct only at a certain latitude and altitude, on account of the fact that the pound-weight, as a unit of force, varies in value as g, the acceleration of gravity, varies. The horsepower when expressed as 746 watts is equal to 550 foot-pounds per second at 50 degrees latitude and at sea level.

BALANCING AUTOMOBILE ENGINE FLYWHEELS

One of the essential points to be observed in the manufacture of a smooth-running and efficient automobile engine is to put all the moving parts in perfect balance. In the following is described the method employed by the White Co., Cleveland, Ohio, maker of high-grade automobiles and motor trucks, for balancing the flywheels used on its engines.

The first operation called the "static balance test," is carried out in the manner illustrated to the right in Fig. 2.

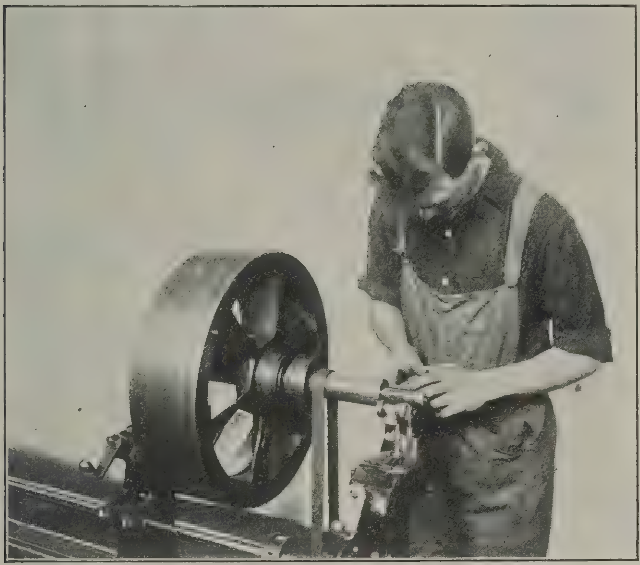

Fig. 1. The Final or Running Balance Test accomplished on a Norton Balancing Machine

Here the flywheel to be balanced is held on a hardened and ground arbor, the latter being located on knife-edges which form an integral part of the balancing stand. The stand has four legs, rigidly braced. When balancing, the operator lets the flywheel oscillate, watching it until it comes to rest. That part of the wheel which is heaviest, of course, always goes to the bottom. A piece of putty is then put on the inside of the rim opposite the heaviest side, and the flywheel is again tried and more putty added, if needed, until a close approximation to a perfect balance is obtained.

The next operation consists in removing the required amount of material from the heavy side of the rim to secure the proper balance. This operation is shown in the center of Fig. 2. The operator places the flywheel on a fixture which is tilted at an angle and is provided with a stud for holding it. The material is removed with a twist drill from that portion of the rim diametrically opposite the chunk of putty. To ascertain the amount of material to remove, the putty is placed on a scale, as shown in the foreground, and the drillings are collected and put on the other pan of the scale. A sufficient amount of material is removed to balance the putty.

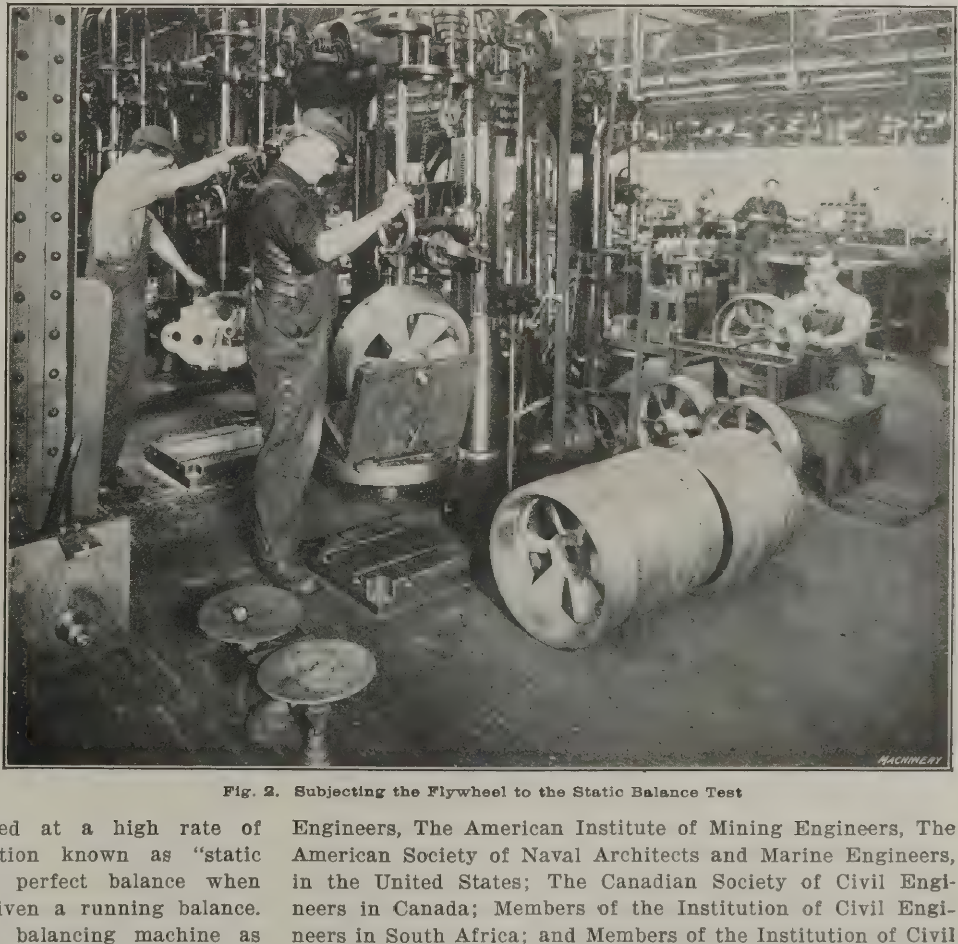

Fig. 2. Subjecting the Flywheel to the Static Balance Test

In the balance test just described, the flywheel is not rotated at a high rate of speed, but is put into the condition known as "static balance." To insure its being in perfect balance when the engine is running, it is next given a running balance. This is accomplished on a Norton balancing machine as illustrated in Fig. 1. The flywheel is again placed on an arbor, the extreme ends of which run on four pairs of rollers, and is rotated by a belt as shown in the illustration.

In order to see where the flywheel is out of balance, the small end of the arbor is coated with red lead, and as it is rotating the operator brings a copper pencil, held in a swinging member, in contact with the arbor. The points on which the pencil bears heaviest indicate the side of the rim from which it is necessary to remove material to make the flywheel balance properly when in service. From the foregoing it will be seen that by following this procedure a flywheel is obtained which aids in producing the much-desired smooth-running automobile engine. D. T. H.

LORD KELVIN MEMORIAL WINDOW SUBSCRIPTION

The engineering societies of the United States are receiving subscriptions for a memorial window to be erected in Westminster Abbey, London, to the memory of the late Lord Kelvin, the distinguished scientist and engineer. Lord Kelvin, formerly Sir William Thomson, was the inventor of the first successful receiving galvanometer for ocean cables, which is a marvel of sensitiveness. His work in the development of testing and recording apparatus for cables made submarine telegraphy a great success. The general committees formed to carry the plan into effect embrace representation from eight engineering societies in England, Ireland, Scotland, America, Canada, Victoria, South Africa and South Australia, and its chairman is William Cawthorne, Unwin, London. The societies represented are: The Institution of Civil Engineers, The Institution of Mechanical Engineers, The Institution of Electrical Engineers, The Institution of Naval Architects, The Iron and Steel Institution, The Institution of Mining and Metallurgy, The Institution of Mining Engineers, The North-east Coast Institution of Engineers and Shipbuilders, all of England; The Institution of Civil Engineers of Ireland; The Institution of Engineers and Shipbuilders in Scotland; The American Society of Civil Engineers, The American Society of Mechanical Engineers, The American Institute of Electrical Engineers, The American Institute of Mining Engineers, The American Society of Naval Architects and Marine Engineers, in the United States; The Canadian Society of Civil Engineers in Canada; Members of the Institution of Civil Engineers in South Africa; and Members of the Institution of Civil Engineers in South Australia.

DOGS AND DRIVERS FOR LATHE WORK

A REVIEW OF THE VARIOUS DESIGNS OF DRIVERS FOR WORK HELD BETWEEN CENTERS

BY H. E. WOOD*

The lathe dog constitutes such an important part of the equipment of a machine shop, and there are so many different types of these devices in use, that it may be of interest to mechanics to follow the writer in a brief review of the most commonly used designs. Many of the lathe dogs shown in the following have been made for special purposes. It may appear that they are not of great utility, but in emergency cases, under special requirements, they have been found useful. A brief reference will be made to each of the lathe dogs shown. The illustrations show clearly the construction, and there is little need for a detailed description.

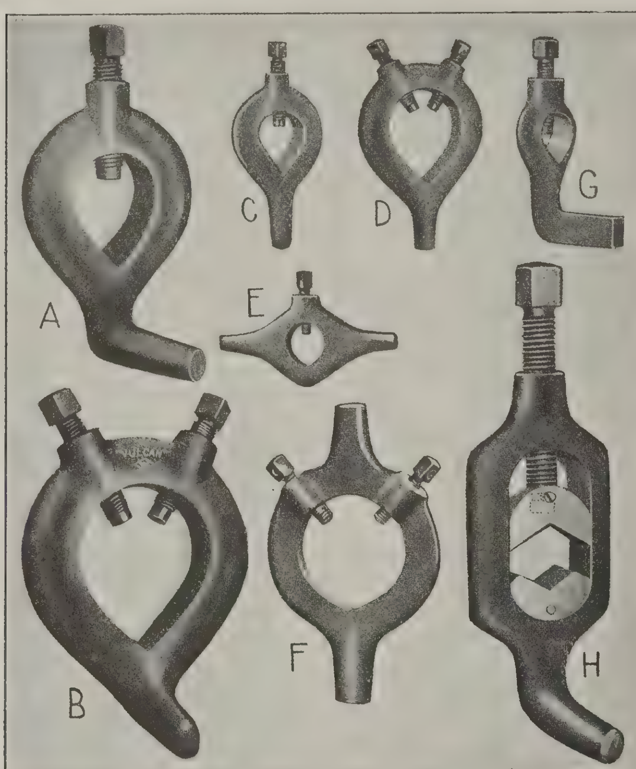

Fig. 1. Miscellaneous Examples of Lathe Dogs

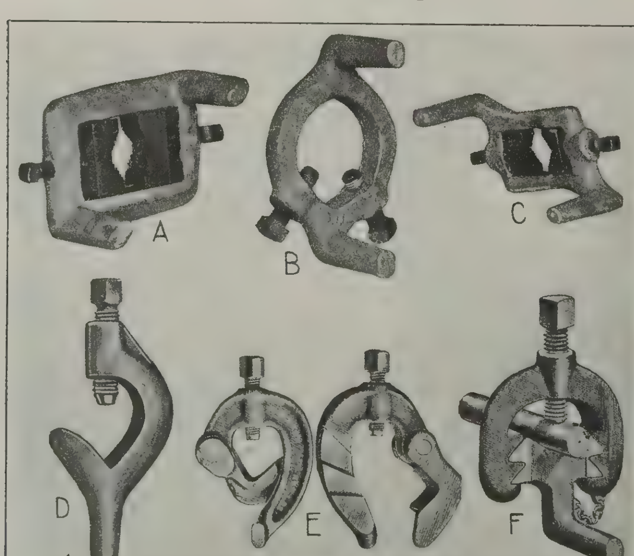

Fig. 2. Lathe Dogs of Special Construction

At *A* in Fig. 1 is shown one of the most commonly used lathe dogs—that with a bent tail and a single screw. At *B* is shown the same type of dog, but having two screws. At *C* is shown what is called a straight-tail dog with one screw, and at *D* the same dog with two screws. When these latter dogs are used, a stud driver, of course, is employed to drive against the tail. At *E* and *F* are shown double-tail dogs with one and two screws, respectively. At *G* is shown a dog which, although similar to that shown at *A*, has a flat tail with parallel sides.

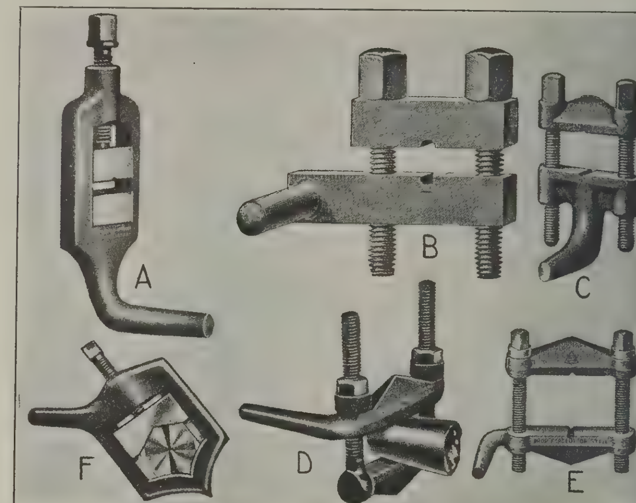

Fig. 3. Die Dog, Clamp Dogs, etc.

This type of dog is used in the milling machine rather than in the lathe, the flat tail making it convenient to secure it with a set-screw when used in the milling machine.

A dog somewhat different from those previously shown is illustrated at *A* in Fig. 3. This is called a die-dog because of its similarity to a thread-cutting die. At *H* in Fig. 1 is shown the so-called "O. K." design of dog. The design of these two dogs is intended to prevent the binding screws from marking the work. At *A*, *B* and *C*, Fig. 2, are shown three double-tailed dogs designed by the Fitchburg Machine Works, which are especially adapted to the Lo-swing lathe made by that company. The prime object of double-tailed dogs is to equalize the pulling strain on the dog on both sides of the center. This relieves the work of undue side strain. At *D* in the same illustration is shown a type of dog called an open-side dog because of the opening at one side which permits of the dog being put onto the work after it is placed on the centers. At *E* is shown the Brinton patented dog which can be slipped on and off the work while it is on its centers, and at *F* is shown a type of dog made in two parts. This dog is adjustable for size, as indicated, there being three possible positions of the lower part within the upper. It is patented by Mr. Richmond Parsons. At *B* in Fig. 3 is shown a very common type of clamp dog, and at *C* the same type of dog with bent tail. At *D* is shown another dog of similar type, but in this design the lower jaw can swivel so as to accommodate tapered work. At *E* is shown still another type of the clamp dog class. At *F* in Fig. 3 is shown a type of patented dog made by the Western Tool & Mfg. Co. Fig. 4 shows what is called a reduction dog.

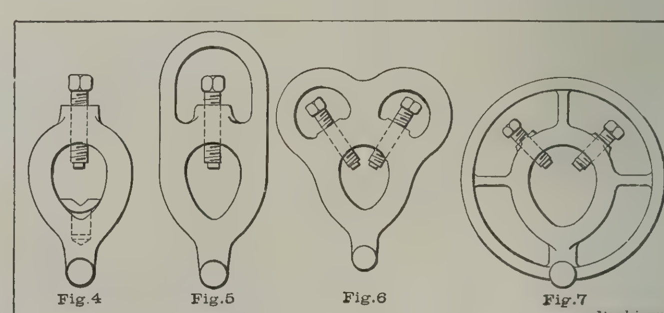

Fig. 4. Adjustable Dog. Figs. 5 to 7. Safety Dogs

Figs. 5, 6, and 7 show three types of dogs with protected screws. It is rather difficult to guard the set-screw on the lathe dog properly so that it cannot cause injury to the operator, but these illustrations indicate what can be done. Fig. 8 shows a somewhat unusual type of double-tail dog provided

* Address: 56 Fifth St., Newark, N. J.

with inserted shoes to assist in the holding of the work. This dog is patented by Mr. William L. Reid. Fig. 9 shows an elaborate type of what is usually termed a hold-back dog. Its object and the manner in which it is used is clearly shown in the engraving, it being used on work where one end runs in a

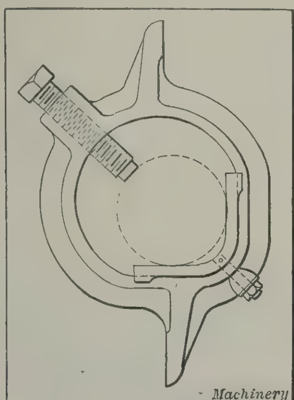

Fig. 8. The Reid Lathe Dog

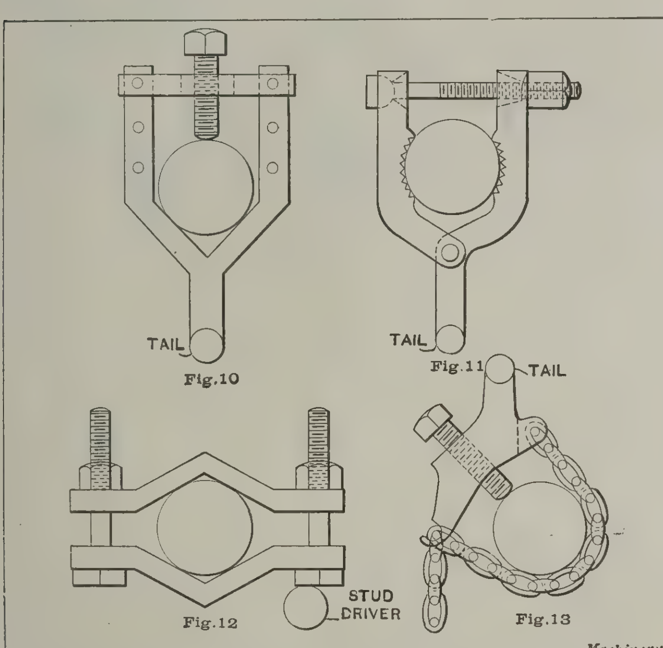
steadyrest, to hold the work against the lathe center. The springs back of the faceplate give the required elasticity to the entire tool. This device eliminates the use of the belt-lace or lashing process which is more or less unhandy. This lathe dog was patented by Mr. Milton B. Hill. In Fig. 10 is



Figs. 10 to 13. Miscellaneous Dogs of Special Construction

shown a "homemade" type of dog. The cross-bar is forked where it fits over the side bars. Fig. 11 shows a dog with corrugated jaws, jointed as indicated. This dog is very convenient for certain purposes. Fig. 12 shows a popular type of driving dog. Dogs of this kind are usually made to suit im-

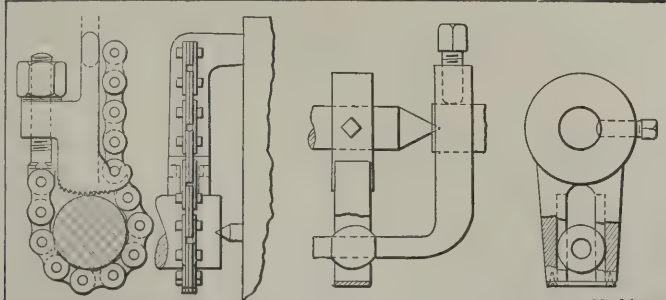


Fig. 14. The Clark Chain Lathe Dog

Fig. 15. The Hill Improved Type of Dog

mediate requirements. Fig. 13 shows a peculiar form of adjustable chain dog. This dog has a capacity for a wide variety of sizes according to the length of the chain. Fig. 14 shows a similar kind of dog patented by Mr. Hugh Elmer Clark, the claim for this dog being that it is easily attached to and detached from the work without removing the latter from the centers.

In Fig. 15 is shown a dog which is more especially adapted for the milling machine, and which is intended for taper work

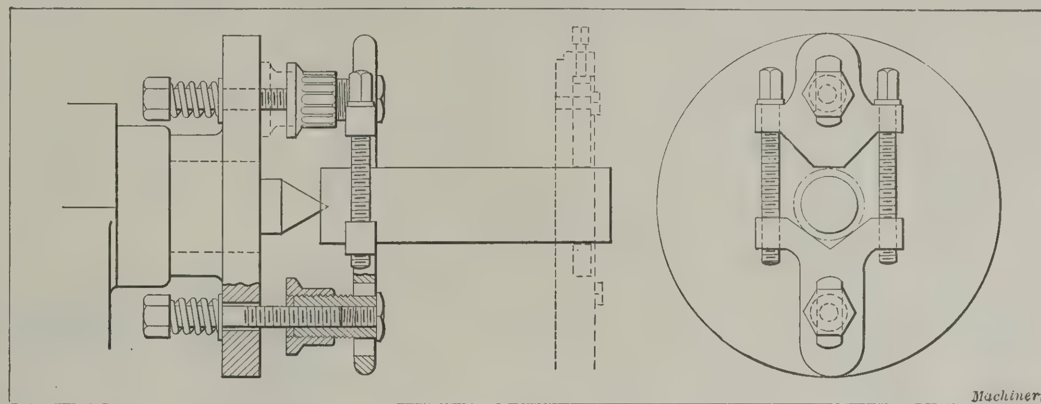

Fig. 9. The Hill Hold-back Dog

when it is necessary to have a radial and transverse movement and at the same time have no backlash in the rotating direction. This dog is patented by Mr. Milton B. Hill.

Fig. 16 shows a dog specially designed for use when producing a large number of pieces of the same size. This dog is termed a faceplate dog, principally because it is secured to the faceplate of the lathe. It is patented by Mr. Adam Tindel. Fig. 17 shows a dog which operates without screws. It is quick-acting, but can drive in one direction only. This design is patented by Mr. Thomas C. Thompson. Fig. 18 shows a dog especially devised for driving work which has irregular surfaces of any sort. It is patented by Mr. Louis Goddun. Fig. 19 shows a lathe dog which can be tightened without a wrench. It is patented by Mr. Frank L. Osgood. It can be attached to and detached from the work without removing the latter from the lathe. Fig. 20 shows a very simple but strong and efficient dog which can also be attached to and removed from the work

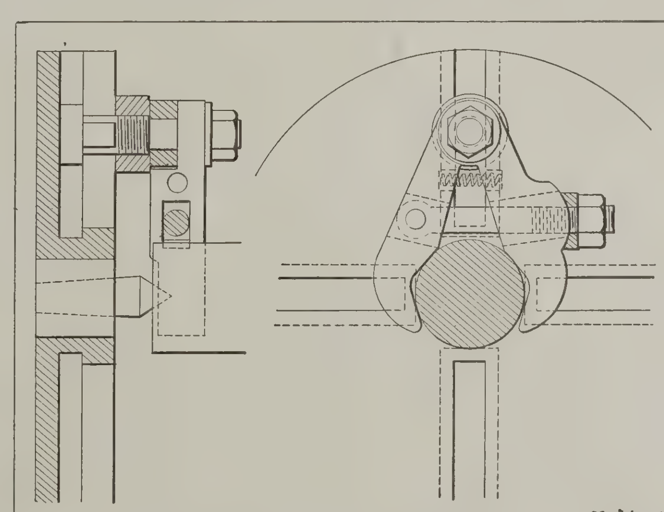

Fig. 16. The Tindel Lathe Dog

while the latter is held between centers. Fig. 21 shows a number of types of clamp dogs. The one at *A* has brass-faced clips to protect finished work from being marred. The dogs shown at *E* and *F* are also provided with soft jaws for protecting the work. Those shown at *D*, *E* and *F* are intended to be self-balancing dogs for grinding machines.

In addition to the devices illustrated, there are shown in the following some devices which can hardly be classed as dogs, but which are merely makeshifts used in place of dogs. Fig. 22 shows a very common method of driving a piece of lathe work, the device consisting of two V-blocks clamped onto the work with an ordinary C-clamp. In Fig. 23 the clamp is used with its screw directly on the piece being turned. It will be noticed that the center line of the screw is a trifle in front of the center line of the work and that there is a block behind the work. This arrangement has been adopted in order to insure

that the screw will not work off the shaft. The use of a stud driver in the faceplate of the lathe is, of course, necessary when these methods are employed. Fig. 24 shows another commonly used method where either a wooden or iron parallel clamp is screwed onto the shaft or work.

Fig. 25 shows a cheap makeshift which is often resorted to. This dog consists simply of a piece of scrap iron with a hole

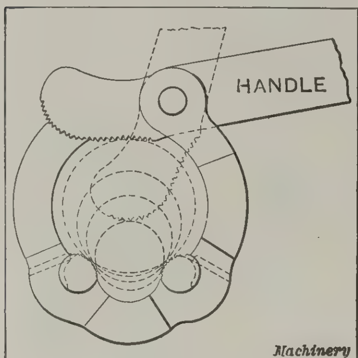

Fig. 17. The Thompson Lathe Dog, which operates without Screws

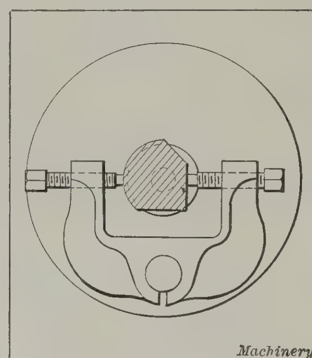

Fig. 18. Lathe Dog for Irregularly Shaped Work

through it, large enough to take the work for which it is wanted. Fig. 26 shows another makeshift consisting of a common collar with an extra set-screw in it and a hole drilled for a piece of round iron driven into the collar and used as a tail. Fig. 27 shows a threaded lathe dog with a split hub and binding screw. When work is threaded on the end, the diam-

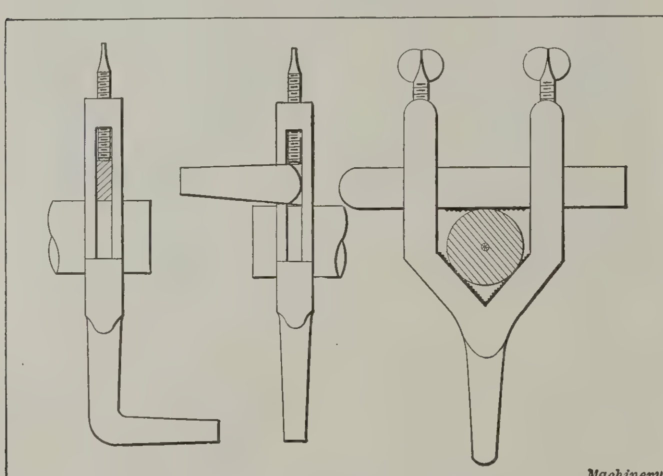

Fig. 19. The Osgood Lathe Dog

eter of the thread being the same as that in the dog, the latter can be screwed onto the work and clamped by the binding screw so as to drive the work without injuring the thread. Fig. 28 shows another type of dog with a threaded hole in it. This dog is intended to be placed on the ends of studs or pieces made in the screw machine, or on any piece not having

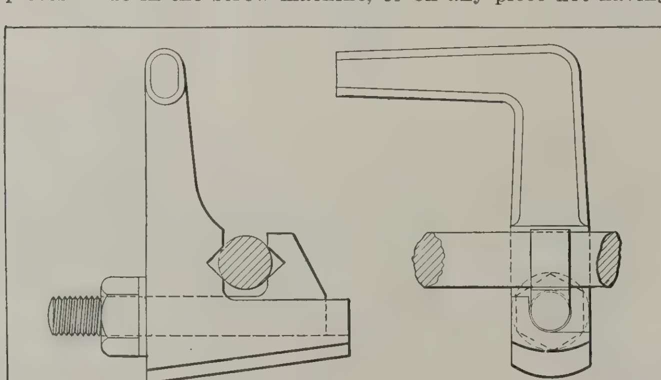

Fig. 20. Type of Open Dog

a center. Fig. 29 shows another cheap, "homemade," open-side, adjustable dog. This type is made from a round piece of cold-rolled steel, bent as shown. Three pin-holes are drilled through it so as to receive the pin which holds the head, which is adjustable from one position to another. Fig. 30 shows a simple method of driving a piece of work, the dog consisting merely of a piece of flat iron bent over to suit the work, with a bolt for binding as shown. Fig. 31 is another type consisting merely of a piece of flat iron, bent as required and drilled and tapped for a set-screw. Fig. 32 is especially intended for use on finished work, when one wishes to avoid any marks which might be made by the lathe dog.

There are, of course, innumerable devices that have been made for special purposes, but those shown are typical and indicate what may be done. In addition there are, also, of course, a number of drivers used on faceplates for driving chucked work not held between the centers. These, however, are not strictly lathe dogs, and as they are often made to suit special requirements and have hardly any common characteristics, they are not dealt with in this connection.

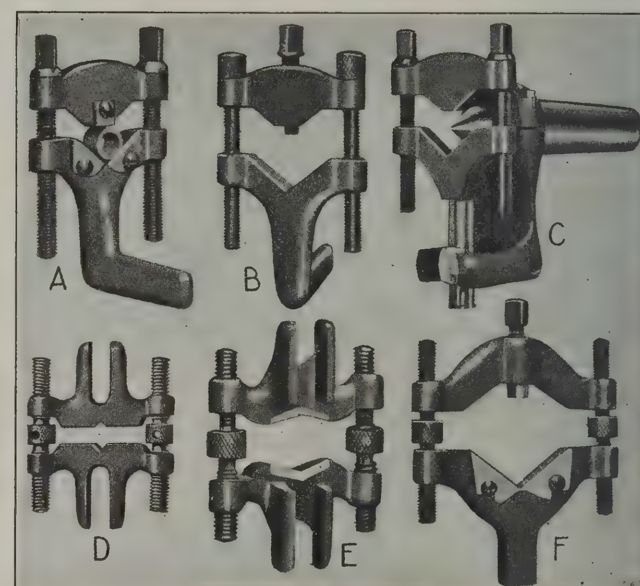

Fig. 21. Hill Clamp Dogs

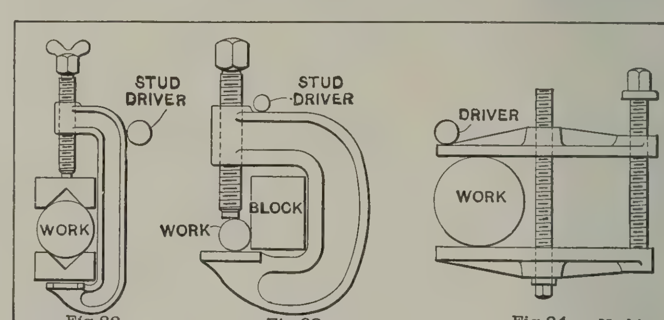
In Fig. 33 is shown a safety lathe dog which has been brought out by Elmer J. Michaud of South Windham, Conn. Every machinist who has operated a lathe realizes the danger incident to the use of the ordinary lathe dog with its unguarded set-screw, which tends to catch in the clothing, especially when filing. This lathe dog is so shaped that it



Figs. 22 to 24. Makeshift Dogs

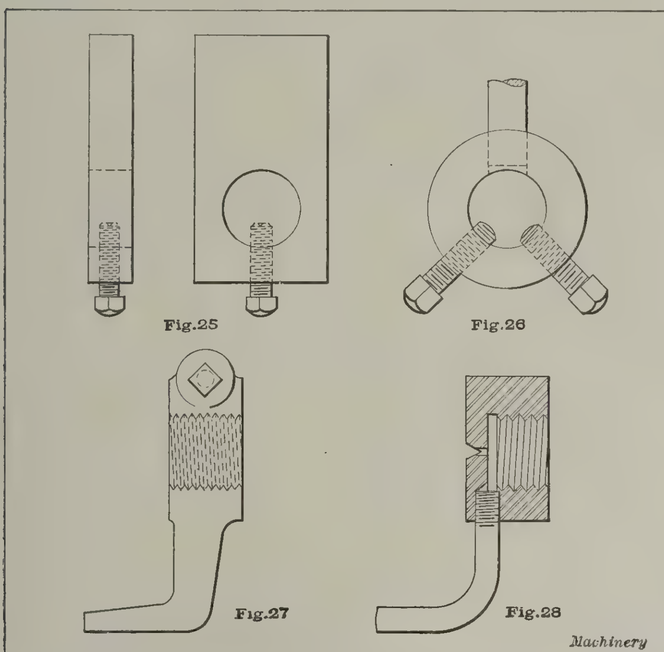
provides a guard, the tail of the dog being curved around in front of the set-screw on the leading side, thus affording protection. It can be clearly seen that this feature does not interfere with loosening or tightening the set-screw.

* * *

A method of accurately shaping very small dies, punches and other tools to an irregular form, developed by the watchmakers of Switzerland, employs a projectoscope or magic lantern as a magnifier. The shape required is drawn carefully to a scale of, say, fifty times actual size. The tools are made to size and shape as nearly as possible by common methods and are finished by stoning off the high parts which extend beyond the limits of the drawing when projected on it by the lantern. The inaccuracies are thus multiplied fifty times and the spots that do not coincide with the drawing are stoned off by a specially devised grinding rig that is controlled by the toolmaker, the tool being worked down without removing it from the lantern.

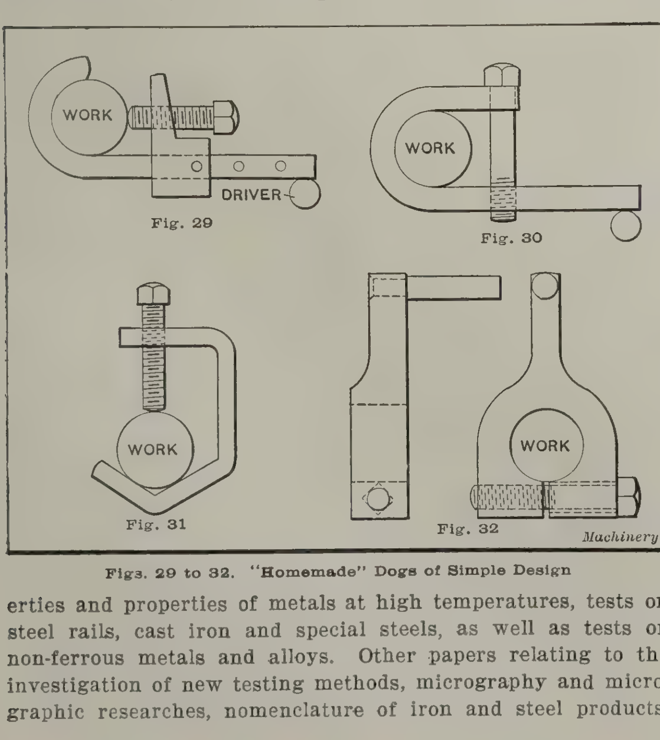
CONGRESS OF INTERNATIONAL ASSOCIATION FOR TESTING MATERIALS

The sixth congress of the International Association for Testing Materials was held in the Engineering Societies Building, New York City, September 2 to 7. Twenty-four nations were represented in the congress, the various foreign governments, as well as engineering societies here and abroad, having sent delegates. The object of the society is to further the progress of engineering by augmenting the knowledge relating to materials, by devising proper means and methods for the testing of materials, by drawing up specifications for materials for various purposes, and, in general, by providing standardized and uniform methods of engineering practice, in as far as the properties of materials of construction are concerned.



Figs. 25 to 28. Other Examples of Makeshift and Special Dogs

The congress was divided into three sections: one on metals, with a sub-section on cast iron and special steels; one on cement and stone; and one on miscellaneous materials. One hundred and fifty-three papers formed the program for the sixth congress. These papers related to hardness testing, to wear tests of steels, impact tests, corrosion tests for pipes, endurance tests, tests relating to magnetic and electric properties and properties of metals at high temperatures, tests on steel rails, cast iron and special steels, as well as tests on non-ferrous metals and alloys. Other papers relating to the investigation of new testing methods, micrography and micrographic researches, nomenclature of iron and steel products, as well as a considerable number of papers relating to cement, stone, paints, timbers, oils, road materials and rubber, were also presented.



Figs. 29 to 32. "Homemade" Dogs of Simple Design

The International Association for Testing Materials meets every three years in a congress devoted to the presentation and discussion of technical papers along the lines outlined. The last congress was held at Copenhagen, Denmark, in 1909. The preparations for the sixth congress have been in the hands of the American Society for Testing Materials, which is affiliated with the International Association. The social features included an informal reception under the auspices of the American Society for Testing Materials, the American Institute of Electrical Engineers, the American Society of Mechanical Engineers, and the American Institute of Mining Engineers, on Monday, September 2, and an excursion on the Hudson River to the military academy at West Point on September 4. On September 5 there was a reception tendered to the foreign members by the American Society of Civil Engineers. For those of the foreign members who desired to see something of America and its industrial development, a special excursion hotel train was arranged after the adjournment of the convention, making a week's tour, visiting Washington, Pittsburg, Buffalo and Niagara Falls.

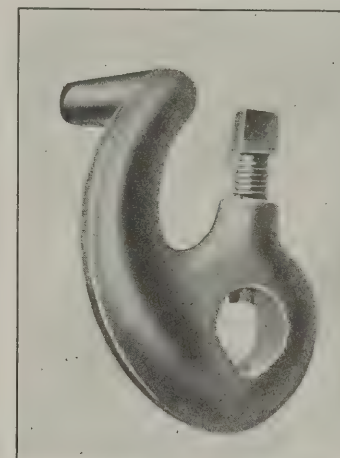


Fig. 33. Michaud Safety Dog

Before adjourning the congress elected as the new president of the International Association, Prof. N. Belelubsky of St. Petersburg, Russia, professor emeritus of the Institute of Engineers of Ways of Communication. The next international congress of the association will be held in 1915 in St. Petersburg.

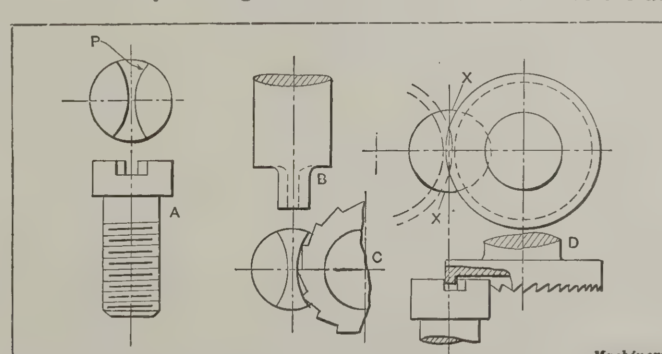
UNUSUAL FORM OF SLOT IN FILLISTER-HEAD SCREW

An unusual form of slot in fillister-head screws is illustrated in a recent issue of the *Mechanical World*. This form of slot is used by an English firm and is claimed to have the advantage of providing a screw slot that is not likely to be injured; it also provides for a strong form of screw-driver. In the illustration *A* shows the screw, *B* the screw-driver, *C* the cutter used for milling the screw-driver, and *D* the annular cutter employed for milling the slot in the screw head. It is evident that two milling operations with this cutter are required for each slot. In addition, an ordinary plain cutter must be run through in order to remove the piece *X*, which otherwise would remain at the ends of the slot. The screw head is strengthened in this way, it is claimed, because the pressure of the screw-driver is received in the direction of the arrow *P*, in which there is a better backing of metal to withstand the pressure. The slot is, in fact, of the same shape that an ordinary plain slot tends to assume after it has been used for some time.



Form of Screw-driver, and Screw-head Slot and Method of Producing it

CHARACTERISTICS OF WROUGHT-IRON

A REVIEW OF KINDS, USES, PECULIARITIES, AND METHODS OF TESTING

BY A. L. HAAS*

Wrought-iron has, to a very large extent, been superseded by mild steel. Nevertheless, a large field remains where its resistance to fatigue and the ease with which it can be welded renders it valuable. Where reliability is of prime importance, no other material is superior to it.

Yorkshire iron of the best quality is still made in large quantities. There is no finer commercial grade of iron to be obtained anywhere than the iron known as Lowmoor or Farnley. The iron made in Staffordshire is of a lower grade, and it is this quality of iron that is threatened with extinction by mild steel. The cost varies, of course, with the quality, the best Yorkshire iron demanding twice the price of low-grade Staffordshire iron.

There are some articles for which wrought-iron is always used, for example, crane chains, lifting hooks, locomotive draw gears, etc. Years ago marine engine shafting was invariably made from wrought-iron. The firm of Blair, of Stockton on Lees, one of the earliest makers of marine engines and one of the most conservative firms at the present time, still makes (or, at least, until very recently did make) its shafting from this material. It is a well-known saying on the Northeast coast that no ship with Blair engines has ever been known to break down at sea from a fractured shaft. Two leading makers of steam fire engines still use Lowmoor plate for their boilers. These boilers are subjected to a heavy duty in spite of their small size. In locomotive practice Lowmoor iron rivets are still used for the boilers.

Pieces of Wrought-iron having been subjected to the "Rams Horn" Test

Corrosion of Wrought-iron

The resistance of wrought-iron to corrosion is remarkable, in spite of any statements to the contrary based on short periods of comparative tests. At Delhi, in India, there is a monumental column of this material which is over one thousand years old. The writer is informed on good authority that in various humid parts of India native-made iron, whose origin is too far back to be definitely known, is still seen fully exposed to weather conditions. At the Epping church, near London, there are some exposed iron hand-rails, one hundred and fifty years old, the section of which has not been diminished below the margin of safety during this period. This iron was probably smelted and puddled in small quantities, using charcoal for fuel, from particularly high-grade and easily reduced ore.

Corrosion in iron takes place in layers on account of its fibrous structure. The make-up of an iron bar can be compared with that of a wire rope, the spaces between the wires being filled with a silicious matter, which latter is naturally more or less weather- or corrosion-proof. In the instance of the hand-rails at the Epping church, the structure is plainly apparent, as corrosion has left the rails knotted like the trunk of an old tree. The pitting characteristic of steel is absent in this ancient iron.

* Address: St. Ives, Crowborough Road, Tooting, London, S. W., England.

It is a fact admitting of no controversy that the use of mild steel for ship plates has reduced the life of the hulls by one-half, and a similar reduction in life has accompanied the adoption of mild steel for boilers. The writer has personally observed steel deck plates around hatches which were originally ⅜ inch thick, that in a fourteen-year old steamer had been reduced to a thickness of 1/16 inch over a considerable area. The same vessel had to have the entire engine and boiler room tank (top, floors and intercostals) renewed after the same period. The original 7/16-inch plate could in a great many places be perforated with a good blow from a sharp scaling hammer.

On the other hand, an old steamer called the *Dodo*, which used to ply regularly between Cardiff and Spain, and which was provided with one of the earliest iron hulls ever built, was 65 years old in 1900. It is still running, and, hence, is now 77 years old. A fireman who sailed in her, and subsequently with the writer, said that he was afraid to break coal in her lower bunker or to scrape up dust with his shovel, using undue violence, for fear he would break through the bottom. A similar steel hull would have been in the ship breaker's hands in half that length of time. In fact, wooden hulls last longer than these do. A collier trading between Newcastle and London was sold for a coal store hulk at the youthful age of 150 years. In many ports scattered throughout the world old British wooden ships converted into stationary hulks can frequently be seen.

Present-day Tendency to Reduce First Cost and Increase Cost of Upkeep

It seems to the writer that the present-day tendency is to reduce the first cost, increase the cost of upkeep, and decrease the length of service without corresponding advantages, by the use of newer materials. Of course, circumstances alter cases, and there are instances where economy is of no account. There is a works in the Birmingham district in England which was recently taken over by an up-to-date concern. In these works there was a beam engine built by Bolton & Watt, which must have been about eighty-five years old. It was found advantageous to run this antique engine as the sole means of power. The engine cost nothing and the new concern built its furnaces with boilers mounted over them, and hence obtained, as one might say, for nothing, easily twice the amount of steam that could be used. The economy of modern engines, or of producer gas, is of no interest to this firm. The fuel has to be burned anyway, and the waste of steam is of no moment.

One of the largest users—as distinguished from producers—of wrought-iron, who employs this material exclusively in the articles of his manufacture, has a strong belief that there will come a revival in its use; yet this man does not belong to the old school, but is a live, prosperous man under fifty. Could some newer process of puddling be devised to produce larger quantities at a single operation, the use of wrought-iron would certainly be extended and its price reduced.

Peculiarities of Wrought-iron

In testing wrought-iron some peculiarities have come to the writer's notice. Best Yorkshire (Lowmoor and Farnley) if nicked ⅛ inch deep around, say, a 1-inch bar, with a sharp set, and broken short over the anvil with a single blow, shows a curious fracture. The bar breaks dead short and square. The fracture is coarsely granular, resembling badly burned steel, only the granular structure is coarser. The bar nicked on one side only, and carefully bent with the nick a couple of inches from the edge of the vise or anvil, shows a beautiful gray, silky, fibrous structure, free from crystals and perfect in every way. Only the best Yorkshire iron shows this peculiarity, which to the writer's knowledge has never been satisfactorily explained.

Some peculiarities have been noted in connection with the welding of wrought-iron. The lower grades make an ap-

parent weld at almost a melting temperature, as well as at low heat. With the better grades of iron, however, this cannot be done, and a heat between closer limits of temperature is necessary. Hence, this kind of iron needs a careful and competent blacksmith, and he must give closer attention to his work than with the cheaper grades. A burned weld and a partial shut cannot pass even a cursory glance, as would similar welds in common grades of iron. Another point with regard to welding is that the less the iron is worked at the weld, the better the job. The writer has seen welds that have been reduced several tons in tensile strength by a smith unversed in this part of the art, unnecessarily working the weld at a comparatively low heat to make a good looking job.

Testing Wrought-iron

When mild steel is tested the strength "with" and "across" the direction of rolling is nearly equal, and for ordinary purposes of design can be so assumed. With wrought-iron, however, this is not the case. In bending tests, also, the angle

through which the iron can be bent with safety varies considerably, according to whether the bending is "with" or "across" the grain. The accompanying tables give a summary of the characteristics of wrought-iron, these tables being the results of long experience with this kind of material.

A number of wrought-iron pieces which have been tested in the manner that was commonly used years ago, and which still survives in some quarters, are shown in the accompanying halftone. Tests of this kind are known as "rams horn" tests, and are intended to indicate both the forging qualities of the iron and the closeness of the piling. A hole, 1¼ times the size of the bar or the thickness of the plate, is drifted hot from the solid, leaving the same distance clear from the end

TABLE II. TENSILE STRENGTH AND ELONGATION OF WROUGHT-IRON PLATE

or the side. The metal between the hole and the end of the bar is split with a sharp set from both sides and turned over as indicated in the engraving, the name of the test being derived from the appearance of the pieces after the bending is completed. When flat plates are tested, one horn is turned sideways and the other forward. Sizes up to two square inches in sectional area can be tested in one heat, but usually two heats are required. A second hole of the same size is drifted lower down the bar at right angles to the first. The test specimen, when cold, should show no defects, the piling should not split, and the surface of the "rams horns" should be free from red-short cracks. A clean fire, an experienced blacksmith, and considerable speed are required in order to make a satisfactory test, especially in the common grades of iron.

The only physical test bearing a direct relation to the prices and quality of iron is the reduction of area at the point of

fracture, when broken in a tensile strength test. In good iron this reduction of area should be 40 per cent. Two pieces of iron, one of which is twice as expensive as the other, will often have the same tensile strength and elongation, but the reduction of area will indicate which is the better iron. The best Yorkshire bar iron has been known to have over 60 per cent reduction of area, and usually it exceeds 50 per cent, but a cheap grade of bar iron rarely reaches 30 per cent. Good Staffordshire iron should have approximately 40 per cent reduction of area.

Chain made from Wrought-iron

As welded chain is one of the principal uses for which wrought-iron is still exclusively employed, a few remarks re-

TABLE IV. SPECIFICATIONS OF DRIFTING TESTS

Description of Iron	B B Staffordshire	B B B Staffordshire
Rounds up to 3 inches in diameter	Drift with grain to 1¼ times diameter, and across grain equal to diameter	Drift with grain to 1½ times diameter and across to 1¼ times diameter
Squares up to 3 inches side	Drift with grain equal to side of square, and across equal to ¾ times side	Drift with grain to 1¼ times side, and across equal to side
Rounds and squares over 3 inches diameter of side	Drift to ⅛ diameter or side	Drift to 1¼ times diameter or side

Flats up to any width over 1 inch thick	Drift to 2 times thickness at a distance from edge equal to thickness	Drift to 2½ times thickness at a distance from edge equal to thickness

lating to the welding of chain of this kind may be of interest. In the making of high-grade crane chain, the value of the reduction of area cited above is clearly shown in the tests of the finished chain. The elongation of a good sample under tensile test bears a direct relation to the reduction of area obtained from the bar iron from which it is made. The greater the reduction of area in the bar, the greater the percentage of elongation in the finished chain.

A well made chain under tensile test never breaks in the weld, but always at the end of the link which is not welded, or at the side. A break at the weld proves poor workmanship, no matter what iron is used. If the chain is of the best quality of iron, and the workmanship is first-class, the chain should stiffen under the breaking stress so that it becomes solid like a piece of bar iron. This stiffening under a breaking load is a certain indication of quality. Chains made from

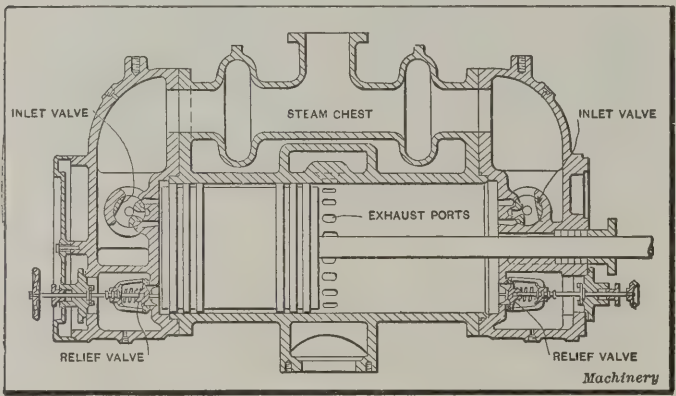
a common grade of iron do not stiffen. The stiffness is such that in good chain the end of the test piece can be held in the hand, and the test piece holds its own weight without movement or bending. If, when in use, a chain sling is found to lack freedom of movement, even to a slight degree, it should be discarded instantly because of the danger attached, as the chain must have been at some time overstressed.

A practical example of the value of annealing can be obtained from a wrought-iron chain by anyone. A link of such a chain of a good class of iron, say a sling chain, known to be in need of annealing, can easily be broken by a single blow of the hammer, with the link held vertically on the anvil. The fracture is coarsely crystalline and the break is sharp and nearly square. After proper heat-treatment the next link can be flattened or maltreated in almost any manner short of actually cutting it, but it will not break.

* * *

THE UNIFLOW STEAM ENGINE

The difference between the temperature of the live steam admitted to an engine cylinder and that of the exhaust leaving it makes the cylinder walls, cylinder head and piston act as reservoirs of heat which alternately fill and discharge at every stroke. The greater the ratio of expansion, the greater the difference in temperatures at the beginning and end of the stroke, and hence the greater the heat loss. This heat loss is commonly attributed to "initial condensation," but this phenomenon is simply the evidence of heat being imparted to the cylinder to raise it to the temperature of the incoming live steam. The abstraction of heat from saturated steam immediately causes condensation, which is followed by evaporation and cooling as the pressure falls.



Longitudinal Section of Uniflow Steam Engine Cylinder

The superior economy of the multiple-cylinder engine is due to the fact that the range of expansion is divided between two or more cylinders and the temperature difference in each cylinder is not so great as in a simple engine working to the same number of expansions. In other words the high pressure cylinder is hotter than the intermediate, and the intermediate is hotter than the low-pressure. If the whole range of expansion was effected in one cylinder its temperature would be an average between that of the live and exhaust steam.

In theory, the greater the number of cylinders, the higher the efficiency, but mechanical losses set a practical limit to the number of cylinders, four being as many as it is profitable to use. It is in this respect that the turbine is at a great advantage over the reciprocating engine. The zones of temperature can be graded by very small differences, thus reducing losses from heat interchange to a minimum. The Parsons turbine is really an expansion nozzle, hot at one end and relatively cold at the other.

Much ingenuity has been expended on steam engine design to reduce the heat losses in simple engines and make their performance approach more nearly in economy that of multiple-cylinder engines. One of the simplest and most effective cylinders is that of the so-called "uniflow" engine, patented in 1886 in Great Britain by Mr. L. J. Todd, and developed by Prof. Stumpf of Charlottenburg, Germany. This type of simple engine has recently been taken up by an American engine builder who claims that he can develop a horsepower on 24½ pounds steam non-condensing, and on 13¼ pounds condensing at 100 per cent load. At 100 per cent overload the consumption rises to 30 pounds and 14½ pounds, respectively.

The principle of the uniflow type of steam engine is that of admitting the steam at the ends of the cylinders as in all Corliss engines and exhausting at the center, thus causing no reversal of steam flow in the cylinder. The cylinder barrel is slightly more than two times the length of the stroke, the excess being in the width of the central exhaust port or ports and the clearances between the piston and cylinder heads. The increased efficiency is due partly to non-reversal of flow, the admission ends thus remaining hotter, but chiefly to reduced time of exhaust. In the common type of engine the cylinder walls are exposed to the exhaust temperature for about ninety per cent of the time required for the return stroke, whereas in the uniflow engine the exhaust period is much less.

On the return or exhaust stroke the steam remaining in the cylinder after the outer edges of the ports are passed by the piston is trapped and compressed in the clearance space to live steam pressure. This feature of the cycle, while apparently economical, is not so, thermodynamically, for the reason that the power required to compress has been generated in a comparatively low efficiency cycle and the resulting available energy in the compressed steam is far below that required for its conversion. But mechanically this feature is unavoidable for two reasons, the first being the very structure of the uniflow type, and second the need of cushioning effect in the cylinder to check the reciprocating parts and prevent shock and noise, a common requirement, of course, of all reciprocating piston engines.

RATHENAU GOLD MEDAL

The Allgemeine Elektricitäts Gesellschaft (A.E.G.) of Berlin has notified President Arthur Williams of the American Museum of Safety, New York, that the Rathenau gold medal has been placed at the disposal of the museum for award annually for the best device or process for safeguarding life and limb or promoting health in the electrical industry. The competition is open to every country in the world, the only condition being that the device or process must be exhibited at the American Museum of Safety in New York City. This is the first time that a high European honor has been given to an American institution and indicates the standing of the American Safety Museum among European scientists.

The Rathenau medal is well known in the European scientific world. It was presented to Dr. Emil Rathenau, president and founder of the Allgemeine Elektricitäts Gesellschaft, the greatest European electric company, on the occasion of his seventieth birthday, with the felicitations of the Kaiser for his services in the field of electro-technics. (He was the man who introduced incandescent lighting into Germany). One medal will now be cast each year from the original die for the American Museum of Safety to award.

* * *

THE USE OF WASTE STEAM

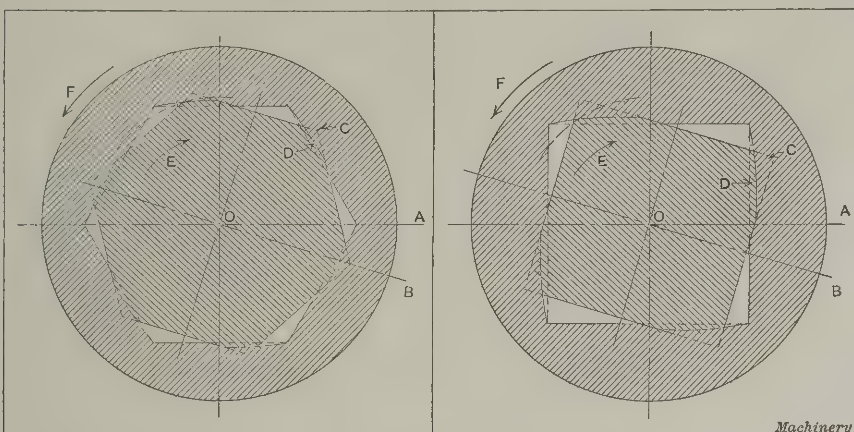
The use to which steam which formerly went to waste has been put at the Indiana Steel & Wire Co., Muncie, Ind., indicates what could be done to increase the efficiency of the steam plant in many industrial plants. In the power plant of this company two 22 by 42 inch Corliss non-condensing engines operate a series of wire-drawing benches. Each engine carries a load averaging from 370 to 400 H. P., and operates continually with the exception of Sundays and holidays. Up to two years ago electric power was purchased from an outside source to drive the machines for making wire fencing, wire nails, etc., but at that time it was decided to utilize the exhaust steam from the Corliss engines to generate this electric power. A 600 K. W. mixed-pressure Curtis turbine was installed and the exhaust steam from the two Corliss engines used to drive this turbine, which, in turn, exhausts into a condenser maintaining a vacuum of 28 inches. In case the engines are shut down, the mixed-pressure turbine automatically cuts in sufficiently high pressure steam to continue to run. The turbine now carries the entire motor load of 600 H. P., using steam that was formerly allowed to go to waste.

SQUARE VS. HEXAGON HOLLOW SET-SCREWS

ANALYSIS OF STRESSES, AND COMPARISON FOR WEAR AND STRENGTH

BY JOHN S. MYERS*

Since hollow set-screws have come into vogue, supplying a long-felt need of the manufacturer with humanitarian instincts, a controversy has arisen as to the respective merits of the square and the hexagonal form of hole, which presents an interesting problem. It is the object of this article to investigate analytically the relative claims to superiority of the two forms.



Figs. 1 and 2. Illustrations showing the Effect of Wear in the Case of a Hexagonal and a Square Wrench and Socket

Any mechanic knows that the corners of an ordinary hexagonal nut are more easily bruised and rounded off than the corners of a square nut, when using an open-ended or monkey wrench. Especially is this the case when, under dire stress of circumstances, one is compelled to use a wrench which does not fit properly, or a monkey wrench with a weak back. Nevertheless, hexagonal nuts have almost entirely superseded square ones in machine construction, for, as it seems, good and sufficient reasons. However, when we consider the case of a socket wrench, the answer to the question as to which form of nut would burr up easiest is not so apparent, for with the hexagonal nut we have six obtuse corners in action, against four square corners on the square nut; whereas, with the open-ended wrench, there are but two corners under pressure in either form. The case of the square versus the hexagonal nut, even with a socket wrench, is, however, considerably different from the case of the hollow set-screw; for, with the same size of bolt the distance across the flats of the square nut is equal to that of the hexagonal one, whereas, with the hollow set-screw, the distance across the corners is the limiting feature.

Comparison for Wear

In Fig. 1 we have a hexagonal inner member driving in the direction of arrow E against a resistance of the outer member in the direction of arrow F. It is assumed that the corners of the inner member have been worn as at C, and the faces of the outer member as at D, permitting a relative angular rotation AOB. Fig. 2 represents a square inner member with an assumed wear sufficient to permit of an angular displacement AOB, equal to the similar angle in Fig. 1. Comparing the two, it is seen that the square form would have to be worn much more than the hexagonal to permit of equal angular looseness, so that, unless the pressure on the corners of the square is sufficiently higher than that on the corners of the hexagon to offset this advantage, we would expect the square form to wear longer than the hexagonal.

Arbitrarily assuming the distance across the corners for the two forms to be equal, the depth of the two inner members to be equal, the torsional moments delivered equal, and the driving forces to be concentrated upon the extreme corners, as represented in Figs. 3 and 4, we may proceed as follows:

For the square form (Fig. 3) F acts at a lever arm $l = \dfrac{C}{2\sqrt{2}}$ (1)

The turning moment of the four forces is

$$T = 4Fl = 4F\frac{C}{2\sqrt{2}}$$

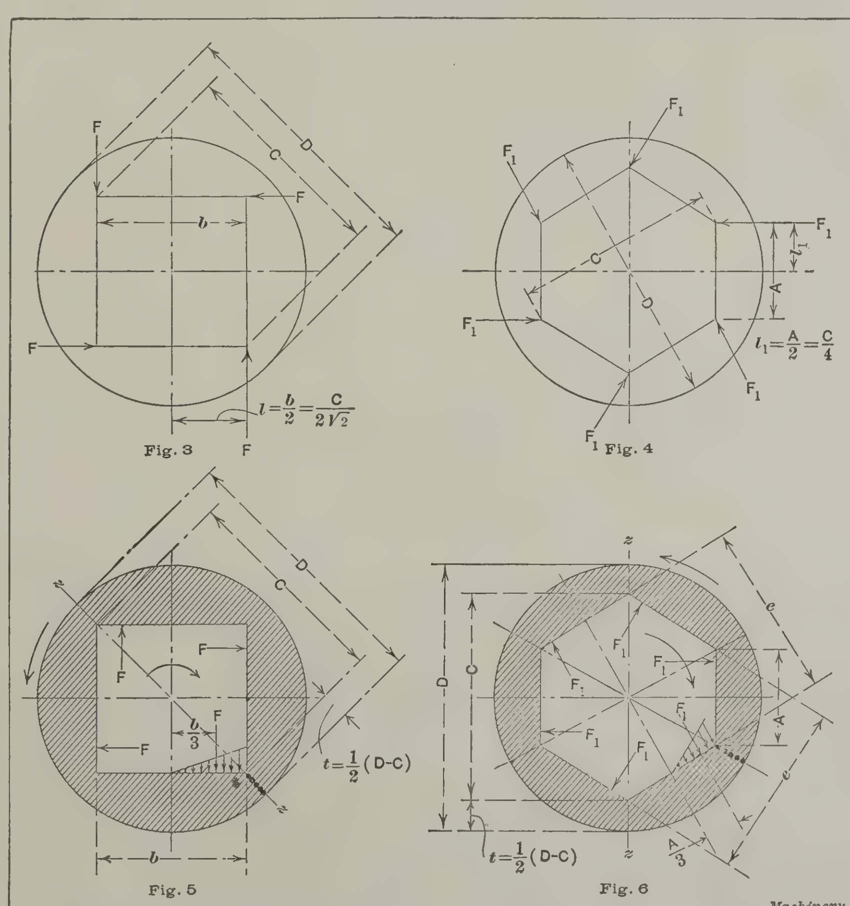
$= FC\sqrt{2}$, from which

$$F = \frac{T}{C\sqrt{2}} = 0.707\frac{T}{C} \qquad (2)$$

For the hexagon (Fig. 4), $l_1 = \dfrac{C}{4}$ (3)

The torsional moment is $T = 6F_1l_1 = 6F_1\dfrac{C}{4}$, or

$$F_1 = \frac{2T}{3C} = 0.667\frac{T}{C} \qquad (4)$$



Figs. 3 to 6. Diagram for Analyzing Relative Strength and Wearing Qualities of Square and Hexagon Hollow Set-screws

From (2) and (4), $\dfrac{F}{F_1} = \dfrac{0.707}{0.667} = 1.06.$ (5)

This indicates that, under the assumed conditions, the total pressure (not the unit pressure) on the corners of the square

* Address: 2456 Almond St., Philadelphia, Pa.

is 6 per cent higher than that on the corners of the hexagon.

Comparison for Strength

Comparing the square and hexagon for torsional strength, we have the torsional section modulus of the square as:

$$Z_{ps} = \frac{C^3_s}{12} \tag{6}$$

and for the hexagon:

$$Z_{ph} = 0.1353\ C^3_h. \quad \text{(See table.)} \tag{7}$$

When $C_s = C_h$, the ratio of relative strengths is:

$$\frac{Z_{ph}}{Z_{ps}} = 0.1353\ C^3_h \times \frac{12}{C^3_s} = 1.62 \tag{8}$$

or, when of equal distances across the corners the hexagon is torsionally 62 per cent stronger than the square.

If we equate $Z_{ps} = Z_{ph}$ and solve, we have:

$$C_s = 1.175\ C_h \quad (9) \qquad \text{or, } C_h = 0.851\ C_s \quad (9a)$$

which indicates that, for equal torsional strength the distance across the corner of the square form should be 1.175 times the same dimension for the hexagon, or, viewed the other way, the distance across the corners of the hexagon need only be 0.851 times the same dimension of the square.

Now, for $C_s = C_h$ we have, from (5), the total pressure on the corners of the square 1.06 times that on the hexagon, while in (8) the hexagon is shown to be torsionally 1.62 times stronger than the square; hence, if both are stressed to their full strength, the pressure on the corners of the hexagon is $\frac{1.62}{1.06} = 1.53$ times the similar pressure on the square (10).

In the case of the hollow set-screw, however, the outer member is of equal (if not of greater) importance than the inner member. The ideal condition would be to have both members of equal strength. Investigating in this direction, we have for the torsional section modulus of a circular section with a square hole (Case V in table):

$$Z_p = \frac{\pi D^3}{16} - \frac{b^4}{3D}. \tag{11}$$

For the square inner member (Case II in table):

$$Z_p = \frac{b^3}{3\sqrt{2}}. \tag{12}$$

Equating these, we have:

$$\frac{b^3}{3\sqrt{2}} = \frac{\pi D^3}{16} - \frac{b^4}{3D}. \tag{13}$$

Now let $b = xD$; then:

$$\frac{x^3 D^3}{3\sqrt{2}} = \frac{\pi D^3}{16} - \frac{x^4 D^4}{3D}, \text{ or } \frac{x^3}{\sqrt{2}} + x^4 = \frac{3}{16}\pi \tag{14}$$

From (14) we have $x = 0.74$, or $b = 0.74D$. (15)

But $b = \frac{C}{\sqrt{2}}$, hence:

$$\frac{C}{\sqrt{2}} = 0.74D \text{ or } C = 1.046D. \tag{16}$$

The significance of Equation (16) is that it is impossible to make a square inner member of torsional strength equal to the round outer member, because the distance across the corners of the square becomes greater than the diameter of the outer member thus splitting it up into four separate sections.

Treating the hexagonal form in a similar manner it is found that, for the inner and outer members to be of equal strength, we would have:

$$C = 0.912D \tag{17}$$

Just how thin the metal over the corners might be made without destroying the continuity of the section, and thus entirely upsetting the conditions upon which the theory of torsion is based, is problematic. It would, however, seem impracticable to give C as large a value as indicated by (17).

Proportion of the Inner to the Outer Member and their Relative Strengths—The Square Form

The problem now resolves itself into one of how large the inner member may be made without danger of rupture in the outer member at the corners. Referring to Fig. 5, the pressure against the sides of the square is maximum at the advancing corner and may be assumed to diminish uniformly to zero at the center of the side. The center of pressure on each face is then at F, at a distance of 1/3 b from the center, and the torsional moment of the four forces is:

$$T = \frac{4Fb}{3}. \tag{18}$$

Taking the depth of the square hole as equal to b, the area of material resisting rupture at the corner, as at z, is:

$$a = tb = \frac{D - C}{2}b, \text{ and, since } C = b\sqrt{2},\ a = \frac{D - b\sqrt{2}}{2}b \tag{19}$$

With a unit stress of S this area is capable of resisting a force of:

$$F_s = aS = \frac{D - b\sqrt{2}}{2}bS \tag{20}$$

Now, for simplicity of treatment as well as safety, we will consider the entire force F in Fig. 5 as concentrated upon this area a. We then have $F = F_s$, and, by substituting the value of F_s as given by (20) for F in (18) we have:

$$T = \frac{4b}{3}\left(\frac{D - b\sqrt{2}}{2}\right)bS = \frac{2}{3}b^2 S(D - b\sqrt{2}) \tag{21}$$

This equation represents the extreme torque of the outer member without causing rupture at the corners.

The torsional strength of the inner member is:

$$T = Z_p S = \frac{Sb^3}{3\sqrt{2}} \tag{22}$$

Equating (21) and (22) we have:

$$\frac{2}{3}b^2 S(D - b\sqrt{2}) = \frac{Sb^3}{3\sqrt{2}}$$

from which

$$b = \frac{2\sqrt{2}}{5}D = 0.566\ D \tag{23}$$

$$\text{or } C = 0.800\ D \tag{23a}$$

Equations (23) and (23a) represent the largest size of square inner member that can be used without danger of rupture of the outer member at the corners.

Substituting the value of b as given by (23) in (12) we have:

$$Z_p = \left(\frac{2\sqrt{2}}{5}D\right)^3 \div 3\sqrt{2} = \frac{16}{375}D^3 = 0.0427\ D^3 \tag{24}$$

which is a measure of the torsional strength of the square form of the inner member.

If we divide the result of Equation (24) by the torsional section modulus of a solid circular section (Case I in table) we have:

$$\frac{16D^3}{375} \times \frac{16}{\pi D^3} = 0.2173. \tag{25}$$

This indicates that a square inner member may approximate 22 per cent of the torsional strength of a solid circular section of a diameter equal to that of the outer member.

Proportion of the Inner to the Outer Member and their Relative Strengths—The Hexagonal Form

Investigating the case of the hexagonal form of inner member in a similar manner (see Fig. 6), we have first that the torsional moment of the six forces F_1 is:

$$T = 6F_1\frac{A}{3} = 2F_1A. \tag{26}$$

Assuming the depth of hole to equal e, the area resisting F_1 is $a = e\frac{D - C}{2}$, and since $e = A\sqrt{3}$,

$$a = A\sqrt{3}\frac{D - C}{2} \tag{27}$$

The force that this area is able to resist is:

$$F_1 = aS = \frac{\sqrt{3}}{2}AS(D - C), \text{ or, since } C = 2A$$

$$F_1 = \frac{\sqrt{3}}{2} A S (D - 2A) \qquad (28)$$

Substituting this value of F_1 in (26) we have:

$$T = \sqrt{3} A^2 S (D - 2A) \qquad (29)$$

The torsional strength of a hexagon (see Case III in table) is:

$$T = Z_p S = \tfrac{5}{8} \sqrt{3} A^3 S \qquad (30)$$

Equating (29) and (30), and reducing gives us:

$$A = \tfrac{8}{21} D = 0.381 D \qquad (31)$$

From (31) we have $C = 0.762 D$ (31a); or $e = 0.66 D$ (31b).

the torsional section modulus of a solid circular section, as given in Case I of the table, we have:

$$0.0598 D^3 \times \frac{16}{\pi D^3} = 0.3048 \qquad (34)$$

which indicates that the hexagonal inner member may develop approximately 30 per cent of the strength of a solid circular section of a diameter equal to the outer member, as against 22 per cent for the square form of inner member. Stated in another way, the hexagonal form is $0.3048 \div 0.2173 = 1.4$, or 40 per cent stronger than the square form for equal sizes of the outer member.

PROPERTIES OF SECTIONS

Case	Section	Polar Moment of Inertia I_p	Polar Section Modulus Z_p	Remarks
I		$I_p = \frac{\pi D^4}{32} = 0.098 D^4$	$Z_p = \frac{\pi D^3}{16} = 0.196 D^3$	
II		$I_p = \frac{b^4}{6} = 0.1667 b^4$	$Z_p = \frac{b^3}{3\sqrt{2}} = 0.236 b^3 = \frac{C^3_s}{12}$	Taking Case II as an inner member for Case V and making $b = 0.566 D$, the inner member would be the weakest and the section modulus for II is $Z_p = 0.043 D^3$
III		$I_p = \frac{5\sqrt{3}}{8} A^4 = 1.0825 A^4$	$Z_p = \frac{5}{8}\sqrt{3} A^3 = 1.0825 A^3$ $= \frac{5\sqrt{3}}{64} C^3_h = 0.1353 C^3_h$ $= \frac{5}{24} e^3 = 0.2083 e^3$	Taking Case III as an inner member for Case VI and making $e = 0.66 D$, the section modulus for III is $Z_p = 0.06 D^3$
IV		$I_p = \frac{\pi}{32}(A^4 - D^4)$ $= 0.098 (A^4 - D^4)$	$Z_p = \frac{\pi}{16}\left(\frac{A^4 - D^4}{A}\right)$ $= 0.196 \left(\frac{A^4 - D^4}{A}\right)$	If the inner section of diameter D is to be of torsional strength equal to the outer hollow member, make $D = 0.82 A$ or $A = 1.22 D$
V		$I_p = \frac{\pi D^4}{32} - \frac{b^4}{6}$ $= 0.098 D^4 - 0.167 b^4$	$Z_p = \frac{\pi D^3}{16} - \frac{b^4}{3D}$ $= 0.196 D^3 - 0.333 \frac{b^4}{D}$ With an inner member the largest probable safe value of b is $b = 0.566 D$, from which $C = 0.8 D$	If the inner section were to be of strength equal to the outer section it would be necessary to make $b = 0.74 D$ or $C = 1.046 D$, which is impossible, since C would be greater than D
VI		$I_p = \frac{\pi D^4}{32} - \frac{5\sqrt{3}}{8} A^4$ $= 0.098 D^4 - 1.0825 A^4$	$Z_p = \frac{\pi D^3}{16} - \frac{5\sqrt{3} A^4}{4D}$ $= 0.196 D^3 - 2.165 \frac{A^4}{D}$ With an inner member the largest probable safe value of e is $e = 0.66 D$, from which $C = 0.762 D$	If the inner section were to be of strength equal to the outer section, make $A = 0.456 D$ or $C = 0.912 D$. This leaves the material very thin at the corners.

Equations (31), (31a) and (31b) represent the various dimensions of the largest size of hexagon that can be used without danger of rupture of the outer member at the corners.

The torsional section modulus of a hexagon (Case III in table) is:

$$Z_p = \tfrac{5}{8} \sqrt{3} A^3 \qquad (32)$$

Substituting the value of A from (31) in (32) gives:

$$Z_p = \tfrac{5}{8} \sqrt{3} \left(\tfrac{8}{21} D\right)^3 = 0.0598 D^3 \qquad (33)$$

Equation (33) is the measure of the torsional strength of the hexagonal form of inner member. If we divide this by

Unit Pressure on Driving Faces—The Square Form

Considering the pressure to be distributed as indicated in Fig. 5, with the depth of the inner member equal to b, we have the unit bearing pressure on the driving faces at the corners of the square as

$$P_s = \frac{F}{b \times \frac{1}{2} b} \times 2 = \frac{4F}{b^2} \qquad (35)$$

From (18) we have $F = \frac{3T}{4b}$. (18a)

Substituting this value of F in (35) gives us:

$$P_s = \frac{4}{b^2} \times \frac{3\,T}{4\,b} = \frac{3\,T}{b^3} \qquad (36)$$

Now substituting in (36) the value of b as given by (23) we have:

$$P_s = 3\,T\left(\frac{5}{2\sqrt{2}\,D}\right)^3 = 16.573\,\frac{T}{D^3} \qquad (37)$$

In (24) we have the section modulus of the square member, which, multiplied by the stress S, gives:

$$T = 0.0427\,D^3 S \qquad (38)$$

Substituting this value of T in (37) we have:

$$P_s = \frac{16.573}{D^3} \times 0.0427\,D^3 S = 0.708\,S \qquad (39)$$

Equation (39) gives the unit bearing pressure on the corners as about 71 per cent of the torsional stress in the inner member, which is a very safe bearing value, and indicates that the inner member would fail by twisting rather than by crushing at the corners.

Unit Pressure on Driving Faces—The Hexagonal Form

Treating the hexagonal form of Fig. 6 in a similar manner, with depth of inner member equal to e, we have for the unit bearing pressure at the corners:

$$P_h = \frac{F_1}{e \times \frac{1}{2} A} \times 2 = \frac{4\,F_1}{e\,A} \qquad (40)$$

Now $e = A\sqrt{3}$, and, from (26), $F_1 = \dfrac{T}{2A}$; then:

$$P_h = \frac{4\,T}{2\,A \times A\sqrt{3}\,A} = \frac{2\sqrt{3}}{3}\,\frac{T}{A^3} \qquad (41)$$

From (31), $A = \dfrac{8}{21}D$, then:

$$P_h = T\,\frac{2\sqrt{3}}{3} \times \left(\frac{21}{8\,D}\right)^3 = 20.886\,\frac{T}{D^3} \qquad (42)$$

From Equation (33) we have, for the strength of the hexagon:

$$T = 0.0598 D^3 S \qquad (43)$$

Substituting this in (42) gives us:

$$P_h = \frac{20.886}{D^3} \times 0.0598\,D^3 S = 1.249\,S \qquad (44)$$

Equation (44) gives the unit bearing pressure at the corners as about 25 per cent higher than the torsional stress in the inner member, which is about in the same relation as the ultimate tensile and shearing strength, so that this bearing pressure is not too high.

When both forms are developing their full respective strengths we have, from (44) and (39), the ratio

$$\frac{P_h}{P_s} = \frac{1.249}{0.708} = 1.76 \qquad (45)$$

or, under this condition, the unit pressure on the corners of the hexagon is about 76 per cent higher than on the corners of the square; so that, if tested to destruction, we would expect the corners of the inner member and the internal faces of the outer member to be much more distorted in the case of the hexagon than in the case of the square.

When both outer members are of equal size and transmit equal torques, we have from (42) and (37) the ratio

$$\frac{P_h}{P_s} = \frac{20.886\,T}{D^3} \times \frac{D^3}{16.573\,T} = 1.26 \qquad (46)$$

or, under this condition, the unit pressure on the corners of the hexagon is about 26 per cent greater than that on the corners of the square.

Conclusions—Comparison of the Two Forms of Set-screws

1.—With the distance across corners equal and the depth of inner members equal for the two forms:

a.—The hexagonal form is torsionally 62 per cent stronger than the square. See Equation (8).

b.—Under the same conditions, and considering the total driving forces as concentrated at the extreme corners,* this force is 6 per cent higher for the square than for the hexagon, if delivering equal torques. See Equation (5).

2.—For equal torsional strength the distance across the corners of the square should be 1.175 times the similar dimension for the hexagon. See Equations (9) and (9a).

3.—It is impossible to have the inner member of torsional strength equal to the outer member, because the outer member would rupture at the corners. This impossible but desirable condition is more nearly attained with the hexagon than with the square. See Equations (16) and (17).

4.—With the depth of hole equal to the distance across the flats of the inner member:

a.—We may, for the square form, make $b = 0.566D$, or $C = 0.8D$. See Equations (23) and (23a).

b.—For the hexagonal forms we may make $e = 0.66D$ or $C = 0.762D$. See Equations (31a) and (31b).

c.—These proportions will prevent rupture at the corners when the full torsional strength is developed.

d.—When so proportioned the square member develops 22 per cent and the hexagonal member 30 per cent of the strength of a solid circular member of diameter D. See Equations (25) and (34).

e.—The hexagonal form is thus 40 per cent stronger than the square form for equal sizes of the outer member.

f.—The unit bearing pressure on the driving faces is 71 per cent of the unit torsional stress for the square, and 125 per cent of the unit torsional stress for the hexagon. See Equations (39) and (44).

g.—When subjected to equal torques, with equal sizes of outer member, the unit bearing pressure on the driving faces is 26 per cent higher for the hexagonal than for the square form. See Equation (46).

5.—The hexagonal form is thus shown to be superior for strength, or for equal strength to be smaller, hence more compact.

6.—The square form is superior in wearing qualities because of less unit bearing pressure on the driving faces.

7.—Hence, the proper field for the hexagonal form is for parts not requiring much adjustment, such as set-screws in collars, wheel-hubs, etc., while the field for the square form is in parts requiring frequent adjustment, such as the screws in lathe and drill chucks. Use the hexagonal form for compactness and strength; the square form for wearing qualities.

* This is an arbitrary assumption. The writer believes the distribution of forces to be more nearly as shown in Figs. 5 and 6.

TESTING STEEL FOR AUTOMOBILE PARTS

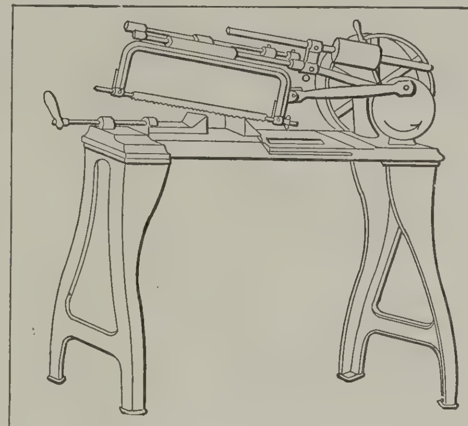
The careful tests to which the products of the G. Derihon Co. of Liege, Belgium, are put, explain the high standard which this firm has reached in the manufacture of automobile parts subjected to high stresses and shock. Since 1904 this firm has employed the Fremont drop test, and the results obtained have been very satisfactory. At the Derihon shops a test piece is taken from every piece out of which an automobile part is forged, and this test piece is forwarded to the customer together with the part ordered and a record of the results of the test. Thus, when sending out an order of twenty-eight steering levers, the company accompanies it with a list of twenty-eight tests. This increases the cost per lever by approximately five cents, but it gives an absolute certainty that the piece will stand as much as it is expected to. This policy makes it necessary for the firm to test from ten thousand to twelve thousand pieces per month, and on account of the experience thus obtained, it is interesting to note some of the conclusions arrived at by this firm with relation to the method of making these tests. For the drop test the firm uses test specimens 10 by 8 millimeters (25/64 by 5/16 inch, approximately) with a one-millimeter nick (3/64 inch approximately). If test pieces of larger dimensions are used, they are not likely to reveal minor defects. While brittleness in steel is often a local condition, it would be none the less objectionable and dangerous in the completed machine detail. As an indication of what can be accomplished by a commercial shop testing department and by taking advantage of the knowledge obtained from the tests made, it may be mentioned that at the outset the Derihon firm had to reject, for brittleness, from 20 to 40 per cent of the pieces tested, whereas during 1911 the total number of rejected parts averaged 0.3 per cent. This result has been obtained entirely from the fact that the testing of the steel has enabled the firm to apply proper heat-treatment to its steel products. In the opinion of M. Derihon it is possible to make all steels of good quality non-brittle. The whole question is simply one of heat-treatment, different steels, of course, requiring entirely different treatment in order that satisfactory results may be obtained.

RECIPROCATING STRAIGHT-BLADE SAWING MACHINES*

DEVELOPMENT OF HACKSAW MACHINES, WITH SPECIAL REFERENCE TO BRITISH PRACTICE

The material presented in the following has been gathered with the idea of setting forth the merits of the straight-blade reciprocating saw for metal work, as compared with those of the band saw and the circular saw. The latter types have been developed to approximately the same degree of efficiency which has been attained in other types of machine tools, while many reciprocating saws remain in essentially the condition in which they were first placed upon the market. The author believes that the Millers Falls Co. placed the first hacksawing machine upon the market. This machine is shown in Fig. 1, from which it will appear that its design is of a character hardly suitable to modern shop conditions. Fig. 2 shows the next hacksaw machine that was introduced. This is a more elaborate and heavier type than the preceding, and the old hacksaw frame has given way to a stronger design.

Another very early pattern of hacksaw was the Eureka, shown in Fig. 3. This machine was made by G. Thompson, Son & Co. It is designed along far better lines than the preceding types, having a solid base and provision for guiding the saws. The thrust is in a direct line, and the upper guide is made to extend in such a way that it admits of a large variation in the length of blade used. The long blade, similar to a band saw, is coiled up and brought out for use as the working part becomes worn. This coil contains about twenty-five feet.



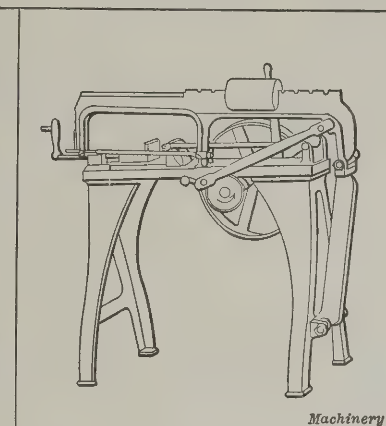


Fig. 1. The Star, the First Type of Hacksaw Machine. Fig. 2. The Simplex, another Early Type

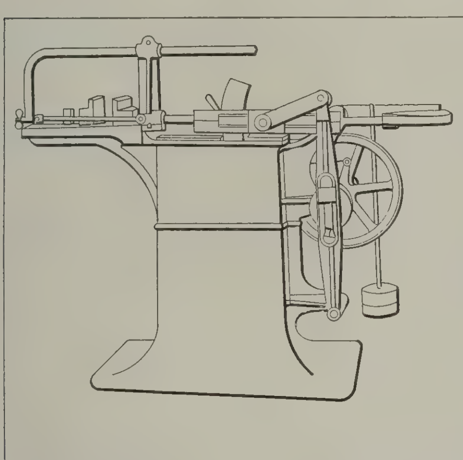

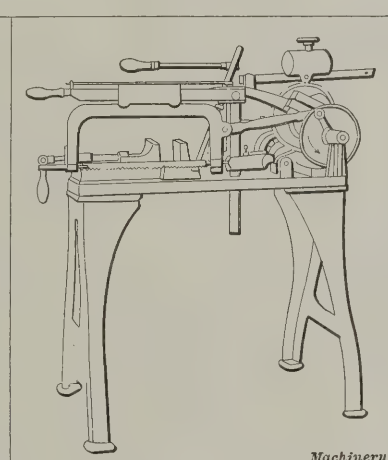

Fig. 3. The Eureka Hacksaw Machine. Fig. 4. The Milford Machine, an Improved Type

The Milford saw, shown in Fig. 4, is a still more carefully designed tool. It is fitted with a quick return and a clutch device for lifting the blade free of the work on the idle or return stroke. It has a gear drive of 4 to 1 and an automatic stop. In the author's opinion, these four designs are a fair illustration of the progress of the original type of hacksawing machine up to a recent date.

Messrs. Herberts of Manchester, England, were the first firm who seriously took up the matter of improving the design of hacksaw machines. The object was to make a stronger machine which would be capable of working more rapidly and of taking larger sections. They have made saws of a capacity hitherto commercially unknown, the largest being capable of taking 18 by 30 inches. Among other improvements they introduced an automatic feed for the work, and an eccentric motion was given to the fulcrum of the saw frame, as shown in Fig. 5. This made it possible for the fulcrum of the saw frame to be moved around slightly at intervals of 20 strokes, thus putting the saw at a different angle to the work. In this way it was working on a comparatively small surface at all times and was thus capable of handling larger sections. Such saws were capable of cutting a 4-inch bar in twenty minutes, as compared with an hour taken by the earlier types of machines. The only disadvantage of this method lay in the strain placed upon the saw blade after each move of the eccentric. The author believes that his firm was the first to use a stronger and better blade, and they were aided in this by the Sterling Co., who used tungsten steel.

Messrs. Holroyd & Co., of Milnrow, England, also introduced an excellent machine for rapid work with the same object in view that Messrs. Herberts had. In the Holroyd machine the bar was slightly turned around at intervals of several strokes instead of altering the angle of the saw. The advantage of this system lay in the fact that as the bar was continually turning around, it was difficult for the saw to run out, and the work would be approximately as true as that produced in a cutting-off lathe.

Advantages of Hacksaw Machines

The advantages of hacksaw machines as compared with other types are briefly as follows: First, the cost of the machine and blades, is comparatively low and the blades can be brought to any temper to suit the work. Second, a hacksaw will cut to any depth that the frame which holds it will permit; extra depth does not necessitate extra cost of blades as in the case of the circular saw, where the bosses limit the depth of cut to approximately 1/3 the diameter of the saw. It may also be mentioned in this connection that a circular saw is necessarily fairly thick and exceedingly difficult to get quite hard. Circular saws are also liable to break if hardened beyond certain limits. Third, in the case of band saws it is frequently necessary to cut the blade in order to thread it through the work, and, like the circular saws, it is almost impossible to get them quite hard. Fourth, another advantage of the straight blade over the circular saw or lathe cutting-off machine lies in the narrowness of the cut, say 1/16 inch instead of ¼ inch.

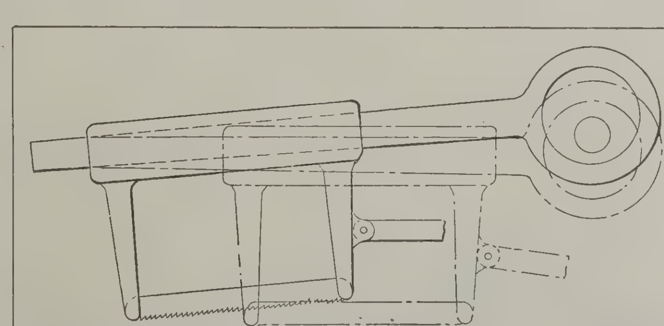

Fig. 5. Eccentric for tilting the Saw

* Abstract of a paper by Mr. Charles Wicksteed read before the Belfast meeting of the Institution of Mechanical Engineers, July, 1912.

This difference in the width of cut makes a great saving possible when working on such expensive materials as high-speed steel. Fifth, the power taken by a hacksaw is about one-fourth of that taken by a circular saw.

When once convinced that the straight-blade sawing machines had as great advantages as their competitors, it did not take long to discover the principles on which the blades must be made and operated. These may be briefly outlined as follows:

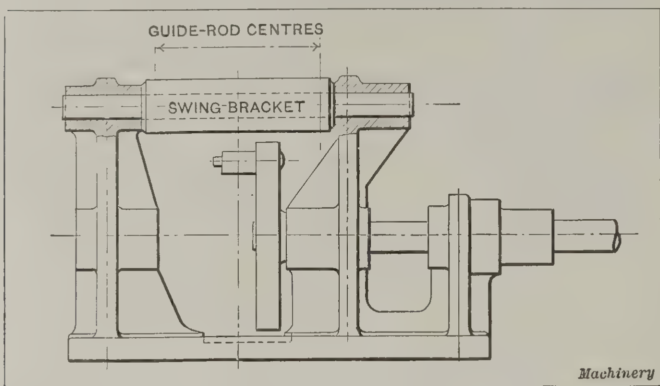

Fig. 6. Arrangement of Bearings for Guide Frame, viewed from the Back

First, the blade must be kept absolutely firm and perfectly square with the work. Second, it must be strong enough to stand all the weight that the teeth will take without breaking. Third, the blade must be made of the highest possible quality of steel with the best cutting edge that is practicable. Fourth, the machine must be well designed and work without

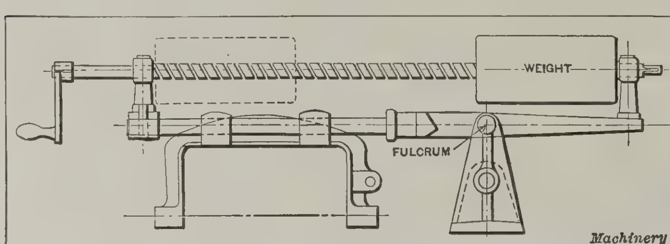

Fig. 7. Method of adjusting Position of Weight

spring or vibration. Fifth, since the pressure on the blade must be considerable, a reliable release on the return stroke must be provided. However, the results of experiments by the author have shown that unless the weight was heavy it made little difference whether the blade was released on the return stroke or not, but where a heavy weight is used, the blade will be quickly destroyed unless this precaution is observed.

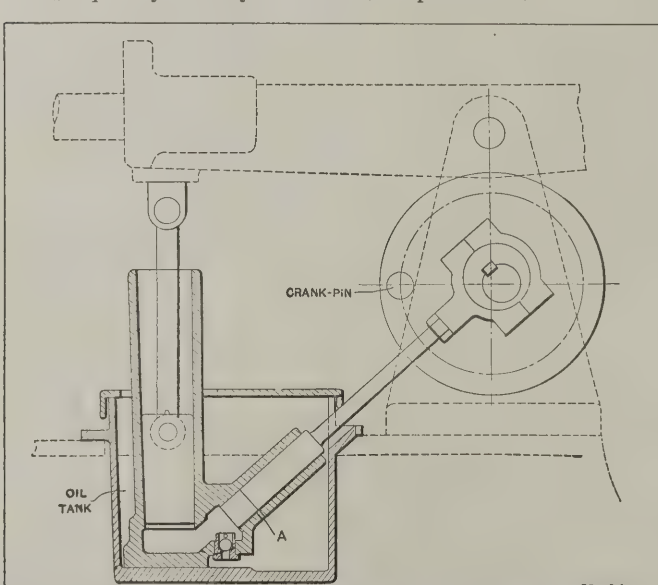

Fig. 8. Pump and Ram used to lift and lower the Saw at End of Stroke

Taking the points just mentioned into consideration, it will be evident that the blades have not been developed to this high standard without the expenditure of a great deal of effort on the part of the manufacturers. These improvements may be briefly outlined as follows: First, for ordinary work, a coarse pitch tooth, not less than 10 to the inch, has been found most suitable. Such teeth cut better, clear themselves better, and give a better opportunity for side clearance which is especially necessary in the deep blades used on heavy machines. Second, to make the teeth strong enough to take all the weight that they will stand, it is not necessary to do any special tempering. If the teeth are properly hardened, the back of the blades will also be of the proper hardness. Third, additional strength must be obtained by increasing the depth and not the thickness of the blade. An increase in thickness means a corresponding increase in the amount of power required to drive the machine. Theoretically, the thinner the blade can be made the better. This is limited, however, by difficulty experienced in hardening deep thin blades in such a way that they are absolutely straight. Deep blades are also more difficult to work and still keep the

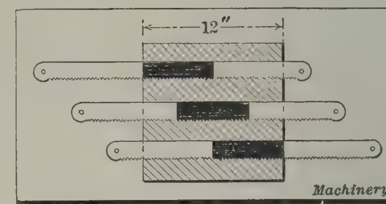

Fig. 9. Diagram showing how Saw is freed of Swarth

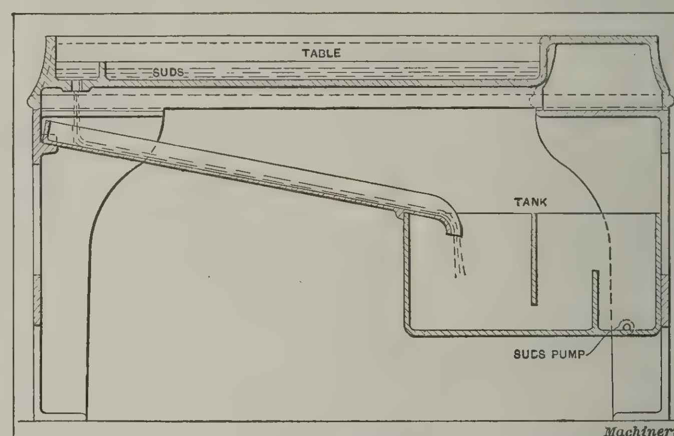

Fig. 10. Arrangement of Tank and Pump Connections

proper clearance. The blades used by the author vary from ¾ inch to 2 inches in depth and from No. 19 to No. 16 wire-gage in thickness. Fourth, the greatest weight that a tooth will take without injury must be ascertained and the blades then made strong enough to carry it. A weight of 210 pounds is about

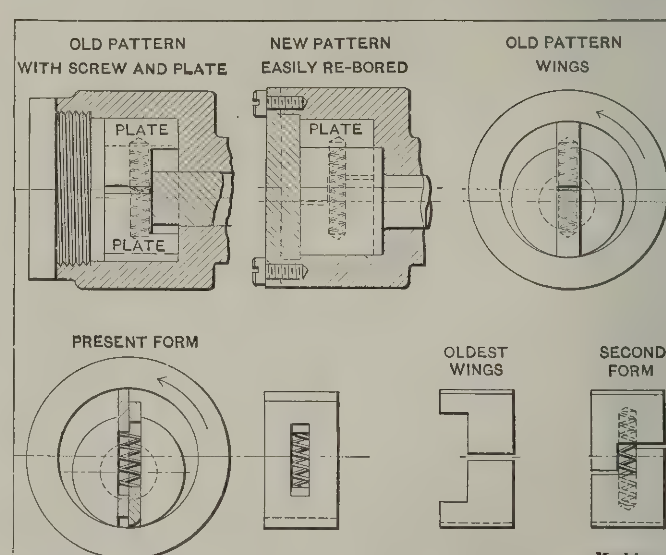

Fig. 11. The Type of Lubrication Pump used

right for a 6-inch machine, and enables the machine to use practically the full capacity of the blade up to a 4-inch round bar. As the machines become larger, the proportion of weight is increased. Thus a 15-inch machine requires 700 pounds on the saw to get the full capacity of the blade when working on a 10-inch surface.

Design of Machines

After having said this much about blades, it is hardly necessary to point out that corresponding improvements were required in the machines that drive them.

One of the greatest faults in early types of hacksaws is found

in the fact that the guide frame was almost universally pivoted on the crankshaft. Narrow bearings were usually employed, thus giving some play to begin with, which was constantly increased by wear. Hence the design lacked the first essential of a good machine. The loose guide allowed the saw to run out, to produce bad work, and to break the blades. To avoid these fundamental defects, the author applied a guide frame which is pivoted on independent bearings of the type shown in Fig. 6. These bearings have no other work to do than to guide the frame, and there is practically no wear. The machine is of rigid construction and the bed is of sufficient width to provide a bearing for the bar on both sides of the saw. The guide bars are placed far apart and all bearings are of ample proportions and bronze-bushed. The weights have been correspondingly increased so that a 6-inch machine weighs 550 pounds and a 15-inch machine 2500 pounds. Such weights are necessary to make the machine perfectly firm and free from vibration.

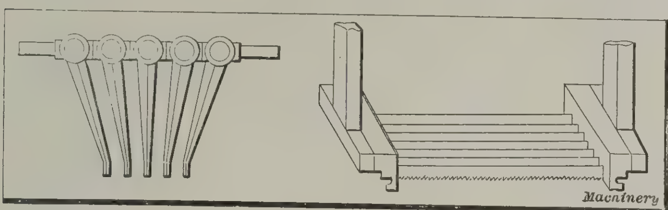

Fig. 12. Two Styles of Saw Racks used on Multiple Machines

The additional weight used on the blade made it necessary to adopt a convenient method of varying it according to the requirements of the work. This is done by means of a sliding weight on a bar which runs from the extreme end of the frame to a point well behind the fulcrum of the spring bracket. In the heavy machines this weight is adjusted by a quick pitch screw, the arrangement being shown in Fig. 7. Having such a heavy weight to deal with, it was next necessary to provide means to protect the machine from breakage in case the blade should break. A reliable release was also required on the return stroke of the blade. The latter is a difficult thing to provide for by purely mechanical means, as the plane of the saw varies at every stroke; but experiments have shown that it is essential for the saw to be lifted off the work at the end of the cutting stroke and put down again accurately at the end of the return stroke. If this is not done the output will either be seriously interfered with or the blade will be injured.

Fig. 8 shows the device by which the release of the saw is obtained. It will be seen that an eccentric set in time with the crank-pin on the crankshaft works a plunger in connection with the dash-pot. This plunger comes down and closes the port *A* at exactly the end of the stroke, thus gently lifting the frame sufficiently off the work during the return stroke and letting it down again as soon as the working stroke begins. There are no complications and no wear in this device, as both pistons are simply made a good fit and worked in oil. A foot-valve is provided to let the oil in when the frame is lifted by hand.

Later modifications of this device have been made to make it useful for other purposes. The port is made small enough to convert the larger cylinder into a dash-pot, thus making it impossible for the frame to fall, as it can only be lowered as fast as the oil is pressed through the small port *A*. This port is about 1/32 inch in diameter in the case of the small machines.

The stroke of the author's machine is from 5 to 8 inches. The longer stroke adopted in the larger machines was not found necessary to get rid of the swarth, but simply because it was found advisable to reduce the strokes as the length of the frames was increased. The question of the relative length of the blade to the stroke and the diameter of the bar is interesting. A long stroke should be avoided, as it entails a correspondingly long blade as well as a more cumbersome machine. If there is no lift on the return stroke, the stroke must be made as long as the section being cut, to get rid of the swarth.

Fig. 9 shows a 12-inch section being cut with a machine operating on a 6-inch stroke. In this diagram the middle part of the blade is shown black. This section has no opportunity of getting rid of its swarth, and will therefore, if not lifted, take the greatest part of it backward and forward. With sufficient lift on the return stroke, however, the swarth is dropped and raked 6 inches forward on the cutting stroke. Consequently it is only necessary to make the teeth deep and large enough to hold the swarth gathered during two strokes.

The lubricant used for saw blades is soap-suds, and great attention has been paid to the pump and tank used for lubricating purposes. The fact that the swarth made by the saws is exceedingly fine, and that it is much more difficult to operate a pump properly with suds than with oil, necessitated a careful provision to keep the swarth away from the pump. Fig. 10 shows the arrangement of the tank and connection, where it will be seen that the suds are first collected by a recess in the bed and then drained at the front end, which is farthest away from the point where the swarth is dropped. The suds then run through a trough to a tank at the back end of the machine. This tank is divided by two weirs, the lubricant going under the first weir and over the second. In this way any light swarth floating on the surface of the fluid is stopped.

Type of Pump Used

Wing pumps were decided upon as most satisfactory for this service, but the best type available was of such construction that it would not wear well. The simple type of pump shown in Fig. 11 was finally adopted. In this type a by-pass is provided, not with a separate valve, but simply by making the wings of the pump taper against the pressure, so that when a full discharge is not required the increased pressure of the suds presses the wings inward. The cover is fastened by screws instead of being secured by a thread in the end of the cylinder, this design making it easy to rebore when necessary. The wings are provided with two small slots of such a length that one spring put in the middle will press up the wings on each side. This is an improvement over the old method where the wings met in the middle, thus leaving very little bearing surface. The gradual wearing of this bearing caused friction which led to the destruction of the pump.

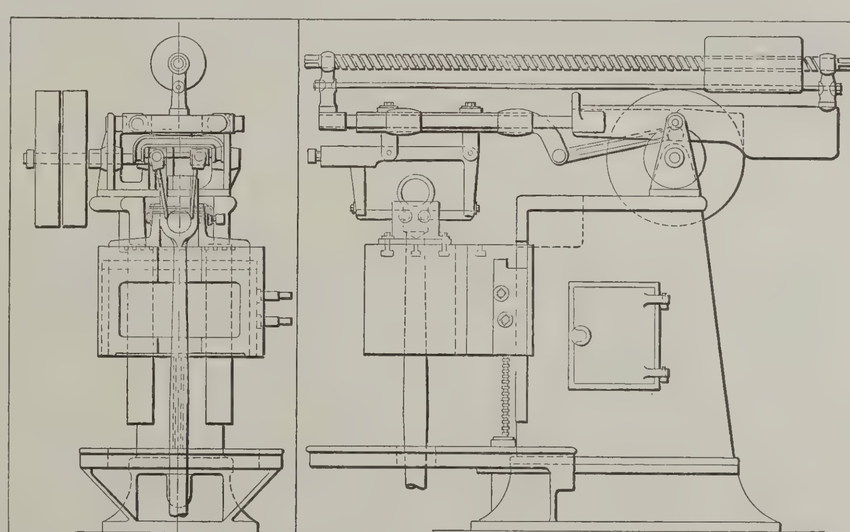

Fig. 13. The Shaping Machine Saw

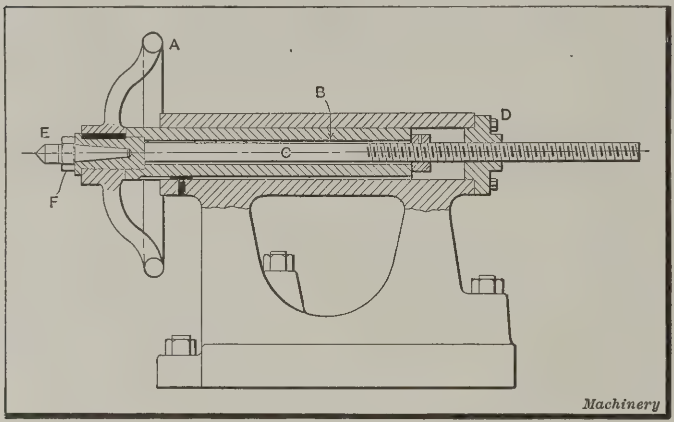
The result of these improvements is that sawing can be done practically true, say to 0.010 inch in cutting a 6-inch bar, and mild steel can be cut at a speed of approximately 1 to 2 inches per minute. The breakage of the blades is also rare. In conclusion, the author states that his purpose in presenting this review is merely to trace the development of a most useful tool, so far as it has gone. He is of the opinion that nothing like perfection has yet been approached, and believes that in rapidity of work, endurance of blades, and in the size of machines, the reciprocating straight-blade sawing machine has many advantages sufficient to warrant making its improvement a matter of careful study.

IMPROVED LARGE LATHE TAILSTOCK

A new form of tailstock for large lathes designed to facilitate adjustment when centering heavy and awkward parts, was recently illustrated in the *Practical Engineer.* The common position of the handwheel on the outer end of the tail spindle is so far from the center point on large lathes that the machinist can reach it with difficulty when watching the center enter the work. On very large forge lathes the adjusting handwheel is sometimes placed on the side of the tailstock, near the inner end of the spindle and is connected to the screw by a shaft and bevel and spur gears to overcome the difficulty. This construction is objectionable, of course, for medium size lathes on the score of cost.

In the new design the handwheel *A* is placed on the inner end of the tailstock where it is mounted on the screw *C*. The center *E* is set in the end of the screw, the screw being made with an enlarged end for the socket. The screw is supported by the quill *B* and is threaded in the nut *D*. A nut *F* is provided on the center for ejecting it as the construction does not permit the self-discharging principle of the common form of tailstock to be used.



Tailstock for Heavy Lathes having Handwheel on Inner End

The contributor of the design points out that it is not well adapted to small lathes because of the interference of the handwheel with the compound rest. By giving the handwheel considerable dish, however, and overhanging the nose of the tailstock this defect might be overcome. The projection of the screw is another objectionable feature which might be avoided by slightly changing the design so that the parts would telescope, the nut being made in the form of a tube with the thread at the end. This construction would necessarily make the quill somewhat larger relatively than shown in the illustration, but would materially reduce the overall length and improve the appearance.

An objection to the design not mentioned by the contributor, of little importance, perhaps on heavy lathes, but of some weight in the design of small lathes, and especially toolroom lathes, is that the tail center is mounted in a revolving part and cannot, therefore, be considered a dead center. Eccentricity of the center point would cause trouble by throwing the centers out of line.

FATIGUE STRESSES IN MACHINE STEEL

In a paper on "Endurance Tests of Machine Steel," presented before the International Association for Testing Materials, New York, September, 1912, Mr. J. O. Roos of Hjelmsäter calls attention to the so-called "fatigue ruptures" which occur in parts which are subjected to continually repeated shocks or stresses of small magnitude. Machine parts which are subjected to continual stresses in varying directions, or to repeated shocks even though of comparatively small magnitude, can hardly be satisfactorily designed (nor can the material be chosen) from a mere knowledge of the behavior of the material under a steady stress, such as imposed upon it by ordinary tensile stress testing machines. From the numerous cases of machine parts broken under actual working conditions, and which Mr. Roos had had occasion to examine in the course of his work, the most tangible and positive result obtained was that at least 80 per cent of these ruptures had been caused by fatigue stresses, the surface of the fracture showing the characteristic crack for this kind of a break. Among the pieces of this kind examined were railway car axles, parts of steam engines, and parts from motor cars and trucks. Most fatigue ruptures in practice are caused by bending stresses, and very frequently by a revolving bending stress. Hence, to test materials for this class of stress, the tests should be made to stress the material in a manner similar to that in which it will be stressed while under actual working conditions. This can be accomplished by subjecting a projecting test piece held at one end to a load at the other end, and revolving the test piece while subjected to the load. A machine for carrying out tests of this kind has been developed in the United States by Mr. Henry Souther of Hartford, Conn.

THE NITROGEN INDUSTRY IN NORWAY

One of the interesting features of the eighth international congress of applied chemistry, held in New York during the early part of September, was a lecture delivered by Dr. Samuel Eyde of Christiania, Norway, in which he described the development of the nitrogen plants that have recently been built in Norway, and in the development of which he has played a leading part. Lantern slides were shown of four great nitrogen plants under Dr. Eyde's control, having a total capacity of 200,000 horsepower and producing yearly 80,000 tons of nitrate of lime for fertilizing purposes, 10,000 tons of nitrate of ammonia for use in explosives, and 10,000 tons of nitrate of soda for use in coloring industries. It is very interesting to note how a country so poor in regard to natural resources as is Norway, except for the enormous power represented by the water falls, has in this way been able to develop an industry requiring practically no other raw materials than air and water. It has been predicted that chemical industries in which electricity plays an important part will, in the future, be largely concentrated in the Scandinavian countries because of their available water power, and hence their cheap supply of electric energy. As Norway, especially, is a country which is not suited for agriculture, the development of these industries is a highly important factor in its prosperity.

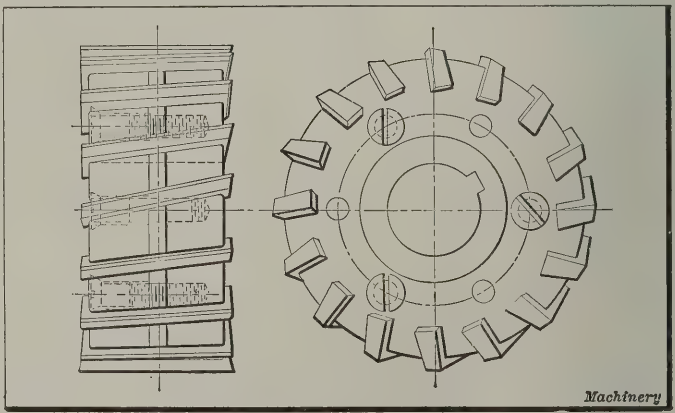
NEW TYPE OF INSERTED-BLADE MILLING CUTTER

The accompanying illustration shows a new development in inserted-blade milling cutters, patented by the Sächsischen Maschinenfabrik in Chemnitz, Germany. The body of this inserted-blade cutter consists of two disk-shaped parts, held together by screws and dowel pins, as indicated in the accompanying illustration. The slots are milled in the two parts at the same time, the disks being held a suitable distance apart. The blades are then inserted and the two parts clamped together by the screws shown. This clamping, of course, binds or wedges the blades firmly in place, as the two disks are brought up against each other. The dowel pins prevent the body parts from rotating with relation to each other.



New Type of Inserted-blade Milling Cutter, of German Design

SCIENTIFICALLY MANAGED PRESS WORK

WORCESTER PRESSED STEEL CO.'S METHOD OF ROUTING MULTIPLE-OPERATION JOBS

BY CHESTER L. LUCAS*

To start sheets of heavy steel at a blanking and drawing press at one end of a row of presses and keep the semi-completed shells moving down the entire line of drawing presses, passing the work from operator to operator, until it emerges after the thirteenth operation a completed steel bowl, is a feat of modern press work of which the Worcester Pressed Steel Co., Worcester, Mass., may well be proud. Fig. 1 shows the line of presses used on this work, and Fig. 2 represents a section of the connected presses, showing how the work is passed from press to press.

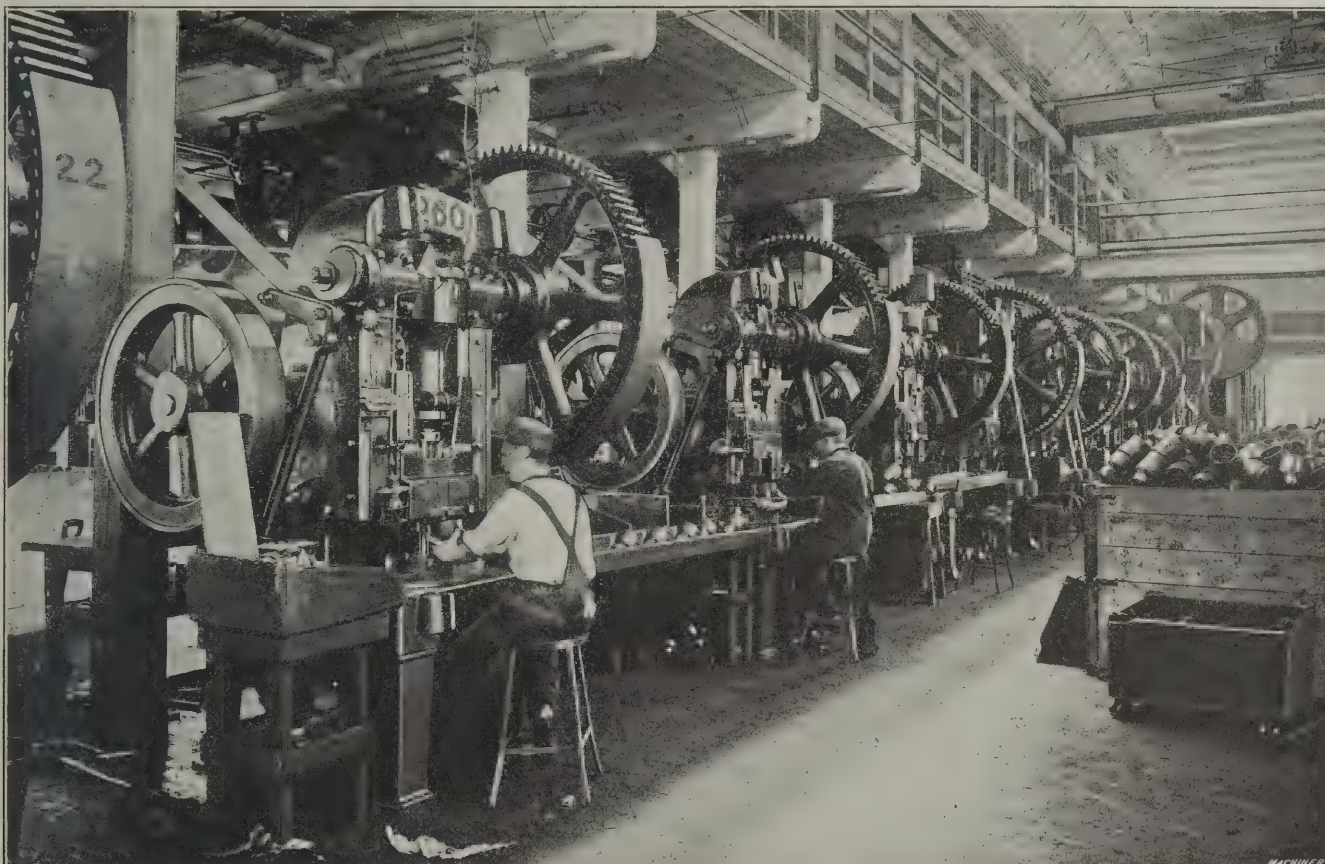


Fig. 1. The Presses used in Producing the Steel Bowls

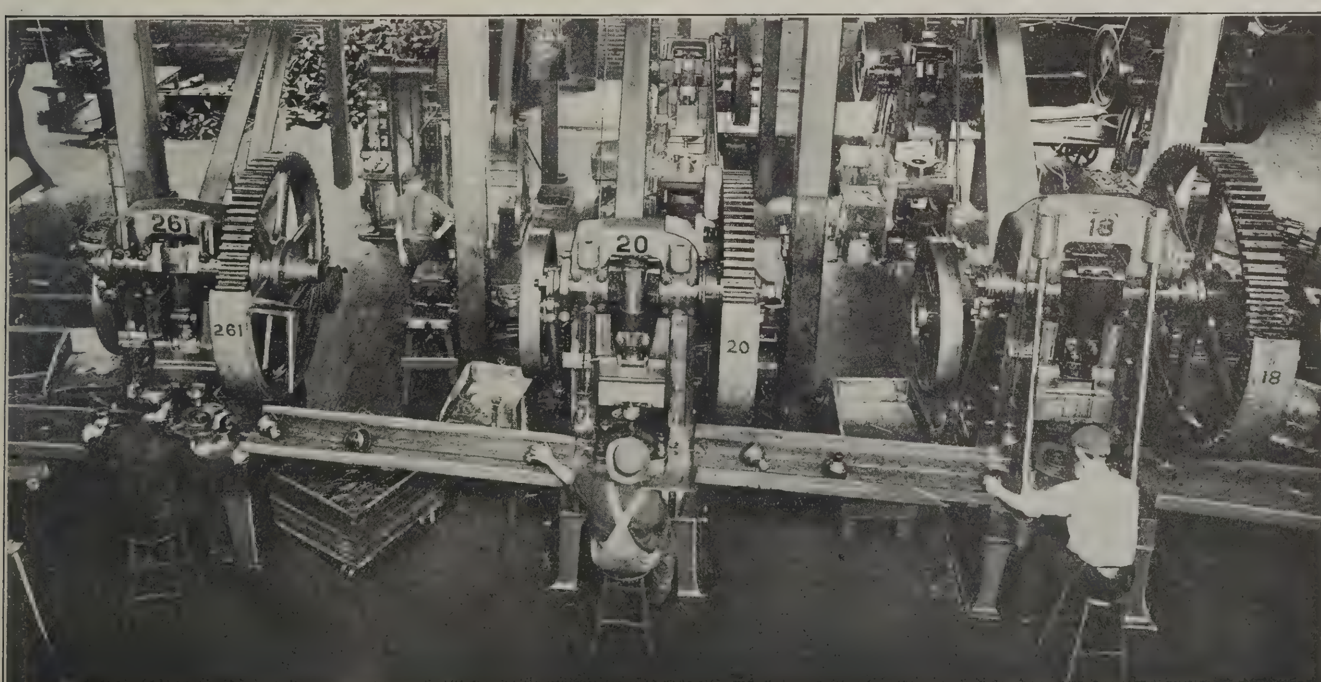

Fig. 2. A Section of the Row, showing Method of Handling the Work

The pressed steel bowl referred to is one which is used in large quantities on a special class of machinery. The completed bowl is approximately as shown in the line engraving, Fig. 3, being five inches in diameter. The fact that the stamping is made from heavy sheet steel, 0.150 inch thick, is the point which makes the production of this piece the more remarkable. The successive steps in drawing the shell

* Associate Editor of MACHINERY.

are clearly indicated in the group illustration, Fig. 4, which shows the results of the work performed in each of the thirteen operations. By comparing the work with the two-foot rule shown in the foreground, a good idea of the dimensions of the pieces can be obtained.

The first operation, namely, that of cutting and drawing the blank, is performed on a large double-action power press, and after leaving this press the shells go to a large single-action press. Another reduction follows which leaves the blank deeper, but smaller in diameter. After this stage the shells are annealed and taken to the first press in the foreground of the illustration Fig. 1. From this point the shells continue down the line of presses, being passed from operator to operator by means of chutes along which the work is thrown. The method of routing the work is more clearly illustrated in Fig. 2. Before the shells are completed another annealing operation becomes necessary, because the final op-

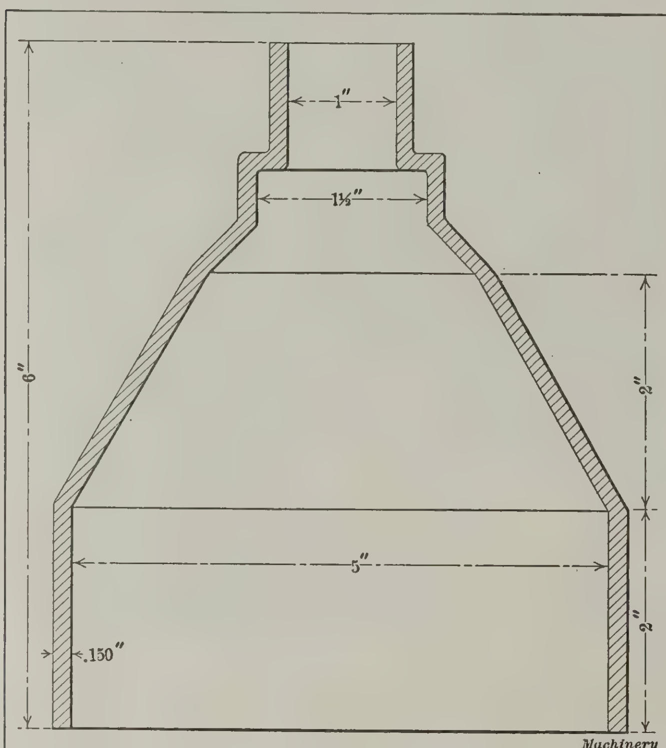

Fig. 3. Details of Steel Bowl

erations, which are for the purpose of setting the metal at the tip end of the shell, require that the stock be as soft as possible. Owing to their location it was impossible to clearly show two of the presses used for final punching and setting operations, but Figs. 1 and 2 adequately illustrate the principle of handling this job.

These shells are made in lots of from 5000 to 10,000, and after the presses are set up and the blanks started, the completed shells are turned out at the rate of 400 per hour. It is obvious that this method of handling press-work pushes the work off the floor and out of the way quickly. Piles

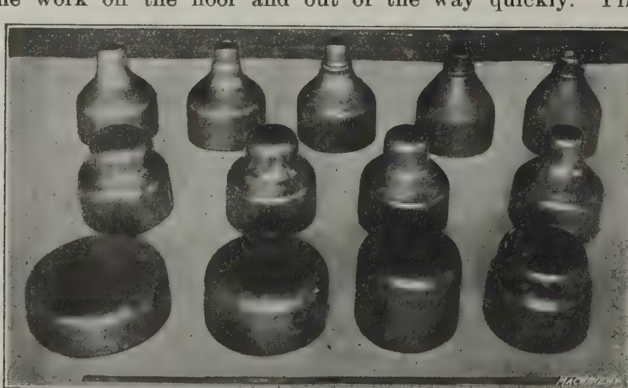

Fig. 4. Successive Steps in the Press-work

of half completed work do not accumulate, and once started, there is a steady stream of completed shells traveling to the shipping room until the last shell has gone "down the line."

In Fig. 5 may be seen a large Toledo double-action drawing press, a machine which handles drawing and forming operations on large work like brake drums, axle housings, cases, shells, etc. This press is one of the largest of its type ever built in this country and has a capacity for exerting a 1000-

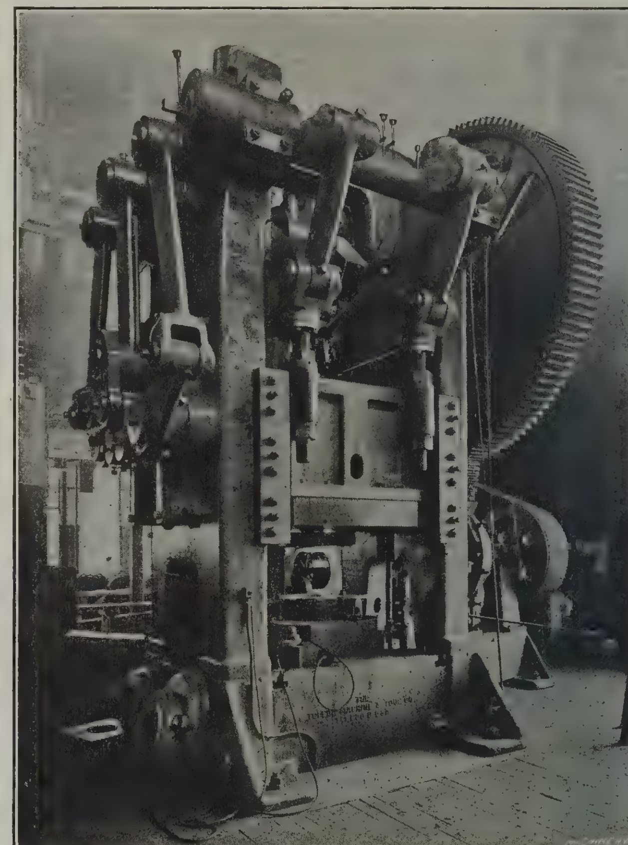

Fig. 5. The Large Toggle Drawing Press

ton pressure. The area of the bed is 60 inches square; the stroke of the plunger is 26 inches; stroke of the blank-holder is 18 inches. The crankshaft of this press is 12 inches in diameter, and the construction of the toggle mechanism is such that a long dwell under heavy pressure is given to the blank-holder. The advantage of this feature is that it provides means for drawing sheet metals with a minimum of trouble from wrinkling. The press frame is of the built-up type, rigidly bound together with forged steel tie-rods 6-inch diameter which have been shrunk into place. The power for operating is furnished by a 75-horsepower motor.

The premium system of piece work is employed on all

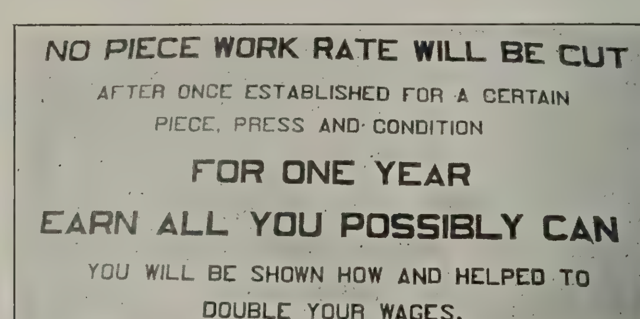

Fig. 6. A Factor in the Success of the Premium System

operations in the factory, and it works out with great success. One of the chief reasons for its success, and one which other factories will do well to note is manifested in the presence of large signs on the bulletin-boards, a facsimile of which is shown in Fig. 6, which assures the men that piecework prices once established will not be reduced for at least a year's time.

INDEX TO MACHINERY

The eighteenth volume of MACHINERY was completed with the August number, and the general index covering the engineering, shop and railway editions is ready for distribution. Copies will be sent to any address on request.

PREVENTION OF ELECTRICAL ACCIDENTS IN MACHINE SHOPS

In an article in the *Engineering Magazine*, Mr. Emmett Campbell Hall deals with the question of electrical accidents and mentions some of the precautions that ought to be taken in order to avoid them.

Considering the extensive use made of electricity both for lighting and power in almost all modern industrial establishments, the general lack of knowledge concerning its dangers, and the not infrequent helplessness and panic which is manifested when someone receives an accidental shock, is somewhat surprising. Most electrical accidents are due to ignorance or carelessness, and not infrequently an ill-advised attempt at rescue results in a second accident. Scarcely less important than a knowledge of how to avoid a shock, is information as to what should be done if such accidents do occur, as they sometimes will through unavoidable causes, even when the greatest care is exercised.

The human body is an electric conductor, although not so good a one as a wire or a metal rail, and current will flow through the body when it is made part of a circuit. The amount of current which will flow through the body depends upon the voltage or pressure of the current, and upon the completeness of the contact between the body and the circuit. A single-cell battery, giving one to two volts, can cause a current to flow through the body, but the current is too small to be felt. A shock, though not a violent one, will be received from a 110-volt circuit; currents of greater strength must be carefully guarded against.

If a perfect insulator could be found, a man might stand upon it and place his hand upon a trolley wire through which a 500-volt current was passing, and receive no shock, because the circuit through the body would not be complete, and no current could flow. If a man should stand on damp earth and handle a charged wire with gloves slightly damp from sweat, he would probably receive a severe shock; if he wore no gloves, the shock would knock him down, and possibly kill him. There is no such thing as a perfect insulator, though for practical purposes a number of things may be so considered. The most that can be done is to insulate the body to such a degree that the current which passes through it will be so small that no shock will be felt. In other words, a small percentage of the total force of the current is almost sure to pass through the body, no matter what form of body insulation is used. It is therefore obvious that the amount of current which will get through the insulation increases as the voltage that is handled increases. It is not difficult to guard against shock from a 110-volt current, comparatively little insulation being effective. It is much more difficult to protect the body from 250 volts, and circuits of 500 volts or more should be carefully approached, no matter what form of insulation is used.

Next to contact with live wires, the most likely cause of shock is contact with parts of machines or equipment that are not supposed or intended to carry current, but which are accidentally charged with electricity. This charging is caused by the failure of insulation, or by a live wire coming in contact with the equipment. The frame of a motor or cutting machine, or the iron casing of an enclosed switch, may become alive and will be as dangerous as a trolley wire.

The frame of an electric locomotive is usually so completely in contact with the track rail that a man cannot get a shock even by standing on the rail and touching the locomotive; but this, under one peculiar condition, may not be true. If the rails have been heavily sanded, the locomotive may be almost completely insulated from them, and in that case a shock may be received from the locomotive frame or from the draw-bars of the cars coupled to the locomotive.

It is impossible to tell whether conditions are safe unless the man concerned has made them so himself—no one can tell by looking at a motor, for instance, whether or not the parts that carry current have come in contact with the frame of the machine. Whenever possible, common sense should dictate that the current be cut off before anything is touched that *might possibly* be charged. If it is impossible to cut off the current, or if repairs must be made to live apparatus, the only way to be safe is to provide something suitable to stand on while doing the work. *Dryness* is the most desirable quality in such an article. Perfectly dry boards, free from nails, are good.

Rubber gloves, or leather gloves in good condition and without metallic fastenings, will protect the body from shock. If the rubber covering of gloves is worn thin, the gloves give almost no protection, and the same is true of leather gloves which from any cause are damp. Rubber boots without nails in the soles or heels are good protection when new, but if the soles are worn or cracked their value is doubtful. Rubber tape on the handles of pliers and other tools cannot be depended on unless the tape has been freshly and carefully applied. If a man has to make some adjustment, he should use but one hand, if possible, and he should also try to place his body in such an attitude that the involuntary recoil from a possible shock will remove his hands from the apparatus instead of causing him to grasp it.

When a man has received a shock which renders him senseless, two things should be done as soon as possible; remove the victim from contact with the electric wire, and revive him by getting him to breathe. Great care should be exercised by the rescuer not to get a shock himself. If a switch is at hand, the current should, of course, be cut off, but if there will be any delay in cutting off the current, remove the body from the circuit by means of a piece of dry wood, using it to push the body aside or to lift from the body whatever is carrying current to it. Tools with *dry* wooden handles, such as picks or shovels, may be used for this purpose. The body can be safely grasped with the hands, if the hands are protected with several thicknesses of *dry* cloth, or if the rescuer stands upon a piece of *dry* wood. Take hold by the victim's clothing only, if practicable, not of the body where bare. If nothing else can be done, it may be possible to short-circuit the current, and thus blow the circuit breakers or fuses. A short circuit may be made by placing a piece of pipe or other metal article so that it will connect the two sides of the circuit. For instance, if the victim is in contact with a trolley wire, the wire, chain, or what not, should be thrown across the trolley wire and the track rail, so as to be in contact with both. In doing this, one must, of course, be sure that the pipe or chain leaves his own hand before it touches the current-carrying part of the circuit.

WAGES IN VARIOUS COUNTRIES

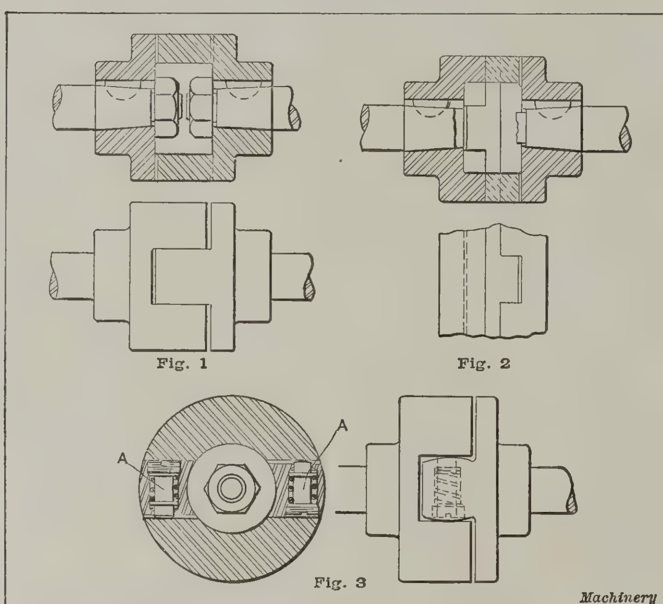
From the results of thorough investigations undertaken by the Board of Trade, England, relating to the wages paid to workmen in England, Germany, France, Belgium and the United States, some interesting data on the comparative wages in these countries may be obtained. These data present a fair average, as not less than ninety-four industrial centers in Great Britain, thirty-three in Germany, thirty in France, fifteen in Belgium and twenty-eight in the United States furnish the basis for the comparison. As a general average it may be stated that the wages of American workmen are 50 per cent higher than those of English workmen. In the European countries wages are highest in England and lowest in Belgium. English workmen are, in general, paid 25 per cent more than German workmen, and 36 per cent more than workmen in France. Relating to wages in the metal industries, the following figures will be of interest: Lathe hands are paid in London $9.50 per week of fifty-four hours; in Berlin, from $9.10 to $9.45 per week of from fifty-seven to sixty hours; in Sheffield, $9.25; in Düsseldorf, from $8.00 to $8.75; and in Antwerp, $5.85, for sixty hours a week. Of European countries, England shows not only the highest wages paid but also the shortest working hours. Belgium with the lowest wages has also the longest working hours. The investigation also covers the cost of living in the different countries. Thus, for example, rents for similar accommodations are nearly twice as high in England as in Belgium, and about twice as high in the United States as in England. The average prices of food products as compared with the English prices are 17 per cent higher in Germany; 18 per cent higher in France; 1 per cent lower in Belgium; and 28 per cent higher in the United States.

AUTOMOBILE MAGNETO COUPLINGS

BY GEORGE E. POPE*

Recently a magneto coupling was to be designed which was to combine simplicity with full freedom of universal-joint action. Several designs were tried, the results obtained being recorded in the following.

The first coupling designed was made as shown in Fig. 1, with the exception that the tongue was made about 0.010 inch smaller than the slot. This design, of course, had a universal-joint action, but the noise was very objectionable. This noise was partly due to the great difference in power transmitted while the armature of the magneto traveled by a gap as compared with that transmitted when it passed a pole. The objectionable noise was eliminated by making the tongue a sliding fit in the groove, as shown in Fig. 1, but this construction necessitated an accurate alignment of the magneto shaft with the driving shaft, and defeated the object of a universal-joint action. Another design, as shown in Fig. 2, was then tried. This is simply an adaptation of what is commonly known as "Oldham's" coupling. This worked very satisfactorily and the only objection was that there was considerable milling work to be done on the intermediate piece.



Figs. 1 to 3. Different Types of Couplings Designed

The next step in the development was to make the tongue of the coupling shown in Fig. 1 with rounded sides, as indicated in Fig. 3. This arrangement gave a satisfactory universal-joint action, especially when the tongue was made 0.010 inch smaller than the groove and the spring pins *A* were added to keep the driving surfaces in contact. In this coupling, however, it is necessary that the tongues be milled properly; and the first operation in doing this work consists of merely milling a slot through the end as if the grooved part of the coupling was about to be made. The permissible maximum width of this groove or slot is readily determined, as indicated in Fig. 5. This slot serves a double purpose; *i. e.*, it relieves the form cutter of most of the work, and it provides a means for preventing the work from turning when milling the upper side of the rounded portion of the tongue, as shown in Fig. 6, where the cylindrical piece *B* enters into the groove milled while one side of the tongue is formed.

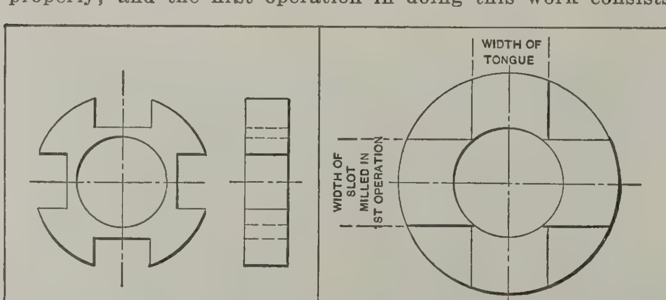


Fig. 4. Alternative Design of Connecting Part in Fig. 2 Fig. 5. Illustration of Method of finding Width of Tongue in Fig. 3

* Address: 586 Warren St., Bridgeport, Conn.

The fixture shown in Fig. 6 is, perhaps, of special interest, on account of its quick action in bringing the set-screws *C* into position. The piece carrying the set-screws is a section of cold-rolled steel placed between the uprights *A*, which take the backward thrust of the screws. These pieces are hinged freely at both ends on pins, the ends of which are milled off, as shown. These ends are in contact with flat springs which hold the parts *D* in an upright position with the screws vertical while the work (of which there can be six or ten pieces in the same fixture) is being removed or inserted.

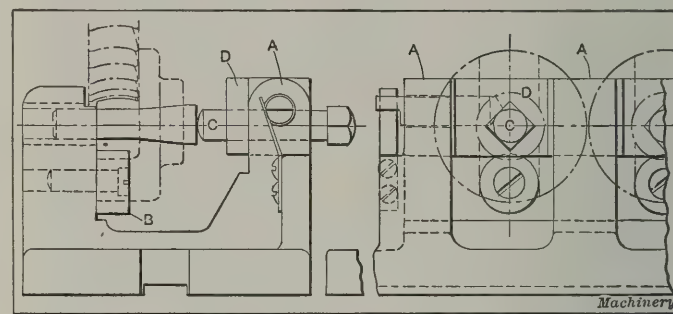

Fig. 6. Milling Fixture used for Milling Tongue in Coupling in Fig. 3

A slightly different design for a coupling of the type shown in Fig. 2 is to have the intermediate piece contain the slots, instead of the tongues. The intermediate piece will then look as indicated in Fig. 4. These pieces can then be milled in gangs on an arbor, but the other parts of the coupling become more difficult to mill, as both of them now have tongues, and it is doubtful if anything is saved by this design.

It may be remarked that although these different designs of couplings were made primarily for automobile magnetos, they probably can be applied to other kinds of work where it is inadvisable or impracticable to accurately align the connecting shafts.

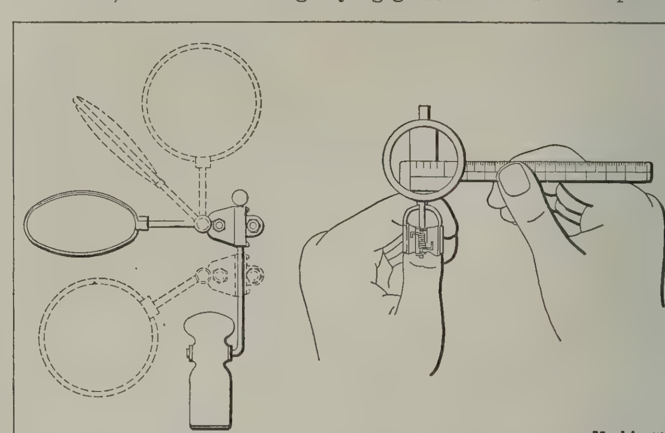
HANDY MAGNIFYING GLASS FOR SHOP USE

The accompanying illustration shows a useful device recently placed on the market by Messrs. Pfeil & Co., Clerkenwell, London, E. C. This device, as illustrated in the *Mechanical World*, consists of a magnifying glass mounted on a special clip which can be clasped onto the left-hand thumb, and is known as the "third hand." The object of the device is to enable an article to be held, examined and turned under the lens, and yet leave the other hand free for holding the measuring instrument. The clip can be clasped on any finger so that small articles can be examined on the palm of one hand and moved and turned around by the other. The illustration to the right suggests one of the uses of the device. As shown by the dotted lines in the illustration to the left, the magnifying glass is universally jointed to the holder so that it can be set in almost any position.



Handy Magnifying Glass that can be attached to the Thumb, leaving Both Hands Free to handle Work and Measuring Instrument

COMMERCIAL GRINDING*

A FEW PRACTICAL EXAMPLES FROM ACTUAL WORK

BY F. B. JACOBS†

Where is the machinist of twenty or more years' experience who cannot recall the time when small and medium-sized shafts, spindles, etc., were always carefully turned from Bessemer steel and finished by filing? In those days, the few grinding machines that existed were generally of the universal type, and were confined to the tool-room, being used only on work that had to be corrected after hardening. While it can not be denied that the shop practice of the "good old days" resulted in excellent mechanics, it is also quite evident that the concern that still employs the old methods finds itself seriously handicapped in meeting prices set by modern practice. In the finishing of accurate machine parts, the grinding machine has replaced the lathe, and the grinding wheel has taken the place of father's file.

The present-day grinding machine owes the greater part of its success to the modern grinding wheel; for no matter how carefully the machine is designed and constructed, its output is always seriously handicapped if wheels of the wrong materials, grits, grades and bonds are used. The following illustrations and descriptions are not intended to show what could be done under ideal conditions; on the other hand they are taken from actual work as the writer found it in various shops under everyday working conditions.

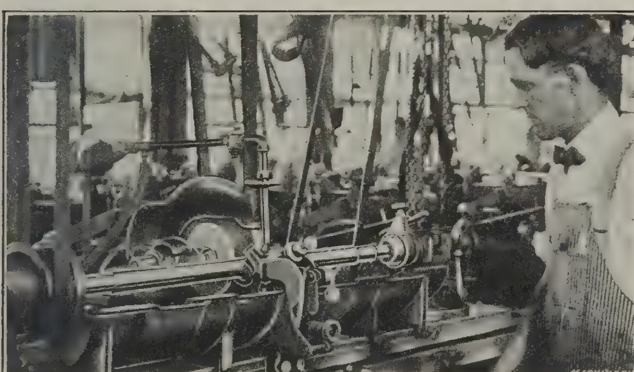


Fig. 1. Finishing Steel Shafts in a Brown & Sharpe Universal Grinder

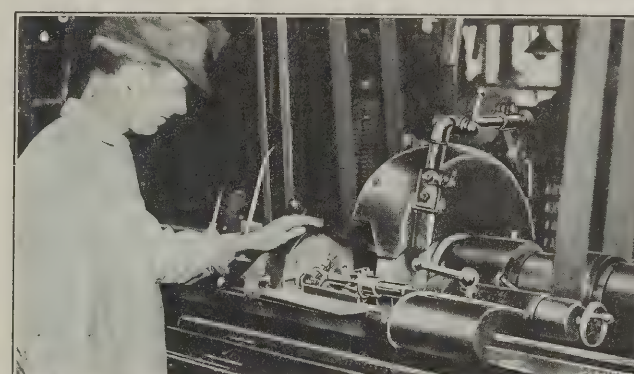

Fig. 2. Grinding Bevel Gear Hub with a Wide-faced Wheel

Fig. 3. Group of Bevel Gears being ground in Fig. 2

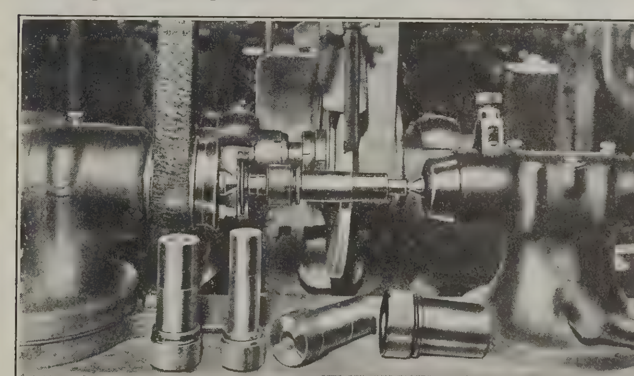

Fig. 4. Grinding Jig Bushings

In Fig. 1 is shown the operation of finishing a 40-point carbon steel shaft in a Brown & Sharpe No. 3 universal grinder, equipped with a carborundum wheel 365 grit, L grade, B3 plus bond. This piece is 2 feet 10½ inches long, and 1⅝ inch in diameter. It is first rough-turned, leaving 0.015 inch for grinding. As the illustration shows, the work is supported by a compound back-rest, this being necessary to overcome chattering under heavy cuts. While removing the greater amount of the stock the back-rest jaws are used "solid," bearing in a groove ground for this purpose. While taking the last few cuts the jaws are held against the work by the springs with which the rest is provided, care being taken to see that the jaws do not bear hard enough on the piece to throw it out of alignment. The time consumed in grinding this piece is twenty minutes, and the finish left is excellent.

*See also "Efficiency in Cylindrical Grinding," MACHINERY, March, 1912, and the articles there referred to.

† Address: Care of Carborundum Co., 826 Arch St., Philadelphia, Pa.

The grinding operation shown in Fig. 2 is a radical departure from ordinary grinding practice, as the traverse feed is discarded except as a means of locating the work in its relative position with the wheel. The work consists of grinding bevel gear pinions used in the differential gear of automobiles, several of which are shown in Fig. 3. These are made of machine steel, pack-hardened. The surface to be ground is 1 7/16 inch long, and 1¾ inch in diameter. The grinding is done on a Norton plain grinder, equipped with an "Aloxite" wheel, made specially for this class of grinding. This wheel is 18 inches in diameter, 2-inch face, 5-inch hole, 246 grit, N grade, D-497 bond, and is run at a speed of 1400 R. P. M. Experience has shown that a saving of as high as fifty per cent of the grinding time is possible in grinding hardened steel pieces of comparatively short lengths by the method described.

As shown in Fig. 2, the work is held between the centers of the grinding machine on an ordinary mandrel or arbor, and is "dogged" in the regular way. The work speed is 140 R. P. M., and for removing 0.020 inch, the grinding time is 1¾ minute per piece. After locating the work between the centers, the operator brings the shoulder of the pinion to bear slightly on the wheel, and then, by means of the cross-feed screw, the wheel is fed directly to the work until the proper diameter is reached. This is shown by the graduations on the cross-feed. Before grinding, the wheel is carefully trued, and owing to its rapid cutting and accurate sizing qualities, many dozen pieces can be accurately finished without altering the adjustment of the cross-feed stop or re-truing the wheel. It may be added that grinding under these conditions is only in its infancy, and it can be safely stated that before many years have passed it will be common practice to use wheels as wide as six or eight inches for finishing work by the method described.

The grinding of jig bushings is an operation that calls for extreme care, otherwise the value of accurate spacing of the holes in the jig is lost. It is not intended, however, to convey the idea that the tool-maker should consume unnecessary time by carefully feeling his way along, because the tool grinding department can be made as efficient as any other, by the use of the proper wheels and methods. The bushings shown

in Fig. 4 average one inch in diameter and are two inches long. They are made of tool steel, hardened, and drawn very slightly. The grinding is done on a Brown & Sharpe No. 2 universal grinder equipped with an "Aloxite" wheel 12 inches in diameter, ½-inch face, 5-inch hole, 405 grit, N grade, D-497 bond. This wheel is run at a speed of 1800 R. P. M. The bushings are held on special arbors as illustrated in Fig. 5. These arbors are straight and a wringing fit in the bushing for the greater part of their length. A slight taper at the end serves to hold the bushing from turning. The illustration shows this taper somewhat exaggerated, to illustrate the principle.

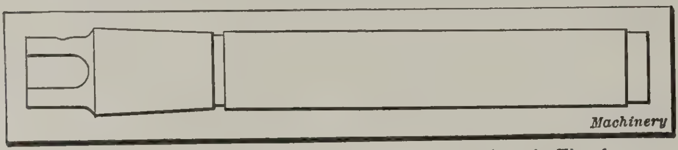

Fig. 5. Arbor used when Grinding the Jig Bushings in Fig. 4

In grinding these bushings, a work speed of seventy-five feet per minute was used, while the traverse feed was the fastest that this machine was capable of giving in connection with this work speed, or one-quarter of the width of the wheel for each revolution of the work. Under these conditions the bushings were ground in five minutes each, which is very rapid when it is considered that the limit of accuracy is approximately 0.0003 inch. The bushings were afterwards finished by lapping to fit the lining bushings.

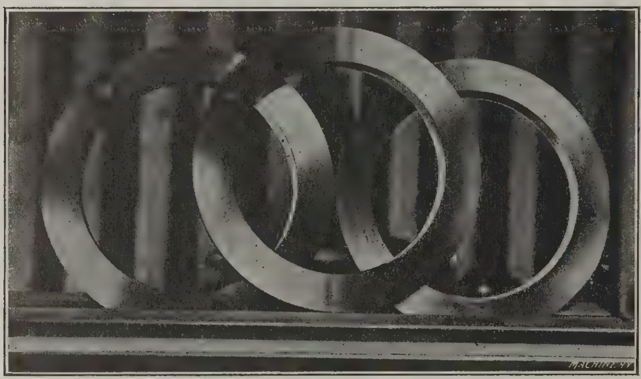

Fig. 6. Thrust-bearing Rings, 8 inches in Diameter, shown being ground in Fig. 7

The process of face grinding, or the finishing of the sides of pieces by holding them in a chuck on the universal grinding machine, and feeding them past the periphery of the grinding wheel, is by no means of recent origin, this method having been employed for many years in finishing tool work, such as the sides of milling cutters and other tools of like nature. In the last few years, however, owing to the rapid cutting qualities of the modern grinding wheel, face grinding has become a regular commercial process. In Fig. 6 are shown several thrust bearing rings, eight inches in diameter, with a six-inch hole. These rings are made of machine steel, and, after being pack-hardened, are rapidly and economically ground on a No. 2 Bath universal grinder as shown in Fig. 7. The grinding wheel used is "Aloxite," 8 inches in diameter, ¾-inch face, 1⅜-inch hole, 365 grit, O grade, D-496 bond, and is run at a speed of 2300 R. P. M.

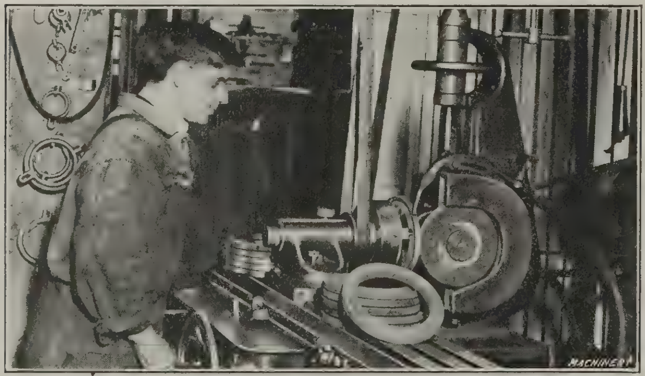

Fig. 7. Grinding Thrust Bearing Rings on a Bath Grinder

The work is held in a three-jaw chuck which is screwed firmly to the headstock spindle and set at an angle of 90 degrees with the wheel spindle. In locating the work in the chuck, the operator exercises care so as not to clamp the jaws too tightly; otherwise the pieces will spring out of shape. The work speed is 140 R. P. M. for both the roughing and finishing operations. In roughing, the operator feeds the wheel directly into the work until the sparks show heavy; then, by means of the traverse feed, the work is automatically carried back and forth past the wheel, the operator feeding the wheel into the work about 0.001 inch at each reversal of the platen. When the piece has been ground nearly to thickness the cross-feed is thrown out, the work still feeding past the wheel. This process, generally called "grinding out," gives an excellent finish even when a comparatively coarse wheel is used. Owing to the rapid cutting qualities of the modern grinding wheel, this is accomplished in five or six strokes. The grinding time for these pieces, including chucking, when removing approximately 0.010 inch, is five minutes, and the finish left is excellent.

* * *

STRENGTH TESTING OF STEELS

In a paper on "Research of the Hardness of Steel," read by Capt. C. Grard before the congress of the International Association for Testing Materials held in New York City, September, 1912, an investigation into the accuracy possible with the Brinell hardness testing method was recorded. From this investigation it appears that when commercial apparatus, as ordinarily used for making the Brinell test, is employed, and the test is carried out with ordinary care and precaution, it is reliable within an error of five Brinell units above or below the actual hardness. In other words, if the hardness of two pieces of metal is tested, and the difference on the Brinell scale is more than ten hardness units, it is certain that there is an absolute difference in the hardness of the pieces tested. With regard to the conditions under which the tests should be made, it may be stated that the pressure should be gradually applied during a time of two minutes or more, and the pressure should be kept on the test piece for a period of at least five minutes.

As has already been pointed out by Mr. Brinell himself, and as mentioned in an article on "The Brinell Method of Testing the Hardness of Metals," published in MACHINERY, engineering edition, September, 1908, this method of testing the hardness of metals offers a convenient means of ascertaining, within close limits, the ultimate strength of iron and steel. This, in fact, is one of the most interesting and important results of this method of measuring hardness. In order to determine the ultimate strength of iron and steel, it is only necessary to establish by experiments a constant coefficient which serves as a factor by which the hardness numerals are multiplied, the product being the ultimate strength. The coefficients, as usually stated, give, when multiplied by the hardness numerals, the ultimate tensile strength of the material in kilograms per square millimeter. Of course, coefficients can easily be worked out by means of which the hardness numerals can be multiplied so that the strength can be obtained in pounds per square inch.

In Capt. Grard's paper, this relation between hardness and tensile strength was exhaustively dealt with, and the following coefficients are given for different grades of steel:

Steels, extra soft	$K = 0.360$
Steels, soft and semi-hard................	$K = 0.355$
Steels, semi-hard	$K = 0.353$
Steels, hard	$K = 0.349$

It will be seen that these coefficients differ by but a slight amount and it was suggested by another member of the congress of testing materials that a uniform constant be adopted by the International Association for Testing Materials, which would be used for calculating the tensile strength directly from the results of the hardness tests. (A complete treatise on the Brinell hardness testing system was published in the September, 1908, number of MACHINERY, engineering edition. This article is reprinted in MACHINERY's Reference Book No. 62, "Testing the Hardness and Durability of Metals").

The oily superintendent is a slick proposition.

STANDARDIZATION OF AUTOMOBILE DRAWINGS*†

SIZE OF SHEETS, PROJECTIONS, LETTERING, ABBREVIATIONS, CROSS-SECTIONING, ALTERATIONS, DIMENSIONS, ETC.

The following items should be considered in connection with the standardization of automobile drawings:

1. Size of sheets. 2. Arrangement of views on the drawing and method of projection. 3. Character and weight of the lines on a drawing. 4. Style of lettering and numerals, and the size of same. 5. Abbreviations for names of materials. 6. Cross-sectioning. 7. Method of making records of alterations. 8. Placing of finish marks on drawings. 9. Methods of dimensioning. 10. Methods of noting working limits or tolerance. 11. Location of general notes on the sheet. 12. Length of undercut. 13. Checking instructions. 14. Notation for tap and die sizes. 15. Nomenclature of parts.

At the Chalmers Motor Co., Detroit, Mich., an effort has been made to develop a logical system of making drawings along the lines outlined. There is a need for general standardization of automobile drawings. This industry is no longer a matter of a few scattered factories—there are hundreds of plants concerned with the making of drawings for identical parts; yet there are probably not five men in the Society of Automobile Engineers who use the same system for making drawings. Nevertheless, there is a constant changing about among the draftsmen and members of the society. They go from one factory to another, and every time a change is made it is necessary for these men to become familiar with an entirely new system of drawings. This increases the chances for error and causes a loss of time. It forces a man to fill his mind with detail matters about drawings when, as a matter of fact, he ought to be concerned with matters of design only.

In addition, almost every company in the country has some parts made outside of its own factory. This is particularly true of forgings, brass castings and pressed steel parts. There are some manufacturers of these parts who handle the work for as many as fifteen automobile factories. Here is a chance for error on account of each factory sending a drawing of a different size, made to a different scale, with notes and instructions made out in a different manner, on different parts of the sheet. It is hardly fair to blame the workman for failing to read correctly one of these drawings, if it is different, as it often is, in every respect, from other drawings which he has been handling previously. No matter, however, who is at fault, the error is there, and it may impede production for a considerable length of time. Hence, there is little use to argue further as to the need of standardization of automobile drawings; it remains merely to discuss the methods now in use and to determine which methods ought to be adopted by all. The following is a record of the practice of the Chalmers factory, as already mentioned.

Size of Sheets

First, in the matter of the size of the sheets, five sizes are used. The first is the standard letter size, 8½ by 11 inches. All other sizes are developed from the first size; that is, all are multiples of 8½ by 11 inches, or of one of those dimensions. No. 1 sheet is always made with a wide blank margin at the left, on the short dimension and a narrower uniform blank margin on the other three sides. The drawing or sketch is placed on the paper to read lengthwise of the sheet. Sheet No. 2 is 11 by 17 inches, with a wide blank margin at the left, on the short dimension, and a narrower blank margin on the other three sides. The drawing is made to read lengthwise of the sheet. Sheet No. 3 is 17 by 22 inches, sheet No. 4, 22 by 34 inches, and sheet No. 5, 34 by 44 inches, with the same arrangement of margins.

These are the sheets which have been used up to this time. However, a change has been considered as follows: To use only sheet No. 2, which is 11 by 17 inches, drawing large objects to a reduced scale on this size sheet, with a statement of the scale used on the sheet margin, so that the drawing will be readily understood. The new method would do away with the necessity of having different sized sheets, and all of the books for shop use would be made up with one size of sheet. In making drawings of such parts as crank-cases, cylinders, etc., they would be drawn to a reduced scale with the machinery dimensions only placed on the sheet. Pattern drawings would, of course, be made full-size, and would be kept in the drafting-room for factory reference. One or two large drawings might also be placed in the tool-room or at some other convenient point, for reference after a job is started. All of the drawings in regular use, however, would be 11 by 17 inches.

In connection with the arrangement of the sheets, a standard stamp should be adopted. A stamp 9½ inches long by 2 inches wide, with space for name, notes, material specifications, heat-treatment, material, by whom drawn, traced, checked, and approved, standard parts, date, and the symbol number, should be used. This stamp is always placed in the lower right-hand corner and along the margin of the sheet. The upper right-hand corner has a space 2⅝ inches wide and as long as necessary, running down the right-hand margin of the sheet, and divided into three portions. This is the revision table; in this space all notations of corrections, the date of correction, by whom made, and the dimension or part corrected are recorded. This table has all of the changes made on any particular drawing, so that it can be referred to at any time; no matter how unimportant the correction, it is always recorded here.

Method of Projection

The second item is the arrangement of the views on the drawing and the method of projection. For simple drawings, three views are about all that are necessary, with perhaps the addition of the necessary sections. No matter how simple the piece, three views should always be shown. The third angle projection is used; this is the best, because it gives the person handling the drawing a clear understanding of the front, top and side elevations.

Character and Weight of Lines

The third point is the character and weight of lines on a drawing. All full lines should be at least 0.030 inch heavy. All dotted lines should be 0.020 inch, with a mean length of dot of 3/16 inch and a spacing not in excess of 1/16 inch. All of the borders should be 0.060 inch heavy. It is, of course, understood that plenty of ink should always be used.

Style and Sizes of Letters

Fourth, the style of letters and numerals and their sizes should be considered. The best practice is to have all letters or notations on drawings made in upper case type, vertical form, and of about 0.020 inch uniform weight of line. For letters, too, plenty of ink should always be used. All notes and instructions on the drawings should be underlined with practically the same weight of line. This not only makes the notes more emphatic, but also has a tendency to keep all of the lettering uniform. Every word should be started with a capital letter approximately 1/8 inch high, the balance of the word being written with smaller sized capital letters, approximately 3/32 inch high.

Abbreviations

No abbreviation should be made so short as to be confusing. When necessary, the word should be written out in full. Mistakes as to materials are about the most serious that can occur; here one cannot be too careful to obviate the chance of error. The following abbreviations are used:

For iron casting—"I. Cast."

For malleable casting—"Mal. Cast."

For steel casting—"St. Cast."

For brass casting—"Brs. Cast."

For bronze casting—"Brz. Cast."

For aluminum casting—"Alum. Cast."

* Abstract of paper by George W. Dunham to be presented before the Society of Automobile Engineers at its Winter meeting in New York, January, 1913.

† The following articles on drafting-room practice and kindred subjects have previously been published in MACHINERY: "The Printing Press in the Drafting-room," January, 1912; "The Drafting-room System of the American Locomotive Co.," June, 1911, and the articles there referred to. See also MACHINERY'S Reference Books No. 2, "Drafting-room Practice"; No. 8, "Working Drawings and Drafting-room Kinks"; and No. 33, "Systems and Practice of the Drafting Room."

The abbreviation for forgings is "Forg."; for steel stampings, "St. Stamp."; for pressed steel, "Press. St." In describing sheet metals always begin with the word "Sheet." This is no abbreviation at all, but it is best to use the full word, since it precludes all possibility of error.

Cross-sectioning

For all detail drawings, a cross-sectioning is used as if the material were cast iron, with lines 0.015 inch heavy, spaced 1/16 or 0.025 inch apart. On assemblies, however, the standard cross-section of various materials should be used. The different characters of sectioning are confined to assembly drawings.

Recording Alterations

The method of making records of alterations should be standardized, because workmen shift about a great deal, and all alterations should be uniform. When several different systems of noting alterations are used, it is impossible for a man to understand all of them without considerable explanation, and, of course, no man likes to confess ignorance of a drawing if he is used to working with drawings. When a figure is changed, a lower case letter should be located alongside the figure changed. This letter should be surrounded by a circle on the tracing; then the same letter should occur again in the upper right-hand corner where notation of alterations is made. Here the letter should be followed with the figure as it originally read, followed by the date and initials of the man who made the correction. In this manner all changes can be so recorded as to enable one to find the dimension as it was prior to the change, and also to discover when and who made the change. If this system were uniform for all automobile drawings, there would never be any confusion in regard to alterations.

Finish Marks

Next we come to the matter of placing finish marks on drawings and to the right lettering to be used. The Chalmers Motor Co. uses the capital "F" with the foot of the letter resting on the line indicated as finished. However, a very good practice in use in other shops, is the placing of a lower case "f" with the cross bar on the intersection of the body of the letter and the line to be finished. Of course care should be taken to see that the letter is always placed at right angles to the line, otherwise the intersection will be less noticeable, and the letter may be overlooked. The method of showing the amount of finish on the drawing is followed by some, but this is inadvisable, as the amount of finish is dependent on the methods used in the shop and changes as the routing system may be altered from time to time.

Methods of Dimensioning

All dimension lines should be 0.015 inch heavy, and should be placed outside of the views, as far as possible. Elevations and end views of an object to be dimensioned should be tied together with projection lines of the same weight as the dimension lines, with the dimensions placed between. All diameters of holes occurring in the body of the drawing should be carried out for dimensioning with full projection lines. Never place the diameter of a hole inside the hole itself, except when the hole is very large. Numerous diameters should never be marked transversely across the face, with the dimension lines intersecting a common center.

All dimensions should read from the bottom and right-hand side, as far as possible. It is not necessary in motor car work to add the customary inch marks to the figures. Section through threads should be shown with two parallel lines approximately the depth of the thread. The customary method of showing threads by inclined lines should be avoided. This has a tendency to blur a drawing badly.

Tolerances

There should be an understood allowable variation or tolerance in rough forgings and castings where a dimension is shown in a common fraction; on finished work where a common fraction is given; and on finished work where a decimal is given. Very close limits or tolerances should be shown by writing the maximum and minimum dimensions allowable, in decimals. These decimals should be written in full, and not with plus or minus marks as is often done. They should be uniformly written, one above the dimension line and the other underneath. For example, for a piece of one and one-half inch diameter, with a minus variation of 0.003 inch, 1.500 should be written above the dimension line and 1.497 underneath.

Notes

Notes should be grouped in one part of the sheet, either in the left- or the right-hand lower corner, as may be thought best. If this manner of making notes is followed generally, workmen will become accustomed to look for notes in a certain part of the drawings. This will eliminate the chance of overlooking important notations, often with embarrassing results.

Length of Undercut

The twelfth item is the diameter and length of undercut at the end of a threaded part or ground shoulder. In most work the undercut is just sufficient to permit the grinding wheel or thread tool to clear itself, and in the case of a ground dimension it is generally necessary to allow at least ⅛ inch in length—sometimes more, if conditions will permit. For threading operations it is well to allow 1/8 inch, although 3/32 inch has been used very successfully.

Checking Instructions—Tap and Die Sizes—Nomenclature

Thirteenth comes the matter of checking instructions. These should be carefully outlined and rigidly followed.

The checker should be instructed to check for general appearance of the drawing. If this is done, the condition of the work turned out of the drafting-room will be kept up to the highest standard. Undoubtedly the quality of the drawings has a very decided effect on the quality of the work in the factory.

All drawings should be checked very carefully for design. If there is any question in a checker's mind as to the design, he should call the matter to the attention of the chief draftsman at once.

All drawings should, of course, be checked for accuracy, and for working limits.

Particular care should be taken that all figures necessary to make the piece are on the drawing.

The finish marks should be carefully checked.

All drawings should be checked for threading and grinding reliefs.

Instructions for hardening, tempering, annealing, plating and polishing should be checked with the utmost care.

Material specifications and treatment require most careful checking.

The general notes should be gone over.

There should be a check on standard parts going with any particular part.

The name and, finally, the number should be checked.

The fourteenth point concerns tap and die sizes. Tap and die sizes should be given together with the pitch diameter and tolerance, wherever possible.

The nomenclature of parts is now under discussion in the nomenclature division of the standards committee of the Society of Automobile Engineers, and this is a matter to which reference can be made first when this committee has completed its work.

* * *

PROPOSED BUREAU OF FARM POWER

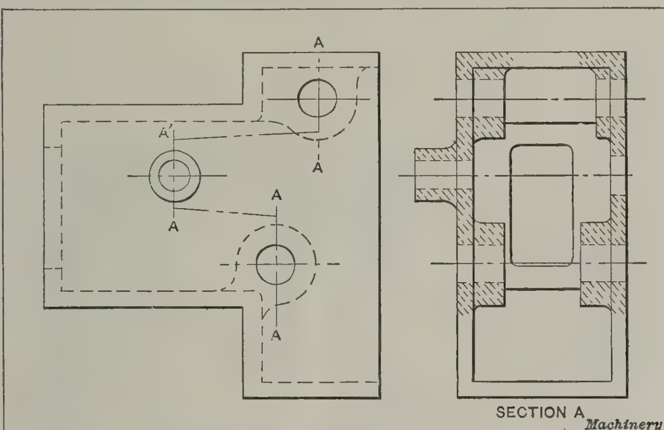
A bill has been brought into the House of Representatives (No. 25,782) by Mr. Henry T. Rainey, with the object of establishing a Bureau of Farm Power in the Department of Agriculture. It is the purpose of the bill to create a bureau which will investigate and report to the Department of Agriculture upon all matters pertaining to the methods of furnishing power on farms, and on all labor-saving machinery adapted for use on farms. This bureau would investigate such subjects, for example, as the use of electricity, gasoline, and steam in propelling farm vehicles, in operating plows, reapers, mowing machines, thrashing machines, and other farm machinery. In general, the bureau should make reports upon all such devices which would tend to lessen the amount of labor necessary in agricultural pursuits, and the expense of producing and marketing farm products.

LETTERS ON PRACTICAL SUBJECTS

We pay only for articles published exclusively in MACHINERY.

DENOTING SECTIONS ON DRAWINGS

In denoting the points at which sections are made it is customary to place different letters at each point and refer to these letters in the title of the view showing the particular section, thus: section at *AB;* section on *ABC;* section through *ABCD.* The method employed by the writer is to use one letter only for any particular section. Every break and the ends of a section are denoted by the same letter, as shown in



Method of Denoting Sections on Drawings

the accompanying engraving. The section is then referred to simply as section *A*, section *B*, etc.

J. COULSON

[The illustration shows a feature of drafting practice not used by draftsmen as much as it could be advantageously, that is, showing the cross-sections of a piece with dotted lines instead of full lines. This use of dotted cross-sections enables the object to be drawn in full lines as though not sectioned, and thus to show in the same view sections on any parallel plane without interfering with the remainder of the drawing. The dotted sectioning is shown in the cross-section at the right in the above illustration.—EDITOR.]

BURNISHING THREADING DIES

In the July number of MACHINERY a contributor recommends the passing of a master threaded plug through dies as a means of smoothing the threads of the dies. This operation is to be performed both after cutting the thread, while the die is still in its soft state, and after hardening. Lard oil is used as a lubricant, but no mention is made of an abrasive.

If one might judge from the effect of running a hardened spindle in an ordinary journal under dry conditions, the effect of the treatment outlined, on the threads of the die, might be thought to be similarly disastrous; because before the plug could act as a burnisher the oil would necessarily have to be squeezed from between the thread surfaces. In the opinion of the writer the removal of 0.001 to 0.0015 inch would tend to tear the thread. If the material is not removed, but simply compressed, the stresses set up in this way would certainly increase the tendency to distort in hardening.

It is also said that another advantage is gained in that the lead of the threads, distorted in the hardening process, is corrected. Now, as the die has been gashed or fluted at the time of the second burnishing operation there would be a tendency for the die to cut the master plug. At any rate, its influence on the master plug would, perhaps, be greater than the influence of the master plug upon the die thread; thus the pitch of the plug would be altered, it seems, at the same time that a correction, or rather a partial correction, of the lead of the die thread was made. Hence this advantage seems of doubtful value, and would almost require the making of a new plug for each die made, which would scarcely pay.

It would seem that the burnishing should rather be left to be done by the work to be cut by the die itself; or, let the die be used at first on a piece of soft material, such as cast iron. It is well known that cast iron has a burnishing effect. In lapping, for instance, a cast-iron plate merely kept wet with benzine is not only a burnisher, but a comparatively fast abrasive. The writer has before him at the moment of writing several dies in which the threads are quite smooth and bright. The only burnishing process to which they have been subjected is use.

Manchester, England. FRANCIS W. SHAW

THE DROP WORM-BOX

An article in the May number of MACHINERY prompts the writer to record some troubles experienced by him in connection with the drop worm-box form of trip motion. The accompanying engraving Fig. 1 shows the most common form, provided with a slight improvement. As pointed out in the previous article, the worm-box often fails to release when the feed shaft runs in the direction denoted by arrow *A*, the tendency being for the worm to cling to the worm-gear.

As a means of obviating this difficulty, the former contributor suggests placing the reversing motion in the worm-box, arranging it in such a way that the feed shaft always

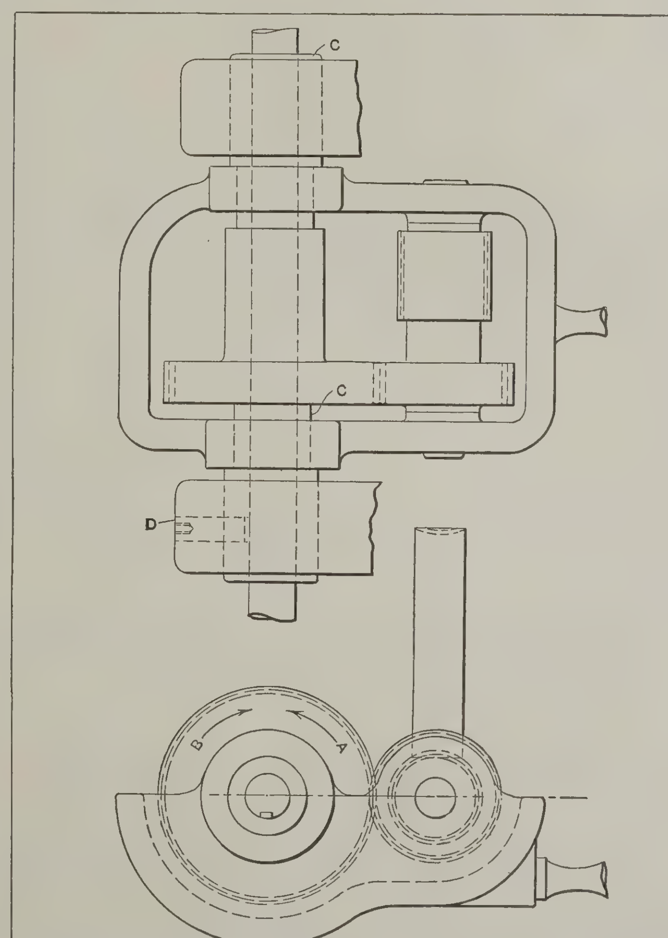


Fig. 1. An Improvement in the Ordinary Design of a Drop Worm-box

would turn in the direction of arrow *B*. This arrangement, however, is not always possible, since the reversing mechanism may have other duties to perform, as in the case of a turret lathe having a turret and a cross sliding saddle, both of which need to be reversed at times. Hence, some means of overcoming the difficulty other than by placing the reverse in the worm-box is necessary.

One method adopted by the writer made use of a sufficiently powerful spring to depress the worm-box after releasing. In Fig. 1, however, is shown how the difficulty was met without

using the spring. Usually the worm-box is mounted directly on the feed shaft, in which case the reaction of the pressure increases the friction on the feed shaft to a sufficient extent to squeeze out the oil film, thus increasing the coefficient of friction. The shaft itself then tends to pull the worm-box upwards, in addition to the direction of pressure at the teeth of the gear. By pivoting the worm-box on bushings at *C*, the friction between the shaft and worm-box is entirely eliminated. In the case in question the trouble entirely ceased with this construction, and springs were not needed.

An additional advantage of this method of pivoting is that the endwise adjustment for allowing the parts of the trip motion to be placed as required is provided. The method of holding bushing *C* is by means of pins *D* having small tapped holes in order to make possible their withdrawal.

Another case in which trouble was met with is shown in Fig. 2. In this case the worm-box contained a two-speed arrangement as shown. The sliding gears were moved by the shipper and rod shown by the dotted lines at the bottom. As the apron in which the worm-box was fitted was sliding along the bed, the endwise friction gradually tended to force the gears to disengage. The sliding gears were simply mounted directly on the feed shaft at that time. By imposing bushing *B*, which fits endwise between the bosses inside of the worm-box, this difficulty was overcome. Key *A* engages with a

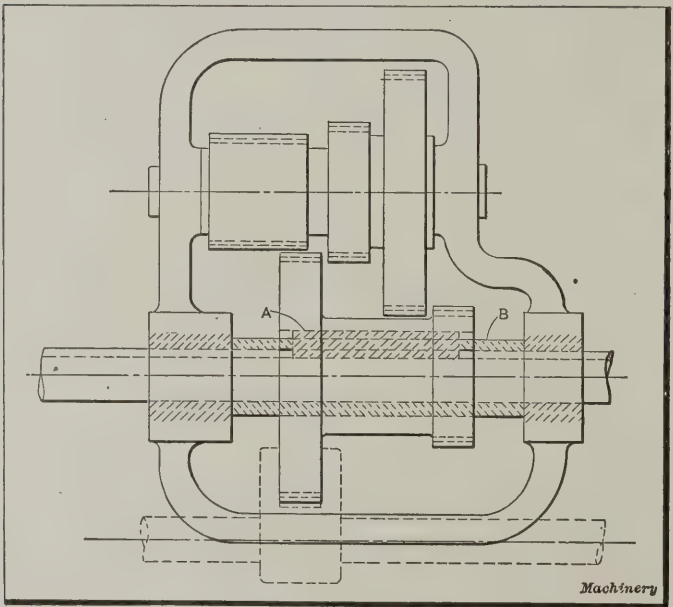

Fig. 2. Method of Overcoming the Tendency of the Gears in the Gear-box to disengage

groove in the feed shaft and in the sliding gears, and fits in bushing *B* in a slot cut clear through it. Previous to applying the bushing *B* the shipper which slides the gears was locked by friction. The faces of the shipper which make contact with the large gear, however, were badly cut up.

J. Coulson

TO ANNEAL AND HARDEN HIGH-SPEED STEELS

Place the piece to be annealed in an iron pot or pipe, pack steel chips around it, ramming them tight, and lute the cover well with fire clay, heat to a lemon yellow and hold the heat six to eight hours. Place the box in charcoal ashes and leave until cold.

Tool bits and small tools made of "Cyclone" special high-speed steel can be hardened successfully by heating to a yellow white heat and quenching in a good size piece of beef suet; plunge the piece into the suet and leave until cold; it will be found hard and tough.

To anneal "Blue Chip," "Novo" and "Rex" high-speed steels, pack the piece in an iron box or pipe with slacked lime rammed tightly around it and lute the box with fire clay. Heat to a yellow and hold the temperature one hour, and then bury the box in charcoal ashes until cold; or, if a blacksmith's forge is used with charcoal for fuel, leave it to cool down with the fire.

Another method is to pack the piece to be annealed in an iron pot or pipe with cast-iron chips and charcoal dust, or burnt molding sand, half-and-half. Ram the mixture well around the article, taking care that there is at least an inch of packing material around each piece. Lute the cover with fire clay and heat very slowly to an orange color. Hold the heat fifteen minutes and bury the box in slacked lime or charcoal ashes until cold. These formulas have all been tried and have given excellent results.

New Britain, Conn.

PRACTICAL METHOD OF MANUFACTURING DOUBLE-ANGLE END-MILLS

A great deal of trouble is often experienced when manufacturing small double-angle end-mills by ordinary methods. It is difficult to align the teeth properly, because of the necessity of resetting the machine when milling the second angle.

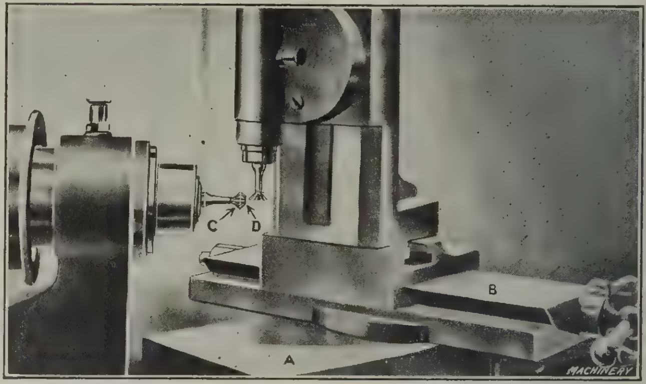

Fig. 1. Milling the Teeth in Double-angle End-mills

The grinding of these end-mills is just as difficult, because of the necessity of raising or lowering the emery wheel to obtain the proper clearance for each angle. In the following is described a method of manufacturing double-angle end-mills without the use of special machinery, so that both angles may be milled at one setting with the same milling cutter without readjustment. This, of course, insures the proper alignment of the teeth. The grinding operation of both angles is performed in the same way.

In Fig. 1 is shown a No. 4 Elgin bench lathe with milling attachment, as manufactured by the Elgin Tool Works, Elgin, Ill., set up for performing the milling operation. The spindle of the milling attachment is set in a vertical direction and the milling cutter is set central with the work. The lower slide *A* is set at the right angle to mill the cutting surface of

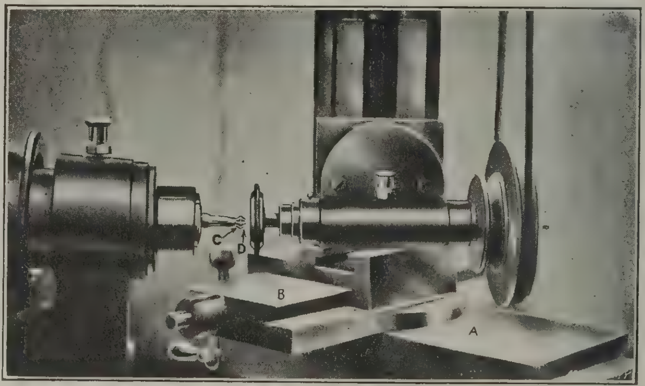

Fig. 2. Grinding the Teeth in Small Double-angle End-mills

the teeth at *C*, while the top slide *B* is set for milling the teeth at *D*. Both cuts are taken on the rear side of the work.

In Fig. 2 is shown the grinding operation, which is done in much the same way, except that slide *A* is used for grinding the teeth at *D*, and slide *B* for grinding the teeth at *C*. The spindle of the milling attachment in this case is set in a horizontal direction, with its center line below that of the cutter, so as to provide proper clearance for the teeth. The emery wheel is dressed flat on the top with a short angular surface on each corner. These surfaces correspond to the angular surfaces on the cutter, thus making it possible to grind both

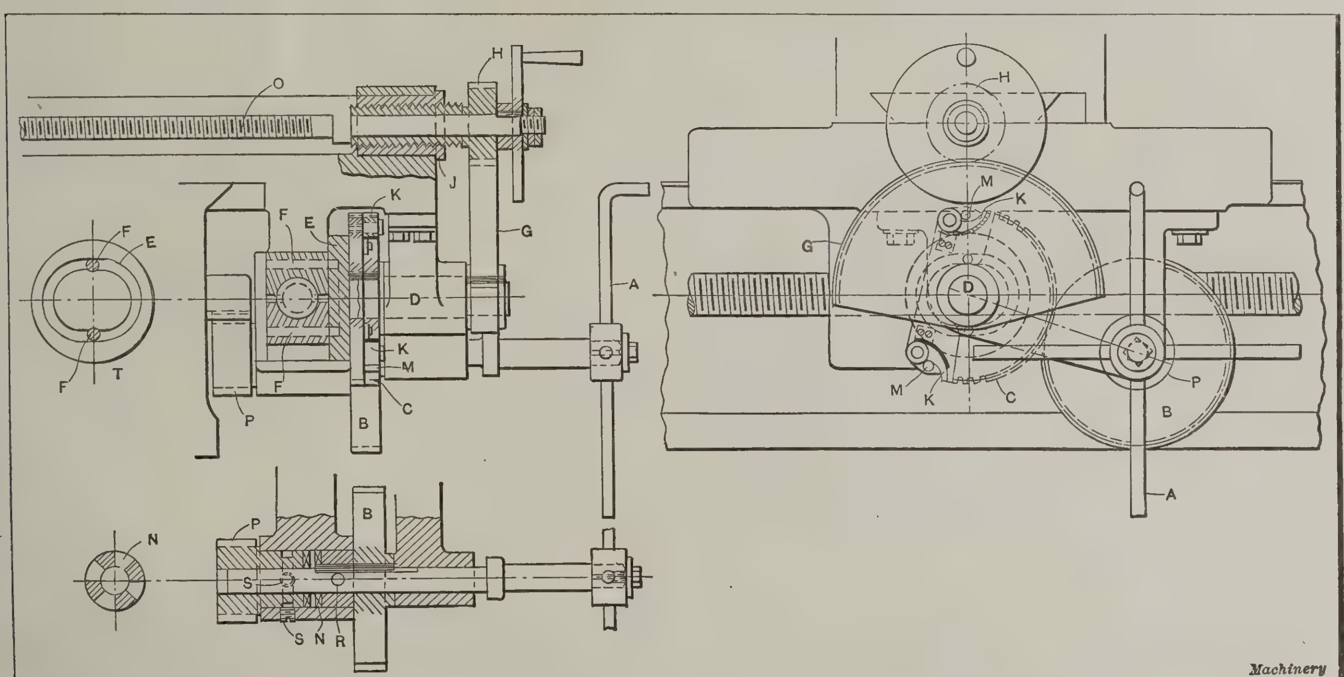
angles at the same setting of the wheel. As the spindle of the attachment is parallel with the axis of the lathe spindle, the extreme sharp point of the cutters can also be blunted by the wheel without resetting by setting the pulley of the grinding attachment over and turning the attachment into a traverse spindle grinder.

Left-hand cutters may be made by this method as well as right-hand. The illustrations show the making of a double 45-degree angle end-mill. Regular angular cutters may be made in the same way by substituting an arbor chuck for the taper chuck being used. The lathe-head index plate is used for the indexing, and as the slide-rest is graduated, it is a simple matter to duplicate the work at any time.

Chicago, Ill. MILTON C. TAYLOR

NOVEL CONSTRUCTION OF APRON MECHANISM FOR SCREW-CUTTING LATHE

The accompanying illustration shows an arrangement used in the apron of a screw-cutting lathe, by means of which only one handle *A* is needed to manipulate the carriage when cutting threads. When one cut is finished it is only necessary to turn handle *A* about one-quarter of a revolution, and the tool is withdrawn from the work. The half-nuts are also unclasped from the lead-screw at the same time, and by pushing handle *A* inwards, the rack-pinion is brought into mesh with the rack so that the carriage can be moved back and another cut begun. To bring the tool back into position, simply pull out the handle and turn it back about one-quarter of a revolution. This both clasps the half-nuts on the lead-screw and brings the tool back to the work.



A Novel Design of Mechanism for Screw-cutting Lathe

When handle *A* is turned, gear *B* turns sector *C*, which is keyed to shaft *D*, on the end of which is cam *E*. The two pins *F* passing through the half-nuts fit in a slot cut in cam *E* and open the nuts. The sector *G* is also turned; this meshes with gear *H*, which is threaded into bushing *J*, fastened to the carriage. Hence, screw *O* is withdrawn and the tool-slide with it. When the half-nuts are opened, sector *C* is in such a position that spring catch *K* only is in engagement with gear *B*. Hence, if this gear is turned further, the catch simply slips so that the handle can be turned around and the carriage brought back with the rack-pinion in engagement with the rack without moving the half-nuts or withdrawing the tool any further. The spring catch *K* fits against pin *M*, so that when gear *B* is turned back it pushes against the catch and brings the sector into mesh with gear *B*, thus closing the half-nuts and bringing the tool in to the work. There are two of these spring catches, one at each end of the sector, so that the carriage can be moved either way, according to whether a right- or left-hand thread is being cut.

In the illustration, the sector is shown in the position it occupies when the nut is closed and the tool is in engagement with the work. In the lower left-hand view is shown a section through the rack-pinion shaft. When the handle *A* is first turned the teeth of clutch *N* are out of engagement with the clutch teeth in the rack-pinion, so that *B* is turned without turning this pinion. When handle *A* is pushed in, however, the shaft and clutch *N* are moved along until the teeth of the clutch engage with the clutch teeth in the rack-pinion. Clutch *N* is fastened to the shaft by pin *R*, and screws *S* hold pinion *P* in position, allowing it simply to revolve on its shaft. When the saddle is moving along when cutting the threads, clutch *N* is out of engagement with the rack pinion, and pinion *P* only revolves. At *T* is shown the slot in the cam for the pins in the half-nuts.

Manchester, England. W. R. OAKES

SYSTEM FOR ALTERING DRAWINGS

In the course of his work in the drawing-room the writer has often had occasion to change large portions of assembly drawings or complicated details. This requires a great deal of time and energy. Below is described a system which has been used to great advantage in cases of this kind.

Suppose that the design of a machine has been changed, which will require the erasing of some details and the drawing of new ones in their places, or making an entirely new drawing, which may not be convenient at the time. First of all make a good Vandyke negative from the tracing; then using a black crayon, mark out every line that is not required in the new drawing, taking care to mark out the lines on both sides of the negative, as otherwise they are likely to show up later. Then make a good black-line print from the Vandyke, using a paper with a smooth surface; this print will now show blank places where the lines were marked out with crayon. Now draw the new parts in ink just the same as if the tracing were altered, and make a blueprint from this black-line print. This will be as good as one made from a tracing. The write print is now filed with the tracings as an original drawing.

One of the chief advantages of this system is that the original tracing is kept intact, and in case it has to be referred to in the future, one does not have to depend on finding an original record-print, but can refer directly to the tracing. From personal experience the writer has found this system to save at least half the time required to change a tracing, and, whereas a tracing can seldom be changed more than once, under this system as many changes as required may be made.

This system is also useful in connection with drawings

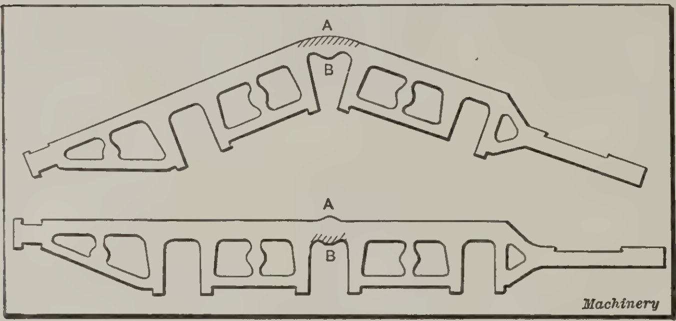
that are changed continually according to specifications. In this case, make the tracing complete in every respect, including dimension lines, but no dimensions. Then make from this a black-line print and fill in on the latter all the dimensions and notes necessary for the shop. Make a blueprint from this print and file the black-line print as a tracing. This does away with the possibility of losing the record-print when marking up blueprints, as is often the case.

Philadelphia, Pa. EDWARD ROBINS GLENN

[See also an article entitled "Changing Drawings Quickly," published in MACHINERY, October, 1907.—EDITOR].

SHORTENING A CAST-STEEL LOCOMOTIVE FRAME

Locomotive frames are usually made of steel castings and weigh from two to four tons each. They are from 25 to 30 feet long, and the top rail has a rectangular section of from 5 by 7 to 6 by 9 inches before finishing. Sometimes, owing to variations in the methods of casting, or improper shrinkage allowance in the pattern, these castings are either too long or too short to true up when machining. It is simple enough to lengthen a frame under a steam hammer, but it is not



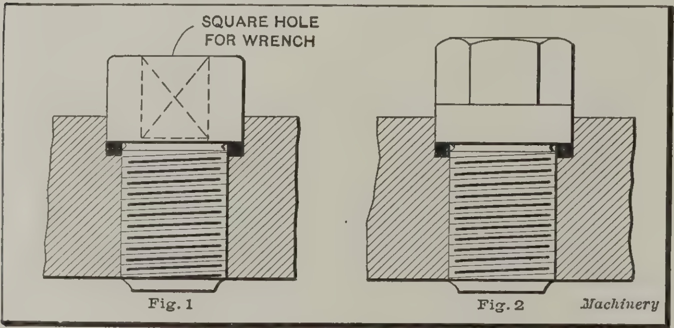
Method for shortening a Cast-steel Locomotive Frame

possible to shorten it by this means. The usual method for shortening a frame is to heat it between two of the pedestal legs, as at *A* and *B* in the illustration; then, by cooling the edge *A* and bending the frame across the anvil, the metal will upset at *B*. The frame is then heated again and cooled at *B*, after which it is straightened. The metal will be upset at *A*, thus shortening the frame. In the two heats a reduction of from ½ to ¾ inch may easily be obtained. It is evident that if the bending were done in the opposite direction, relative to the parts being cooled while bending, the frame would be lengthened instead of shortened.

Rochelle, Ill. J. H. MAYSILLES

AN EXAMPLE OF POOR DESIGN

The designer is often blamed for poor designs when he has done his very best to compromise between the conflicting practical requirements, and between conflicting orders issued



Figs. 1 and 2. An Example of a Poorly Designed Screw for Hydraulic High-pressure Work, and the Design used to replace it

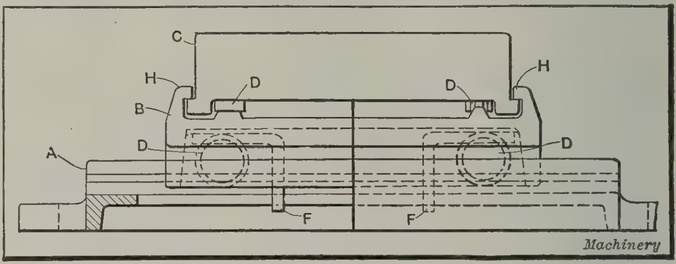
to him. In some cases, however, we find objectionable designs due to either lack of judgment or an effort to unduly reduce the first cost.

An intensifying hydraulic pump failed to reach the desired pressure on account of leakage. The leak was through the stop-screw on the delivery valve on the high-pressure side. With the idea of a quick repair, the screws on the suction side and the high-pressure side were changed. In tightening the leaking screw on the suction side, however, it broke off. The screw was designed as shown in Fig. 1, and the cause of the defect is easily seen. The section of metal at the bottom of the head is very thin and the leakage took place in this square hole in the head of the screw. The screw was replaced with the type shown in Fig. 2, which was made from a solid bar. The screw shown in Fig. 1 was of cast brass, which is objectionable for hydraulic high-pressure work because it is liable to be of a porous texture.

London, England A. L. HAAS

A TAPPING FIXTURE

The accompanying illustration shows a tapping fixture which is easily operated and which can be used for a wide range of work. It consists of a baseplate *A*, bolted to the table of



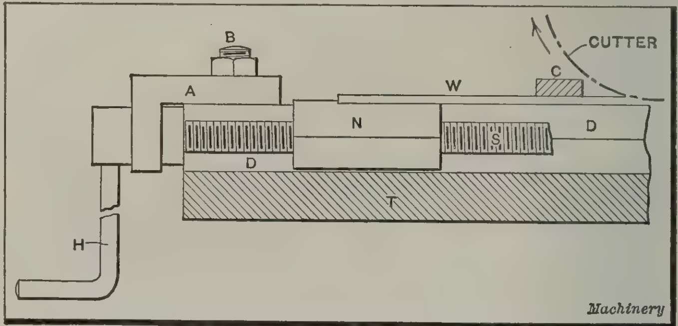
A Convenient Tapping Fixture

a drill press with a tapping attachment, and a center plate *B* and top plate *C*, which are each provided with two plain and two grooved rollers *D*, rolling in tracks at right angles to each other. In this way it is possible to move a piece of work clamped to the upper plate to any position, without having to shift it on the table itself. Stops *F* are provided to prevent the plates from over-running. The overlapping projections *H* are provided so that the plates cannot separate when subjected to pressure.

M. W. W.

MILLING FIXTURE FOR THIN STOCK

About one hundred feet of rectangular-section steel rods was required for a set of models, the section of the steel being 0.088 by ⅞ inch. As this section was not available as a standard size, and as it was impossible to get so small a



A Simple Method of Milling Flat Stock

quantity rolled, it was decided to mill down ⅛ by ⅞-inch drawn steel, which was on hand, to the required size. This was done in a milling machine with the aid of the simple fixture shown in the accompanying engraving. In this illustration, *T* is a section of the milling machine table, through one of the T-slots *D*. The screw *S*, a standard stock part in the shop where this work was done, was provided with a handle *H* and a bearing *A*, which was also a stock part. This bearing was bolted to one of the other slots. The screw when so arranged operated a cast-iron nut *N* the entire length of the T-slot. Nut *N* was provided with a lip or shoulder rising 1/16 inch above the table for the purpose of driving the strip to be milled under the cutter. The lengths in which the flat steel rods were required were slightly less than the travel of the nut, which made this arrangement possible. Two clamps *C*, one of which is not shown, were placed at the front of, and behind, the cutter, and fastened so that the pieces to be milled would just slide under them as the work was being milled. By beveling the entering end of the strip to be

milled on top and feeding the piece lightly until it had reached under the second clamp, which held down the work on the side already milled, no trouble was experienced from the lifting up of the work. Had this occurred it would have been necessary to feed with the cutter. A spiral cutter with nicked teeth was used. Of course, the width of the slot in the milling machine table was less than the width of the strip. In this case the slot was 9/16 inch wide.

Middletown, N. Y. DONALD A. HAMPSON

A FIXTURE FOR SQUARE GRINDING

In the manufacture of high-grade automobiles, the square shaft is replacing the old-style feather key to a very considerable extent, especially in the transmission and heavy driving parts. There are also some parts of the motor in which the square hole and shaft has an advantage; one piece in particular is the valve push-rod, perhaps better known as the

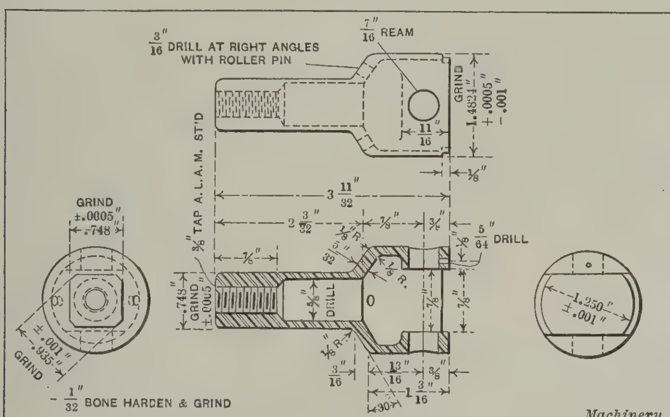


Fig. 1. The Valve Push-rod to be ground

valve tappet, shown in Fig. 1. This push-rod is made from machine steel, carbonized and hardened so that it is necessary to grind all of the working parts. The square part is 0.748 inch across the flats and has an allowable variation of only 0.0005 inch; this requirement, of course, necessitated the making of a very accurate fixture.

The first operation is that of grinding the large diameter, and rough grinding the corners of the square. This is accomplished in the usual manner, that is, by using a long center to enter the bottom of the hole of the large end and an ordinary center in the square end. The next operation is the grinding of the square body which must be perfectly concentric and parallel with the large diameter. The fixture for accomplishing this operation is shown in Fig. 2. It worked successfully, and was quickly and easily operated.

One of the greatest difficulties encountered in grinding fixtures, is that of preventing emery dust from collecting on the working parts, and considerable care was taken to design and make this fixture as nearly dust-proof as possible, regardless of the extra first cost. Another difficulty to overcome was the distance the tailstock was required to travel to allow the push-rod to be removed from the chuck. The size of the square also necessitated the making of a special tailstock, which will be described later. In designing this fixture, the question of future use, as well as that of accuracy and production, was considered. It frequently happens in the manufacture of automobiles that slight changes in the parts necessitate a complete new fixture unless some provision has previously been made. By making new collets, this fixture may be used for many purposes. The entire fixture was made as small and compact as possible. It has been the writer's experience that a neatly designed and well made fixture receives much better care in the hands of the ordinary workman than one that is poorly designed, unhandy and roughly made; and it is upon the care such tools receive that their continued accuracy and usefulness depends.

Referring to Fig. 2, the casting *A* is bored taper to receive the bronze bushing *B*, slotted through on one side to allow for adjustment, which is accomplished by lock-nuts *C* drawing the bushing *B* into the tapered hole in the casting. Spindle *D* has a very important function to fill—that of indexing—and is made from hardened and ground tool steel. To insure the greatest degree of accuracy, the indexing holes in the spindle must be protected from emery dust; consequently, they are placed under cover as much as possible, and are also protected by dust cap *E*, which is made from machine steel and fitted closely on the threaded portion of the spindle *D*. This cap is also closely fitted to the end of casting *A*, the latter having a groove cut in it to receive the felt washer *F*. In the forward end of cap *E* is another felt washer *G*, which in connection with the washer *F* makes it almost impossible for any dust to get into the bearing or indexing holes.

To retain the correct relation of the roller pin hole in the push-rod, Fig. 1, to the square body, the locating plug *H* is fitted into the bushing *I*, which is pressed firmly into the spindle *D* and passes through one side of cap *E* and chuck *J*. As this plug *H* is made to fit closely in the roller pin hole, Fig. 1, it is evident that the hole will be held in the correct relation to the square body.

The chuck *J* is of the ordinary spring collet type, keyed to the spindle *D*, and is operated by the handwheel *K* and draw-in bolt *L* which are held together by tapered pin *M*. Handwheel *K* is also used for indexing the spindle. The front end of the handwheel bears against spindle *D* so that when it is turned in the proper direction, it draws the chuck back into the spindle, thus closing it on the work. Felt washers *N* and *O* are inserted in the dust cap *P*, forming a perfect protection for the working parts in this end of the fixture. The indexing device is of the ordinary spring plunger type and is held in the boss *Q* on the casting. The indexing device consists of a spring *R*, bushing *S*, stop-pin *T*, plunger *U* and knob *V* for operating.

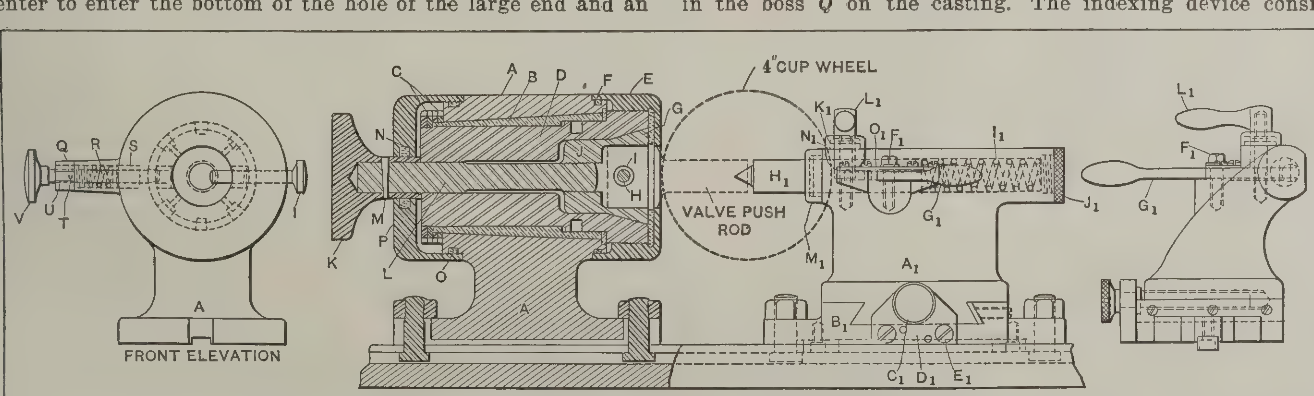

Fig. 2. Fixture used in Grinding the Square Body of the Valve Push-rod shown in Fig. 1

Some difficulty was experienced in obtaining parallel sides on the square body, as the work was performed with a cup grinding wheel on a plain grinding machine (an old style Landis grinder) having no table adjustment. The dovetailed base of the tailstock A_1 shown to the right in Fig. 2, overcame this difficulty and gave good results. The upper part of the tailstock fits in a dovetailed groove in the base B_1 and is adjusted to the desired position by the screw C_1 held in the block D_1, the latter being fastened to the base by screws E_1. The fulcrum pin F_1 is placed in the lever G_1 in such a position that an angular movement of the lever of about 52 degrees gives a 1½-inch lateral travel of center H_1.

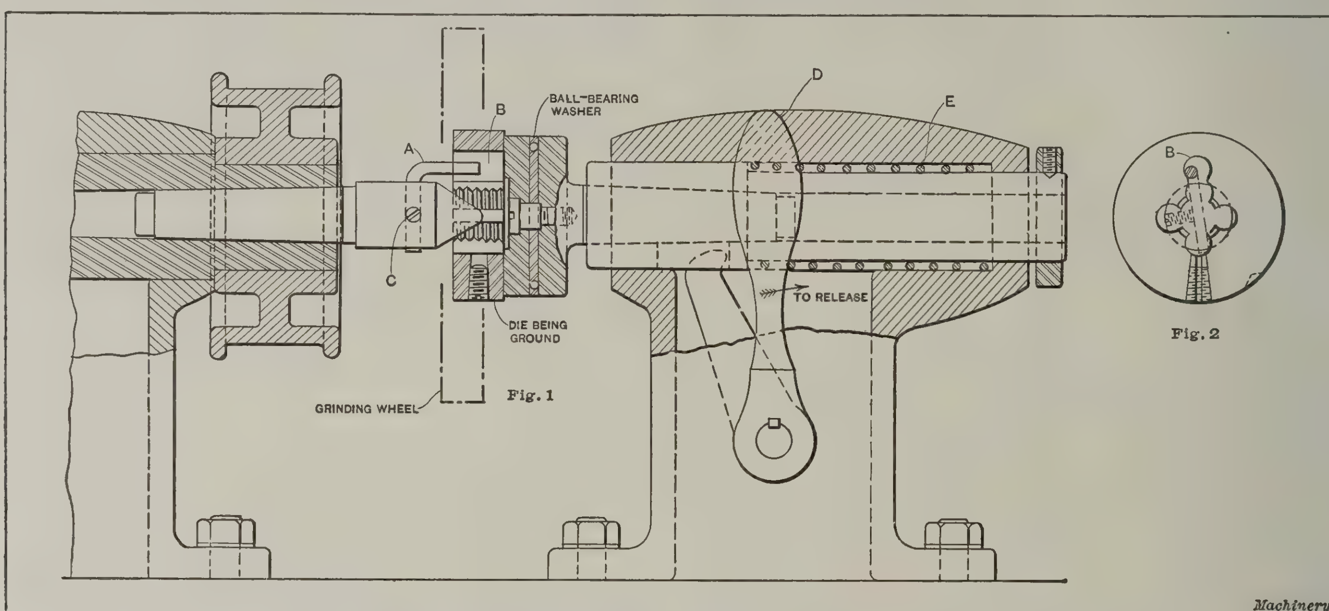
The tension spring I_1 is sufficiently strong to keep the

proper pressure on the valve push-rod, and it is retained in the spindle by a cap-nut J_1. The center H_1 can be locked in any position by clamp-block K_1 and handle L_1. The dust-caps M_1 and N_1 and plate O_1 protect the working parts of the tailstock spindle from dust. As the square body of the valve push-rod to be ground is ¾ inch, it necessitated the flattening of one side of the center bearing in the casting, and also the off-setting of the center point on the movable center H_1. This fixture has been in use for two seasons, grinding about 50,000 push-rods with good results, and is still in good condition.

Lansing, Mich. E. H. Pratt

METHOD OF GRINDING THREADING DIES

The accompanying engraving shows a method which has been successfully used for grinding the outside of threading



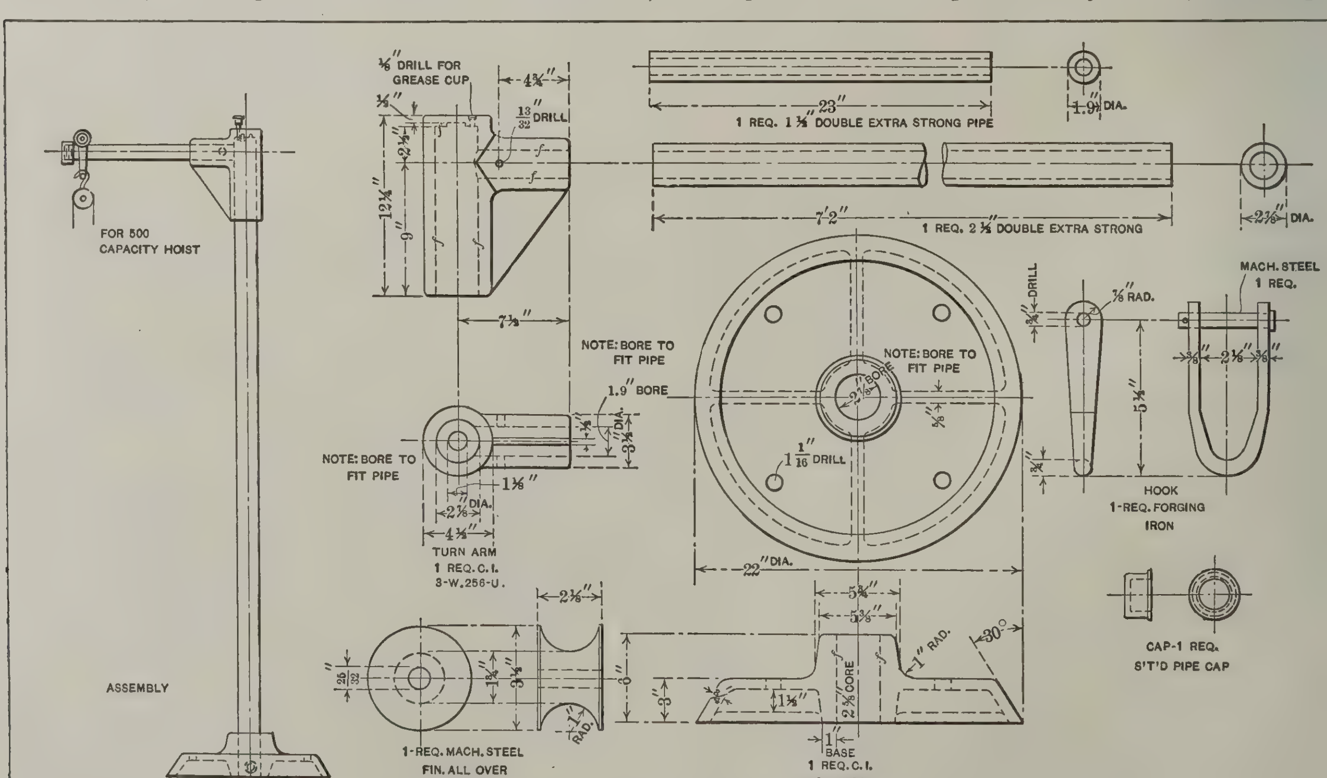
Figs. 1 and 2. Method of Grinding Threading Dies on the Outside after Hardening

dies after hardening. Fig. 1 shows the arrangement with the die in position in the machine, while Fig. 2 shows an end view of the die, indicating how it is driven. The steel wire A, which is about 5/32 inch in diameter and bent so as to enter the hole B in the die, acts as a driving dog. It is held by set-screw C in the center.

When placing a die in the machine, the operator pulls the tailstock center by means of lever D, thus compressing the spring E. With his left hand he then places the die against the driving center and immediately releases lever D, allowing the tailstock pad or center to bear against the die by the action of the spring. The tailstock pad is provided with a ball-bearing washer to eliminate friction. The die is now held in position for grinding. Server

HOIST FOR LATHE CHUCKS, FACEPLATES AND HEAVY WORK

The accompanying illustration shows assembled and detail views of a handy and substantial hoist of cheap construction, which has been found convenient for handling heavy work, large chucks, faceplates, etc., on the lathe. It is bolted to the floor, back of a large lathe, or whatever machine it is used in connection with. It is especially valuable where it is impossible to use a portable or jib crane, and being of



A Handy Hoist for Lifting Lathe Chucks, Faceplates, etc.

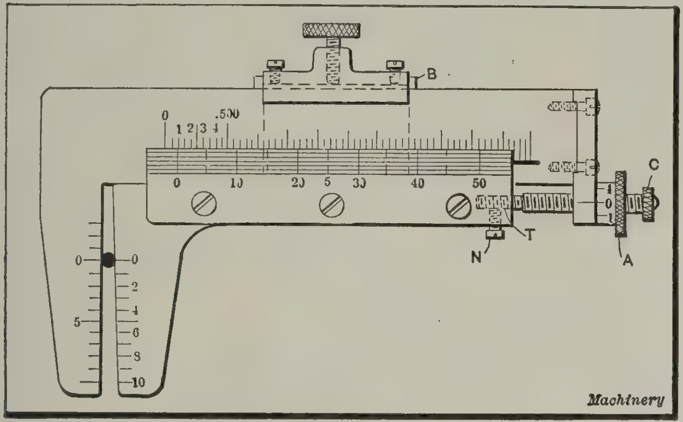
cheap but substantial construction, it can be used for a large range of work.

The hoist consists mainly of two castings, the base and the

bearing for the revolving arm. The upright and arm are of extra strong pipe, and the forged yoke with the steel roller completes the device.
M. W. W.

THE VALUE OF A DECIMAL GAGE

The use of numbers in wire gage measurements may originally have been considered a convenience, but when another "number" gage differing from the original in the sizes designated by the numbers was added, the system became complicated. The basis of these different number gages is that each succeeding number designates a dimension differing by some fractional part of an inch from the preceding one, but each originator of a gage made the difference from each succeeding number different from the others, so that if we now compare the sizes and numbers of the different wire gages we find that no two are alike. There might, in former years, have appeared to be a reason for these different wire gages, with the numbered plates having slots corresponding to a letter or number designating the size of the wire, but since the micrometer and vernier scales have come into more common use, wire manufacturers generally prefer, when an order is given, to have the order specify the diameter of the wire in thousandths of an inch. Then why not discontinue the old gage numbers entirely?



A Convenient Decimal Wire Gage

In a catalogue before the writer, the standard wire gage of a large wire company gives No. 1 as 0.2830 inch; the same company's steel music wire gage No. 1 is 0.0156 inch. The B. & S. jewelers' wire gage No. 1 is 0.001 inch. Why should there be this difference in the designation of the sizes of wire? Whether the wire be brass wire, or music wire, or jewelers' wire, why should not the diameter corresponding to the given number be the same?

Now, why could not a new system be adopted in which, for example, No. 50 would mean 0.050 inch in diameter, and No. 200 would mean 0.200 inch in diameter? The B. & S. jewelers' wire gage is based on this system, and is the only practical system of wire gages in use. Many years ago, the writer made and sold a decimal wire gage to a number of manufacturing concerns based on this system of decimal identification number. This gage, as shown in the accompanying illustration, was adapted for measuring wire from the very smallest size up to 0.500 inch and was especially useful for inspecting wire in the stock-room. It was more easily used on wire than the ordinary micrometer and could be read to 0.00025 inch with accuracy.

This measuring instrument, as shown, has hardened taper jaws, the taper being such that the distance across at graduation 10 is 0.010 inch larger than that at 0; the gage bar is graduated as indicated, each graduation being 0.050 inch. A vernier scale is provided so that measurements as close as 0.010 inch can be read directly on this, and finally the graduations on the taper jaws give the dimensions in 0.001 inch; hence, it is possible to use this gage as graduated to measure wire of any size from 0 to 0.500 inch in diameter. The nut and screw at the right end of the gage are for the purpose of quickly and definitely locating the vernier at the reading required. The screw upon which the locating nut revolves has 20 threads per inch; thus one revolution of the nut agrees with one graduation on the bar.

Assume that it is required to set the gage to read ⅛ or 0.125 inch. First move the sliding jaw so that its zero line is opposite the second line from 0 on the bar, and from that reading continue to move the sliding jaw until 20 on the vernier scale coincides with the nearest line on the gage bar. The reading of the vernier, then, is the 0.120 inch. Now if we insert a piece of ⅛-inch wire between the taper of the measuring jaws we find that it will enter between the jaws until the graduation marked 5 is reached, the desired dimension being $0.120 + 0.005 = 0.125$ inch. Now if the piece inserted should only enter halfway between the 5 and 6 graduations on the jaws, it would be one-half of a thousandth inch too large. If it should enter as far as between the graduations 5 and 4, it would be one-half of a thousandth inch too small.

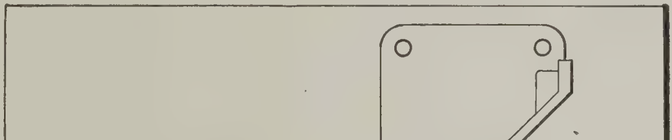
As another example, assume that we first set the zero of the sliding jaw opposite the three-tenths graduation on the bar, then move the vernier scale until line 15 coincides with the nearest graduation on the bar, and insert a wire that would enter between the jaws to the graduation corresponding to 7; the dimension of this wire would then be $0.300 + 0.015 + 0.007 = 0.322$ inch.

The adjusting nut A at the right end of the gage is graduated with five graduations. This makes it possible to set the vernier rapidly and accurately, as each graduation is equivalent to a 0.010-inch movement of the sliding jaw. The screw C on which the nut revolves is stationary and as there is a thread of different pitch at the end T of this screw, an accurate setting for the correct reading of the nut can be obtained. A set-screw N with a brass shoe at its end is employed to bind the adjusting screw in place. The gib B and gib screws on the top of the bar are to hold the sliding jaw tightly, so that it will move without lost motion. The set-screw on the top fastens the slide in the desired position.

Springfield, Mass. FRANCIS W. CLOUGH

MODIFIED FORM OF MILLING FIXTURE

The accompanying illustration shows a knee or angle plate which differs from the average type. Instead of having two flat faces as usual, this angle plate has one flat face, while the other is provided with a V-groove; wings are formed at the edges of the V, and these are planed off so that the knee can be placed with the V-side as a base, whenever flat work is to be clamped to the plain flat face. Lugs are cast upon these wings which are drilled for bolts for clamping purposes. An example of the work for which the fixture is adapted is shown at A in the illustration. Any part having a cylindrical stem and a slot, groove, or keyway cut across the end can be securely held in this plate while milling. Unless the work has a very long stem it can be done better and quicker by using this device than by gripping it in a vise and feeding in a vertical direction.



Modified Form of Angle Plate and Type of Work for which it is adapted

Middletown, N. Y. DONALD A. HAMPSON

SHOP RECEIPTS AND FORMULAS

A DEPARTMENT FOR USEFUL MIXTURES

This page is intended to be used only for the publication of such shop receipts as the contributors know from experience to be practicable. Receipts are solicited on the condition that the contributors personally know that they are reliable. The fact that a receipt is old and supposedly well-known does not bar it, provided it has not already appeared here.

HIGH-PRESSURE HYDRAULIC JOINTS

When oil is the fluid conveyed in a high-pressure hydraulic pipe line, glue makes an excellent material for applying to the threaded pipe connections, caps, etc. It will set and become hard very quickly. It is necessary to have the parts clean before the glue is applied.

Toronto, Canada. J. CRANFORD SMITH

HARDENING SOLUTION FOR NOVO STEEL

The following receipt for hardening "Novo" and "Novo Superior" steel will be found useful: To one quart of kerosene oil add one pound of table salt, thus making a saturated solution. Heat the steel to a bright cherry red, rub cyanide of potassium on the parts to be hardened and heat again to a bright cherry red. Then dip the steel into the solution until cold.

Bristol, Conn. IRVING E. SCHUBERT

ENAMEL FOR INSULATED WIRE

The following is a satisfactory solution for coating wire with an enamel insulation. It consists of seven parts by weight of tri-acetyl-cellulose $[C_6H_7\ (C_2H_3O)_3\ O_5]$; ninety parts chloroform ($CHCl_3$); and three parts phenol (C_6H_5OH); thyme (a compact under shrub); and castor oil, added as a softener. This solution can be saponified, though not very easily, by a solution of potash. It can be more readily saponified, however, by the use of alcoholic potash. This enameling solution is much less inflammable than celluloid. It is colorless, but can be rendered visible by adding an aniline dye.

Pittsburg, Pa. H. M. NICHOLS

CEMENT FOR FILLING HOLES IN CAST IRON

The following is a good mixture for a cement for filling holes in cast iron, and may be well known to many: powdered cast iron, 40 parts; powdered sal-ammoniac, 1 part; powdered sulphur, ½ part. These ingredients are thoroughly mixed together and placed in an air-tight receptacle in a perfectly dry condition until wanted. When a hole in a casting is to be filled, take what appears to be the required quantity of the mixed powder, moisten it with water to the consistency of paste or putty, and fill the hole or depression, smoothing it up and allowing it to set.

When very deep depressions are to be filled, add to the above mixture an equal weight of fresh "vulcanite" Portland cement before dampening. After the water has been added, so that the mixture has the desired consistency, add non-volatile oil to the extent of 8 per cent by weight of the dry mixture used, and work the mass until the oil is fully emulsified; then apply the paste, finishing with a facing of the original mixture containing no Portland cement. This will produce a filler which will not shrink in setting.

St. Louis, Mo. C. H. CASEBOLT

OILS AND FATS AS HARDENING MEDIUMS FOR STEEL

Oils and fats produce, as a rule, less hardness in steel than does water. The hardness which they produce is usually accompanied by toughness. Thus such tools as are liable to crack in hardening, and where the greatest possible hardness is not required, are usually hardened in oil or fat. According to the *Metallarbeiter*, petroleum hardens more sharply than any other oil; then follows glycerine, which is too little known in this connection; then the lighter mineral oils; and at the foot of the list come the vegetable oils, as, for example, linseed oil. Among the fats, melted tallow and whale oil are the most used, the former giving a greater degree of hardness than the oils.

No matter what substance is used, however, one must not lose sight of the fact that there must be sufficient of it to permit the article being hardened to be moved quickly to and fro in the hardening medium, just as when water is used, so that the bath will not get hot. In most cases there is usually too little oil employed; the lack of success is then attributed to the use of the oil or fat, instead of to the fact that too little of it was used. R. G.

PRODUCING A BLUE COLOR ON NICKELED STEEL

By the use of the well-known bath of hyposulphite of soda and acetate of lead it is possible, by simply dipping, to produce a blue color on various metals. This is used for the purpose of producing an imitation steel finish on different metals. As is well known, the action is very satisfactory, and the articles thus treated look exactly as though they were made of steel that had been blued by annealing. Although this color can be produced on all metals, it is best brought out on nickel and nickel-plated articles. The brilliant white color of the nickel constitutes a good background for the thin blue coating; and for this reason the color is especially lively.

If this blue color is to be produced on unpolished nickel, it is recommended to color directly after plating, in order to prevent the surface getting spotted. With polished nickel, great care must be taken in cleaning. For this reason it is desirable to rub the nickel with rouge (crocus powder), as this can be readily removed from the metal and contains less mineral oil than "Vienna chalk."

For those who do not know the dip process thoroughly, it might be stated that the liquid for producing the blue color consists of 226 grams (8 ounces) each of sodium hyposulphite and lead acetate, and nine liters (8 quarts) of water. The solution is used boiling hot. The color is first yellow, then purple, and at last blue. When the right color is obtained, the articles are rinsed and dried, and then lacquered—otherwise the color will fade.

Dresden Germany. ROBERT GRIMSHAW

THE CHEAP BLACKENING OF BRASS

The following solution for blackening brass is nothing new; in fact, it has been known for a long time. Owing to its cheapness, ease in working and adaptability for many purposes, it has been deemed advisable to bring it again to notice, Many platers, of course, will recognize it as an old solution known to the plating industry for many years, but they may not have realized its advantages for some classes of work. The solution is made as follows:

Water	1 gallon
Sugar of lead	8 ounces
Hyposulphite of soda	8 ounces

The solution is used as hot as possible and the brass work, is simply dipped in it and allowed to remain until black. This takes about a minute or less. The articles are then rinsed in cold water, then in hot water and dried. If scratch-brushed dry, the black deposit will have a high luster.

When dipped into the solution, the surface of the brass article becomes yellow, then blue and finally black. The article should not be taken out until all the surface has become blackened. The deposit on it is sulphide of lead. The articles should always be lacquered as the black deposit is likely to oxidize and fade if not; but if coated with lacquer, it seems to be quite permanent.

For a cheap class of goods that require a black finish, this solution can frequently be used to a good advantage. It requires no electric current, being used as a dip. The color, to be sure, is not coal black, but resembles a graphite black more than anything else and has a slight gray shade. It is sufficiently black, however, to answer many purposes and it is so easily applied that it can be used on cheap goods with only a slight increase in cost.—*Brass World.*

Always provide some means for holding bolts from turning while the nuts are being screwed on, if a wrench cannot be used on the head of a bolt.

SHOP KINKS

PRACTICAL IDEAS FOR THE SHOP AND DRAFTING-ROOM

Contributions of kinks, devices and methods of doing work are solicited for this department. Write on one side of the paper only and draw sketches on separate sheets.

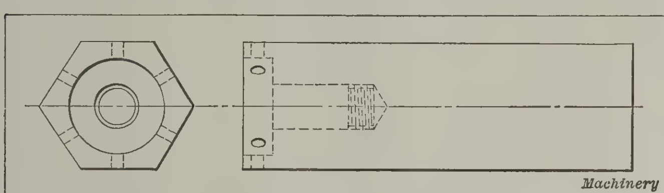
MARKING ON BLUEPRINTS

The most simple and at the same time probably the most effective method of marking on blueprints is to use a common soap-stone pencil, similar to those used in machine shops and tool-rooms. The end of the pencil should be ground to a sharp point on an emery wheel. Lines and letters made in this manner cannot be distinguished, when first made, from those originally on the blueprint, and will stand an almost indefinite amount of wear before becoming obliterated.

Indianapolis, Ind. F. B. HAYS

A SIMPLE DRILL JIG

On a number of special capstan-head screws, six holes were to be drilled, as indicated by the illustration, which shows the jig used for the drilling operation. This jig was made from a piece of hexagon steel rod. Instead of tapping out

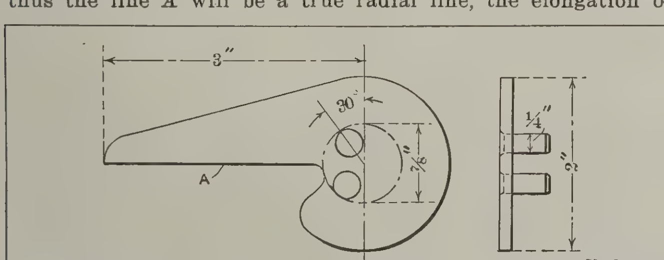


the full length of the hole for the screw, only a few threads were cut at the bottom, which saved time in handling the product to be drilled. In this instance the heads of the screws extended far enough out of the jig so that they could be turned by hand. This jig was casehardened and has proved itself good for long service. Jigs of this type are quickly made, and the cost is so small that even for experimental work it often pays to make such a jig.

Middletown, N. Y. DONALD A. HAMPSON

MILLING CUTTER TOOTH TESTING GAGE

The gage shown in the accompanying illustration is intended for testing the radial direction of the faces of formed milling cutters, especially gear tooth cutters. The two pins shown bear on the inner side of the hole in the cutter, and thus the line *A* will be a true radial line, the elongation of



which passes through the cutter center. Gear cutters should be tested, from time to time, with this gage to make sure that the faces of the teeth are in a radial direction, as, otherwise, the shape of the gear tooth being cut will not be an exact duplicate of the original gear cutter form. J. S. B.

REPAIRING LATHE CHUCK SCREWS

The square heads of chuck-jaw screws sometimes become so badly worn that their keys will no longer fit them, and it becomes difficult to use the chuck. To order a new screw sometimes means quite a delay. The writer has used the following method successfully: Remove the jaw, take out the screw and heat it to a cherry red; then, with a few sharp blows, upset the square end of the screw until it is large enough to file to its original size; take care not to injure the threads of the screw during this operation. Then file the head of the screw to fit the chuck key. After hardening, the screw is as good as new. W. H. ADDIS

Lafayette, Ind.

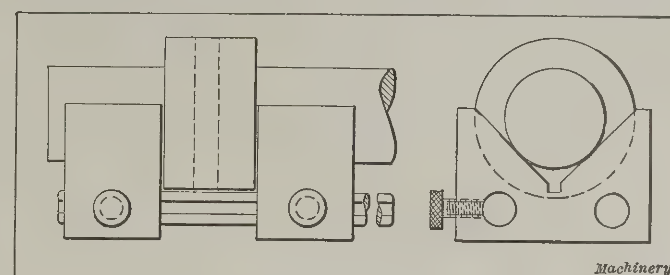
LATHE FILE HANDLES

The writer generally saves all ends cut off from new belts and cuts them up into pieces, about 1¼ inch square, into which he drills a hole, about No. 40, ⅝ inch deep. These pieces are used by the tool- and die-makers when they want a handle for a small file. Usually they drive a piece of leather onto the file tang and then shape it to suit their requirements. The toolmakers prefer these to wooden handles.

St. Louis, Mo. JAMES S. GLEW

CONNECTED V-BLOCKS

The accompanying illustration shows two uniform V-blocks which are connected so as to be used as one unit. Blocks so

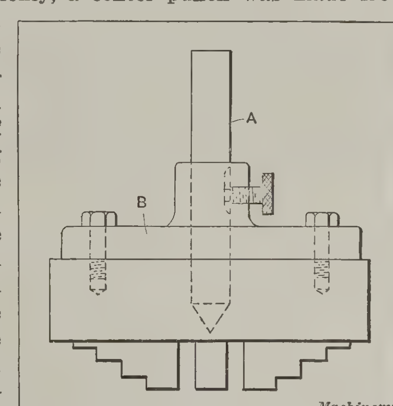


connected are handy for work of the kind shown in the illustration; in fact, they form a very effective jig, or rather jig replacer.

Manchester, England FRANCIS W. SHAW

AN ACCURATE CENTER PUNCH

The writer had a number of different sizes of rods to center, and to do this work quickly, a center punch was made from a three-jaw universal chuck, as shown in the illustration. A faceplate *B* was made and bolted to the back of the chuck, for carrying the punch *A*. In one side of the center punch a flat was milled for the end of a screw which prevented the punch from dropping out. The chuck was set over the end of the shaft, and the jaws were tightened with a chuck wrench, and then the punch struck with a hammer. This method of centering was very quick and accurate.



Superior, Neb. J. N. BAGLEY

CUTTING COARSE INTERNAL THREADS IN THE LATHE

In cutting coarse internal threads with a cutter held in a bar which is clamped rigidly in a fixture fastened in the T-slot of the compound rest, it is impossible to have the cutter cut one side of the thread at a time. To accomplish this result, engage the split nut on the lead-screw to the full capacity of its engagement for a few cuts; then engage the nut a little less than full, holding it there by the hand so that the carriage will lag a little behind the previous cut. Continue doing this for a few cuts, and then engage the split nut to its full capacity, and so on. Lead-screws which are provided with an Acme thread allow the accomplishment of this "trick" without any trouble.

It might be considered bad practice to only partially engage the split nut, because of the uneven wear on the nut and screw, but this does not seem objectionable to me, as the engagement is so nearly full that the consequent wear is very slight. In the general run of shop work, nuts having a coarse thread to be cut are the exception rather than the rule, so that this kink would not be frequently employed.

Los Angeles, Cal. JOHN A. WOOD

HOW AND WHY

DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST

Give details in full and name and address. The name and address will not be published with the answer.

CAVEATS NOT GRANTED BY PATENT OFFICE

F. A. G.—Are caveats no longer granted by the United States Patent Office?

A.—Section 4902 R. S., authorizing the filing of caveats for inventions was repealed by act of Congress June 25, 1910, the new law taking effect July 1, 1910. Since this date there has been no provision of law for the filing of a caveat in the United States Patent Office, and it is no longer permissible for an applicant to file a caveat for the purpose of obtaining further time in which to mature his invention.

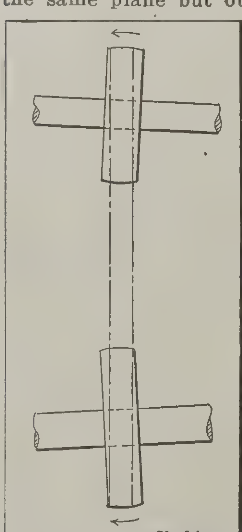
ALLOWABLE SHAFT DEFLECTION FOR GEARING

D. E. W. Co.—In calculating the size of shafts carrying gears how much should be allowed as the maximum permissible deflection? We are unable to find anything printed on this subject that is at all satisfactory and we are therefore appealing to you. Any information that you can give us on this subject will be very much appreciated.

A.—None of the available authorities specifies the allowable shaft deflections for gearing. The general rule is to mount all gears close to the bearings so as to minimize the bending moment, and most designers apparently proceed on the assumption that the deflections are negligible when the shafts are sufficiently strong to stand the torsional stresses and the gears are mounted close to the bearings. Data from practice followed when gears are not set closely to the bearings is requested.

WHY BELTS RUN TO THE HIGH SIDE OF PULLEYS

T. J. C.—It is common experience noted by all mechanics that an open belt running over pulleys mounted on shafts in the same plane but out of parallel, runs to the "high side." Why is this so?



Illustrating the Tendency of Belts to run to the High Side of Pulleys

A.—A belt runs to the high side of the pulleys because of the direction of motion of the parts of the belt between them. As the free part of the belt winds onto the leading side it tends to follow the same line of motion around the pulley face, and if the shafts are out of parallel the belt path becomes at first a helix which if continued would run off the pulley on the high side. The illustration of an exaggerated case shows the belt leading to the left or high side of the pulleys, the edges of the belt being projected in a straight line to emphasize the drift to the side. When the pulleys are crowned, the crowning counteracts the tendency of the belt to run off unless the shafts are badly out. The crown of the pulleys, by the way, acts in the same manner on both sides of the belt when the shafts are parallel. Both sides of the belt crowd toward the center which is the highest part of the pulleys, and it is thus that crowning prevents belts running off the pulleys.

SOLUTION OF A TRIANGLE

F. B.—In the triangle shown in the accompanying illustration, angle A and side b are known. It is also known that the length of side a is to the length of side c, as 10 is to 8. What is a simple method for solving this problem? I have looked for a solution in various textbooks in vain.

A.—The sides of a triangle are to each other as the sines of the angles opposite the respective sides. Hence, in the triangle shown,

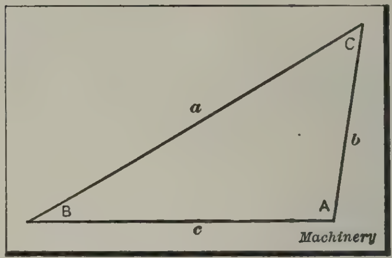
$$\frac{\sin A}{\sin C} = \frac{a}{c}$$

From this we get

$$\sin C = \frac{c \sin A}{a}$$

but, as

$$\frac{a}{c} = \frac{10}{8}, \text{ we have } \frac{c}{a} = 0.8$$



Solution of a Triangle

and, therefore, $0.8 \times \sin A = \sin C$. The angle A being known, angle C is thus determined, and the triangle is solved in the same manner as any triangle in which one side and the angles are known. (See MACHINERY's Reference Book No. 54, "The Solution of Triangles," page 49.)

METALS USED FOR STEAM TURBINE BLADES

In an article in *La Technique moderne*, M. P. Breuil deals with the metals used in the construction of steam turbine blades, the data given referring to continental European practice. In the Zoelly turbine, blades made from 5 per cent nickel steel are used, while Harlé & Cie. prefer steel with 32 per cent nickel. The advantage of this steel, however, might be considered doubtful, as Rateau has found steel with 25 per cent nickel unsuitable for turbine blades. The opinions of French manufacturers of special steels differ widely as to the contents of nickel. It does not seem as if the influence that nickel has on metal used for turbine blades has been fully investigated, and there is considerable uncertainty as to the behavior of the metal in a turbine blade. The bronzes, as well as the monel metal, which are used for turbine blades by some of the manufacturers, soften considerably at temperatures above 570 degrees F., and have a relatively low elastic limit, but they have the advantage of being but little affected by corrosion.

Attention is further called to the fact that on the side of the admission of steam the first blades work in high temperatures, with dry steam at great velocity; the blades further back are subject to lower temperatures and lower velocities of steam, but the steam is wet, and there is, besides, the friction of metal particles carried away by the steam. The guide blades are stationary, and are not subject to the action of centrifugal forces like the rotor blades. It appears, therefore, that different metals ought to be used for each of these three classes of blades, but in all cases the metal used must possess great resistance to chemical and mechanical corrosion, and be easily machined by ordinary shop processes.

As to the chemical corrosion of metals by hot steam there are practically no reliable data. From investigations of the action of salt water on metals it would appear that aluminum and manganese bronzes and monel metal would give good results, but it is quite possible that chemical corrosion is altogether very slight as compared with physical, and the material used ought to be chosen on the basis of resistance to the latter, with respect to which nickel steel appears to have very high qualities, with its breaking strength of 80,000 pounds per square inch, elastic limit of 57,000 pounds per square inch, hardness (Brinell) of 180, and elongation of 20 to 22 per cent. It is, moreover, naturally hard, not brittle, and comparatively cheap. There are no data as to its probable behavior at high temperatures, but having a low percentage of nickel it would probably behave like other steel, and would reach the minimum of its elastic limit and elongation at about 570 degrees F., without, however, becoming brittle. The firm of Wickers Maxim makes turbine blades of laminated bars with a steel core and nickel surface, the nickel layer being extremely thin.

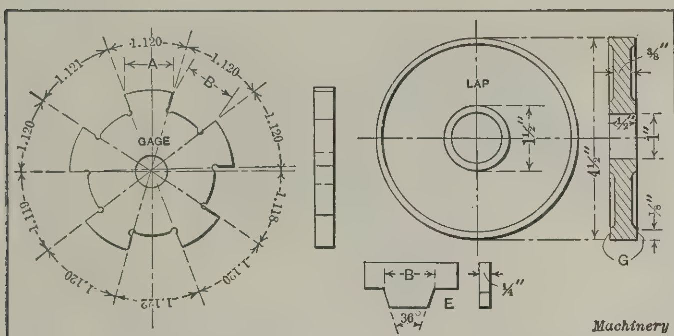
* * *

As an example of the importance of having the walls of shops and factories painted in light colors in order to increase the light in the workroom, it may be of interest to note that in one case where the intensity of the illumination in a saw-tooth roof building was 9.7 foot-candles in the center of the building, it was 13.5 foot-candles at a distance of three feet from the whitewashed walls, showing an increase of nearly 50 per cent due to reflected light from the walls.

MAKING A HUB CLUTCH GAGE

BY J. M. HENRY

In the following article is described a successful method for making a hub clutch gage of the type illustrated in the accompanying engraving. The first difficulty met with is that of distortion in hardening, which, however, may be overcome by using "Ketos" or "Paragon" oil-hardening steels, in which case it is possible to machine the gage to within 0.002 inch of the finish size, and finish it by lapping. For the lapping, a disk lap is used, and the operation is performed in a milling machine.



The Gage to be lapped, the Disk Lap, and the Templet

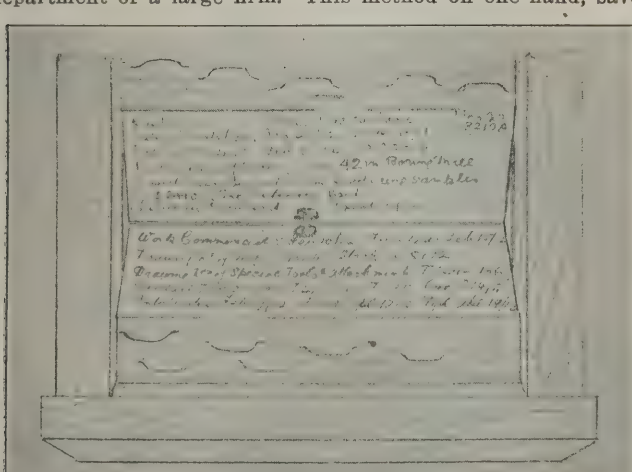
The disk lap is turned as shown in the engraving, and placed on an arbor in the milling machine. It is trued up on the sides *G* to insure its running parallel with the ways so as to be completely in contact with the work. The gage is then mounted on the index centers and one side of the lap is set central with it. The blank is indexed around until it just touches the lap, a sounder being used to determine when this takes place. The lap is now charged with emery and oil, the machine is started, and the gage rapidly passed by the lap a number of times. After having lapped the first surface, the gage is indexed around to the next lug and the operation repeated, thus continuing around the gage until having lapped one side of the lugs. The opposite side of the lap disk is then set central with the gage, and the gage indexed around the opposite way until the other side of one of the lugs touches the lap, after which the lapping is continued until the dimension *A* is correct on all the lugs. A templet *E* is used, from time to time, to test the accuracy of the spacing.

* * *

UTILIZING BOTH SIDES OF INDEX CARDS

BY CARD INDEX

The accompanying illustration shows how both sides of the cards used in a card index were utilized in the tool-designing department of a large firm. This method on one hand, saved



Card Index, in which Both Sides of the Cards are utilized

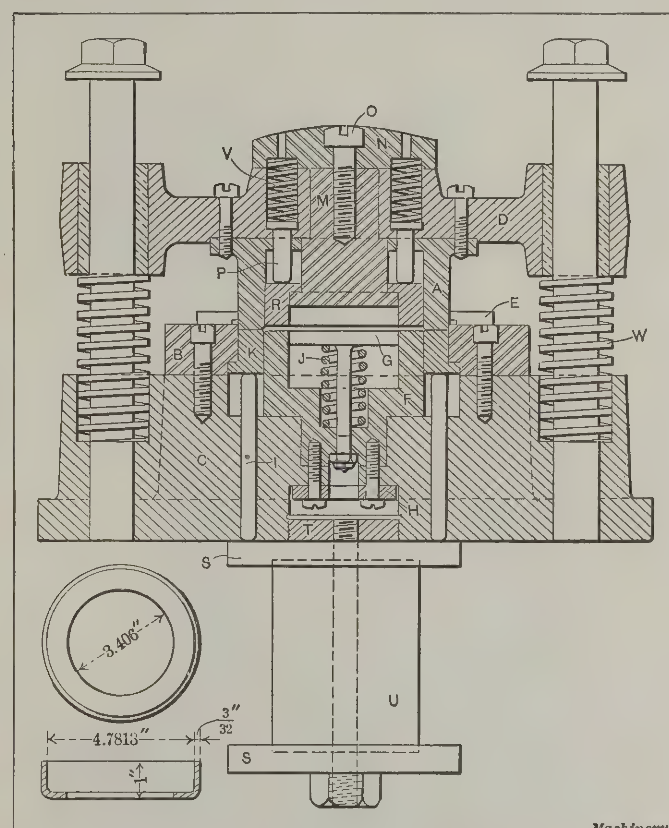
extra cards, and on the other, made it possible to record all the necessary information relating to each item on one card. On the back of the card the information was entered upside down so that when the cards were pressed towards the front of the drawer, the information entered could be easily read. In the engraving two separate cards are shown for convenience, but it is understood, of course, that all the information pertaining to one subject is entered on the two sides of the same card.

A COMBINATION DIE

BY A. J. DUDLEY

The shell shown in the lower left-hand corner of the accompanying engraving is a retainer for the ball races of an automobile clutch. This retainer is a sheet-metal stamping made in a powerful trimming press having a 5-inch stroke. The style of die used is a combination die which produces the shell complete in one operation within the limits of tolerance required—0.001 inch for all dimensions except for the height of the shell. The blank for the shell is approximately 6⅝ inches in diameter. The material is hot-rolled steel, 3/32 inch gage, fed into the die in the form of a strip.

In the illustration, *A* is the blanking punch and drawing die, made of tool steel, hardened and ground; *B* is the blanking die which is secured to a cast-iron die-block *C*. A stripper *E* is secured to die *B* by screws (not shown). The drawing punch, and die for the center hole in the shell, is shown at *F*, and the retaining plate for this punch at *H*. Punch *F* is also made of tool steel, hardened and ground. A knockout *G*, op-



A Combination Blanking and Drawing Die and Work for which it is used

erated by a helical spring *J*, ejects the waste center blank. Some difficulties were first experienced with this knockout owing to the sticking of the blank, but this was overcome by placing a small knob in the center of the knockout (and a corresponding recess in the face of punch *M*) which deflected the blank enough to prevent it from sticking. Punch *M* does not operate until nearly at the end of the stroke. At *K* is shown the shell stripper which also acts as the spring pressure pad during the drawing operation. This is supported by four pins *I* resting upon the flange *S*. A powerful rubber spring *U* effects the stripping of the finished shell from punch *F*.

Another pressure pad and stripper is provided at *R*. It is supported by pins *P* and helical springs *V* and bottoms on the inside flanges of punch *A*. The buffer plate *N* acts as a retainer for punch *M* and is provided with vent holes to release the air pressure produced by pins *P* and pad *R*. Heavy square helical springs *W* open the die after each stroke, the rubber spring *U* assisting in this operation during part of the stroke.

Owing to the limited height available between the bolster plates of the press, it was impossible to use an adapter—hence, the necessity for spring operation. The die has worked successfully for several months, but it has been found necessary to lubricate it copiously when in operation.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

COCHRANE-BLY UNIVERSAL SHAPER

Diemakers and toolmakers are often obliged to use a number of machines for making a die or jig, especially if the shape is at all complicated or irregular. This means that the work must be reset in each machine, which not only requires extra time but often makes it difficult to secure accuracy between the different surfaces, thereby increasing, in many instances, the amount of hand work necessary for fitting and finishing. The Cochrane-Bly Co., of Rochester, N. Y., is now manufacturing a universal machine that has been designed to perform quite a variety of operations at one setting of the work; therefore it is especially adapted to the making of dies, jigs or to general tool-room work. This machine is known as a universal shaper, but, in reality, it is a shaper, slotter, milling and drilling machine combined.

Fig. 1 shows a view of the right-hand side and Fig. 2 the left-hand side with the circular table in position. This machine consists principally of a column supporting the knee and table, a shaper ram, a milling and drilling spindle, and suitable speed- and feed-changing mechanisms. The milling spindle and shaper ram have universal adjustments so that tools can be presented to the work at any desired angle. Fig. 4 shows the heads in a vertical position drilling a die, and Fig. 3 shows the shaper ram set in a horizontal position.

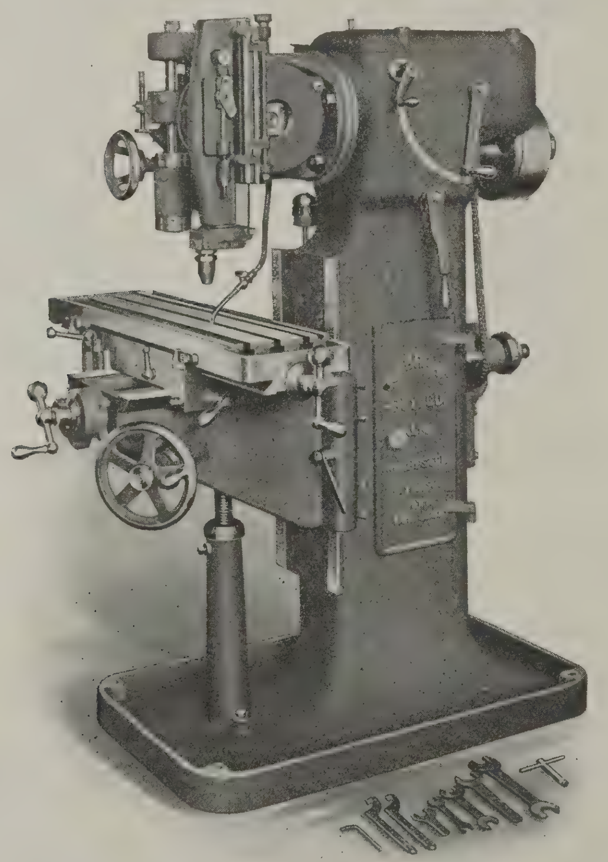


Fig. 1. Combined Universal Shaper and Milling Machine for Die, Jig and General Tool Work

The drive is from a constant-speed clutch pulley at the rear; this transmits the power through a double cone of spur gears to the main head, which carries bevel gears for driving both the shaper ram and milling spindles. The cones of spur gears provide means for varying the speeds, and their arrangement is shown by the sectional view, Fig. 5. The speed changes are effected by means of a driving key A which is shifted into engagement with any one of the five upper gears, thus giving five speed changes for the shaper ram and milling spindle. The position of this key is controlled by the large lever seen in Fig. 1 near the top of the column. The end of this lever swings around a graduated quadrant which shows the number of ram strokes per minute for any one of the five positions. The key in the gear cone, as well as the gears and shafts, is hardened, and all bearings are provided with bushings. The clutch pulley, when idle, runs on roller bearings, and the clutch is engaged or disengaged by the vertical lever seen at the side of the column in Fig. 1.

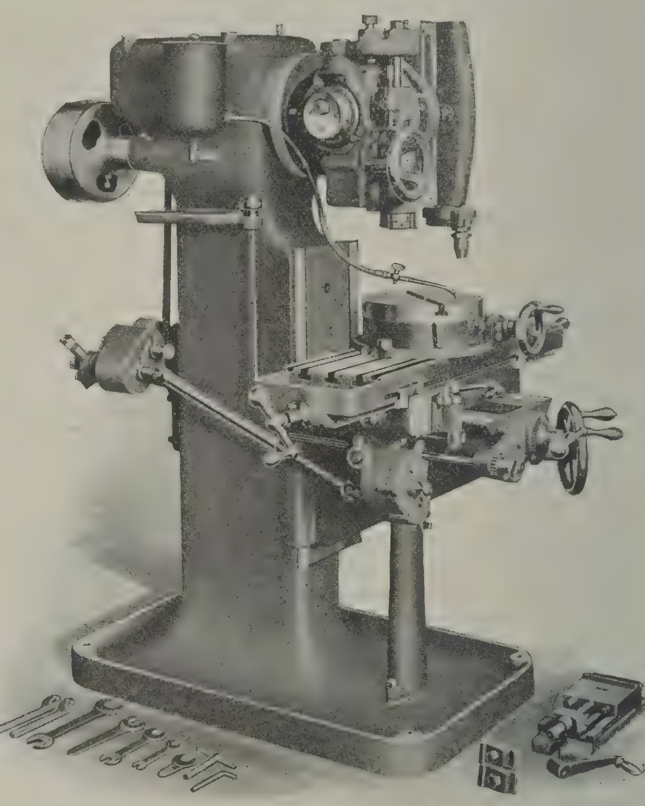

Fig. 2. Universal Shaper equipped with Circular Table Attachment

The main head has a bearing in the column and is locked in position by three bolts which engage a circular T-slot. The entire head, including the shaper ram and milling spindle, can be revolved about a horizontal axis (after loosening the clamping bolts) by turning a small crank which is located at the upper end of the graduated quadrant previously referred to (Fig. 1). This crank operates the worm B, Fig. 5, which,

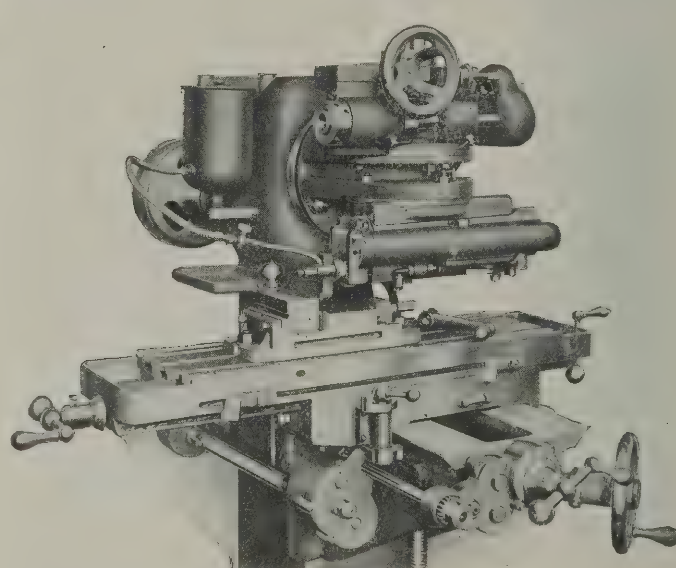

Fig. 3. Shaper Ram set in a Horizontal Position

in turn, engages a worm-wheel attached to the inner end of the main head. The shaper and milling heads each have an independent adjustment about an axis at right angles to the main head, which makes it possible to locate them at any angle. All three heads have large circular bases which are graduated to degrees.

The milling spindle is driven by bevel and spur gears from the main head and runs either right or left. It has a slide movement of 3½ inches for drilling and boring, which is controlled by a handwheel operating through worm-gearing. A micrometer screw-stop, reading to thousandths of an inch, is provided to facilitate accurate adjustments. The spindle is fitted with taper bronze bushings and adjusting collars to take up wear.

The shaper ram is driven through bevel gears and a crank-and-link mechanism. It has a quick return and the stroke can be adjusted from zero to six inches. The tool-head of the ram swivels and can be set to work at any angle. The ram is equipped with a mechanism (illustrated in Fig. 6) which provides a positive relief for the tool on the upward or return stroke. The clapper is held firmly against the tool-head during the cutting stroke by means of a knuckle-joint mechanism, and it is released at the end of the stroke by a relief dog, which strikes the lower roll or tappet shown in the illustration. The clapper remains in the released position on the return stroke and it is thrown into the working position again when the dog engages the upper roll. These rolls are adjusted for any length of stroke by means of a right- and left-hand screw which is turned by a knurled knob at the top.

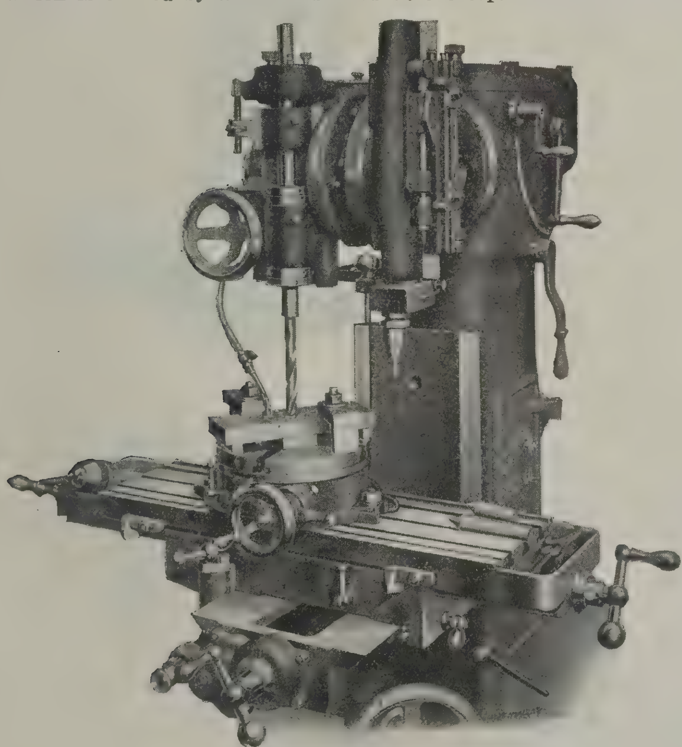

Fig. 4. Drilling a Die with Milling Spindle

Power feed is provided for the longitudinal and transverse movements of the table and also for the circular table, if desired. The feeding motion is derived from a sprocket *C*, Fig. 5, which is connected by a silent chain with the feed-box, seen at the rear in Fig. 2. From this point the motion is transmitted to the front of the machine by a universally jointed, telescoping shaft in the usual manner. When the milling spindle is being used, the feed is continuous, whereas an intermittent feed, which takes place on the return stroke, is required for the shaper ram. Either a continuous or intermittent feed is obtained from the rear feed-box, which is shown in detail in Fig. 7. For a continuous feed, the drive is through spur gears, and for an intermittent feed, a crank-and-ratchet mechanism is brought into action, provision being made for disengaging either the gear or crank mechanisms.

Tool-holders for various styles of shaping tools are interchangeable in the tool-head. Three forms of tool-holders are illustrated in Fig. 8, which also shows a set of standard slotting tools such as are carried in stock by this company. The slotter tool-holder *A* takes all shapes of slotting tools having 3/8-inch square or 7/16-inch round shanks, and it is used when shaping out small dies, for broaching and for cutting

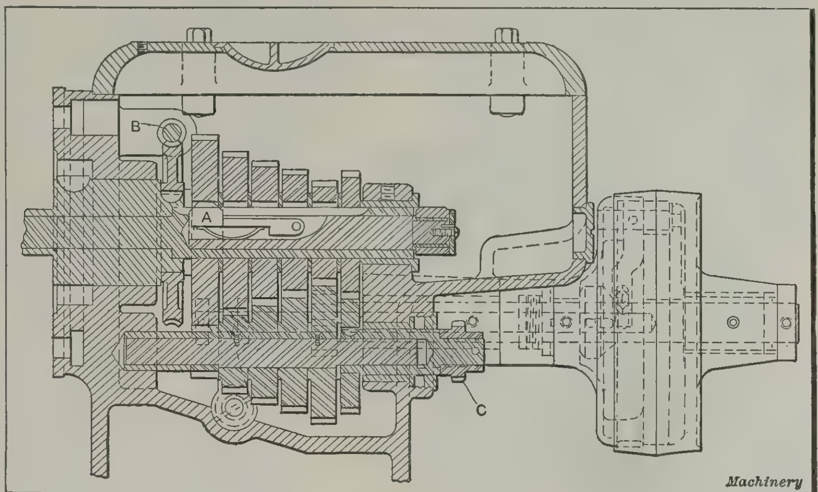

Fig. 5. The Constant-speed Clutch Pulley and Speed-changing Mechanism

internal keyways, etc. The shaper toolpost *B* holds lathe or shaper tools of ½-inch or ¾-inch size, and is used when the machine is working either as a horizontal shaper (as shown in Fig. 3) or as a vertical shaper. The extension holder *C* takes ⅜-inch square bits and can be used for inside or outside shaping operations.

The table of this machine has a working surface of 28 by 9 inches and there are three ⅝-inch T-slots for clamps. The feed-screws are accurately cut and are provided with ball thrust bearings. There are also compensating nuts for taking up wear and large graduated dials reading to thousandths of an inch. The saddle has a bearing on the knee 12 inches wide, and provides a way 18¼ inches long for the table. Both of these slides are fitted with taper gibs. The saddle carries the feed mechanism and the feed-control handle is mounted at the front. The knee has a bearing 10 inches wide and 13½ inches long on the column, and is fitted with an adjustable gib and locking screws. The thrust on the elevating screw is taken by a ball bearing. The circular table is 12 inches in diameter and is furnished with or without power feed. It is graduated in degrees and is revolved by a handwheel, the dial of which reads to five minutes. Provision is made for disengaging the worm-gear, when it is desirable to revolve the table quickly by hand. The column is cast in one piece and has sufficient metal to absorb all vibration. The head of the column containing the driving and speed-changing gears, forms an oil-tight box so that these gears run in a bath of oil.

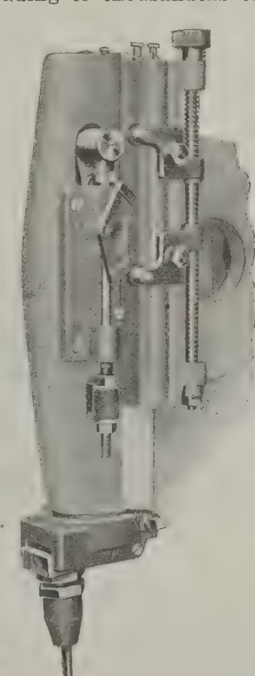

Fig. 6. Detail View of Shaper Ram showing Relief Mechanism

The machine has been designed throughout to provide convenient operation, all control levers being within reach of the operator from the front of the machine. The durability of the construction has also received careful consideration, the spindles, shafts and driving gears being hardened and all bearings bushed. While this machine was designed to be accurate and sensitive on fine work, the driving mechanism is sufficiently powerful to permit taking heavy cuts for removing stock rapidly.

Some of the principal dimensions of this machine are as follows: Longitudinal travel of the table, 22 inches; transverse movement, 10 inches; vertical adjustment, 18 inches; angular adjustment of the main head, 360 degrees; maximum stroke of shaper ram, 6 inches; maximum distance from end of ram to table, 15 inches; number of speeds, five; number of strokes per minute, from 25 to 150; angular adjustment, 30 degrees each way from the center; maximum distance from end of milling spindle to table, 16 inches; maximum distance from center of spindle to face of column, 13½ inches; number of taper, No. 9 B. & S.; size of hole through spindle, 17/32 inch; angular adjustment, 45 degrees each way from the center; number of speed changes, five; variation, from 55 to 330 revolutions per minute; micrometer stop adjustment, 3½ inches. The shaper ram has an intermittent feed varying from 0.002 to 0.032 inch per stroke, and the milling spindle has six feed changes varying from 0.004 to 0.048 inch per revolution. The net weight of the machine is 2000 pounds; the height over all, 65 inches.

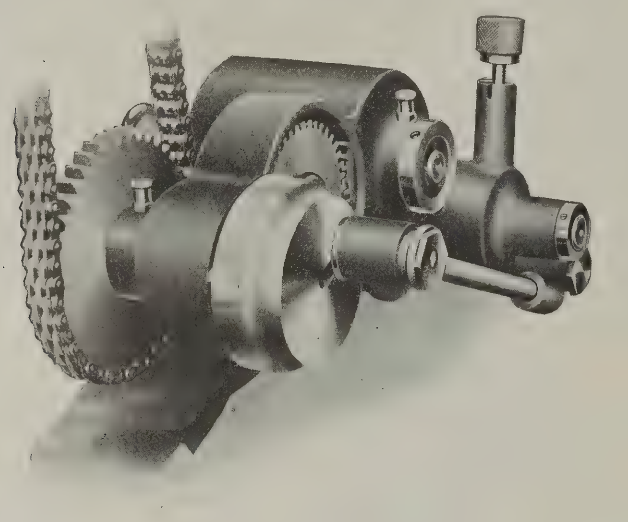

Fig. 7. Mechanism for Obtaining Continuous Feed for Milling and Intermittent Feed for Slotting

The equipment includes an oil tank and hose; shaper, slotter and extension tool-holders; a spud-bar for the milling spindle; a set of slotter tools; wrenches, etc. The following extra equipment can also be furnished, if desired: A circular table with or without power feed; a milling machine vise; draw-rods for the milling spindle; spring collet with bushing and nut; drill chuck; expanding milling arbors; milling machine center; center for circular table; sleeves for the spindle, and a self-contained motor drive.

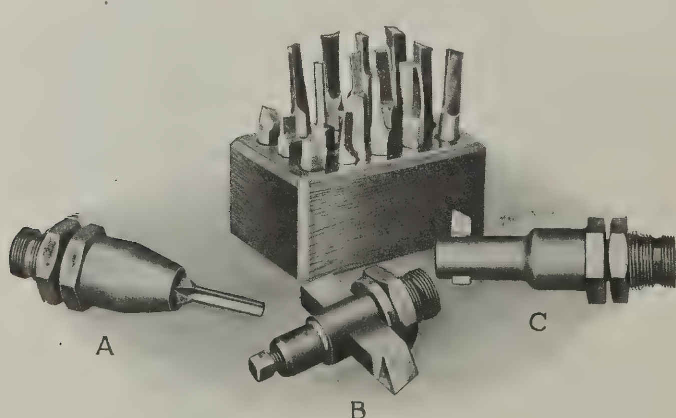

Fig. 8. Set of Slotting Tools and Different Tool-holders

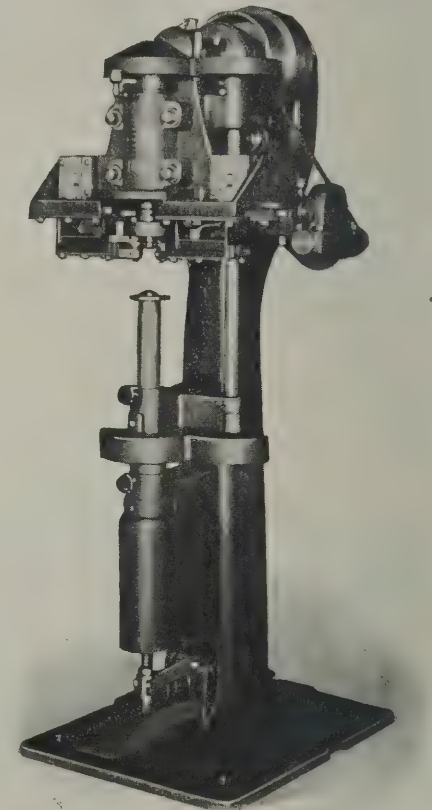
The full universal features of this machine, in conjunction with the various tools which can be used, make it possible to machine a large variety of such work as blanking and forging dies; punches; forming tools, such as are used in turret lathes, automatic machines, etc.; jigs, especially when shaping, milling and boring operations are required; and similar classes of work. While the machine was designed more particularly for the tool-room, the universal features make it possible to handle with the regular equipment and standard tools, a large variety of wōrk which ordinarily would require several machines of different types and also special tools and fixtures.

NEW SQUARE CAN DOUBLE SEAMER

A new automatic double seamer has recently been designed and built by the E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y. This machine is adapted for square, oval and oblong work and will seam cans ranging from ¾ inch to 5½ inches in height. The rate of production depends somewhat on the size of the can, and the expertness of the operator, and varies from 12,000 to 20,000 ends in ten hours.

The machine is driven by an automatic friction clutch encased in the two-step driving cone. A hand brake arranged on the end of the driving shaft, automatically engages and releases after the work is done and insures stopping the spindle in exactly the same position after every cycle. By referring to the accompanying illustration, it will be noted that the lower spindle drive is positive, the lower spindle starting and stopping in unison with the upper spindle. This insures a perfectly straight body after double seaming.



Bliss Automatic Double Seamer

All movements are automatic so that the operator has nothing to do but place the can on the chuck and depress the treadle. This causes the lower spindle to rise and engages the clutch, thus starting the driving shaft which is connected to the chuck spindle by bevel gears, and bringing the double seaming rolls into action. The can is automatically revolved the required number of times, and the double seamer rolls, after going through their motions, are automatically retired, the clutch is automatically disengaged, the chuck is stopped, the lower plate is dropped and the can released. The weight of the machine is 1100 pounds.

STANDARD MACHINERY CO.'S PRESSES

The press shown in the accompanying views represents a new line that has just been brought out by the Standard Machinery Co., 7 Beverly St., Providence, R. I. The particular machine illustrated has a net weight of 13,500 pounds. It is heavily back-geared with cut steel gearing, and is equipped with this company's instantaneous roller friction-clutch. This clutch allows the machine to run continuously or to be automatically stopped after each revolution either by hand or foot. The clutch grips the instant the treadle or handle is depressed, instead of allowing the flywheel to turn from one-half to a full revolution before coming into engagement. After engagement, there is less than 1/32 inch travel on the periphery of the balance wheel. Another noteworthy feature of the clutch is that it enables the press to be stopped at more than one point in a revolution. Most of the clutches applied to these presses are made to stop on the up stroke and down stroke, which adapts the machines for heavy forming, embossing or

similar operations in connection with which it is essential to have the dies dwell after striking.

This machine is extra heavy and rigid in design. It is fitted with stay-rods and is of the open-side and open-back type. The construction of the upper and lower connections as well as the adjusting and clamping device is worthy of note. The lower connection consists of a forged steel ball fitted into a hemispherical center in the ram. On the upper part of this ball there is a bronze retainer which is also hemispherical on the lower part. The upper part of the lower connection is threaded and fits into the upper connection. The clamping is effected by the four screws shown in the upper connection. This connection is split through the center and each of the screws passes through to the opposite side. Around each screw there is a bronze bushing. These bushings and the holes in the upper connections are threaded, and in order to clamp the upper connection to the lower, after the ram is adjusted to the proper height, the screws are tightened and the bronze bushings, which are fitted to the threads of the lower connection, are forced against the shank of the lower connection. This gives a positive grip which will not slip. The bronze bushings around the clamping screws prevent the lower connection from being marred or bruised. The upper connection is bronze-bushed around the wrist-pin and the latter is five inches in diameter.

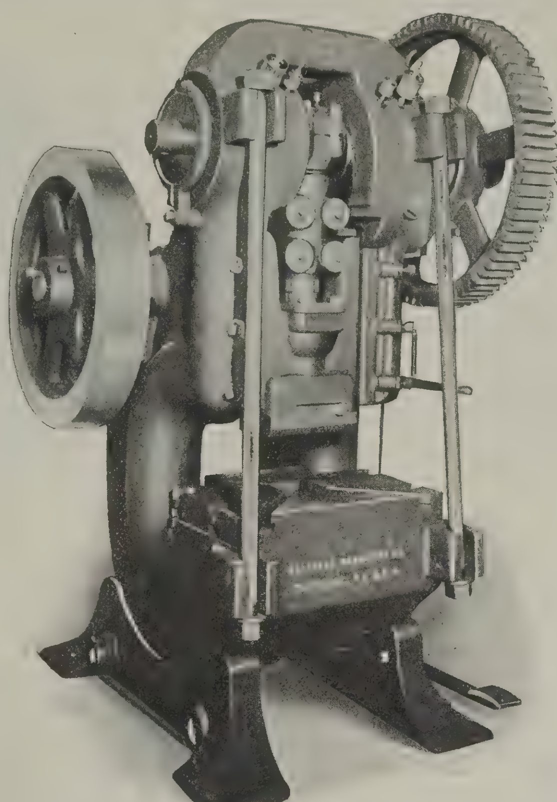


Fig. 1. Heavy Back-geared Press built by Standard Machinery Co

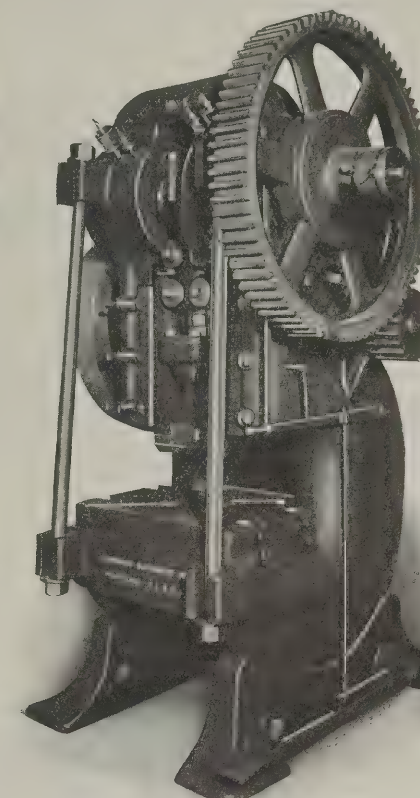

Fig. 2. Another View of Standard Press

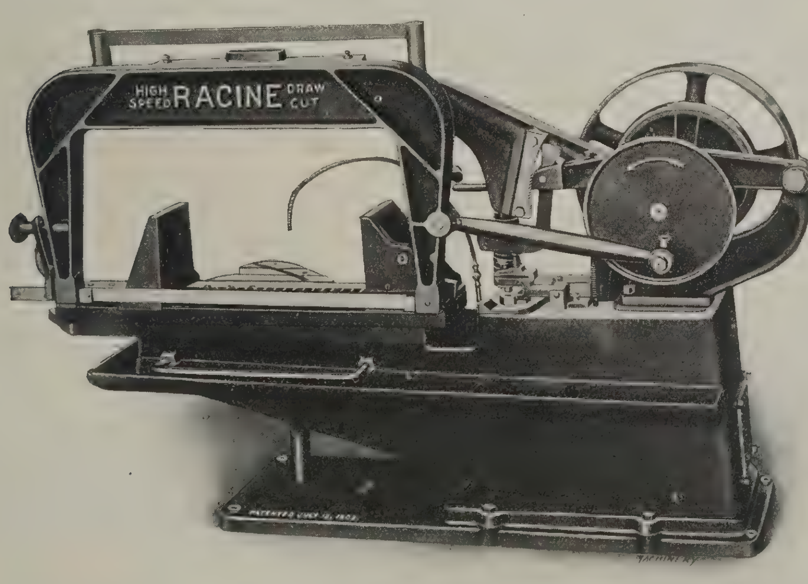
The boxes of the main bearings can be adjusted for wear and the press is arranged, on the left side of the crankshaft, to permit the attachment of a roll or dial feed. The bolster plate is fitted with T-slots so that die-holders and dies of various sizes can be attached. The hole in the bed is generally made to specifications. The boxes for the back-gear shaft are bronze lined and have large oil grooves. The pinion is of cut steel and the driving or clutch gear is made of special "gun iron." The machines are equipped with a tight-and-loose pulley drive in addition to the balance wheel, when so specified. The main frame is liberally proportioned to endure all kinds of shocks incident to cutting and embossing operations. This particular line of presses is not only made single back-geared but double back-geared and either plain or motor driven.

The weight of the press is 13,500 pounds and the weight of the flywheel, 900 pounds. The gear ratio is 1 to 4½. The stroke of the press is 3 inches; diameter of the crankpin, 5 inches; adjustment of the slide, 6½ inches; distance from the slide to the bolster plate, with the stroke down and adjustment up, 7 inches; distance between the uprights, 16 inches; width of bed from front to back, 18 inches; width from right to left, 30½ inches; and the overall height, 8 feet 6 inches.

RACINE METAL-CUTTING MACHINE



Racine Twelve-inch Metal-cutting Machine

The Racine Tool & Machine Co., Racine Junction, Wis., has brought out a new 12-inch metal cutting machine. This machine, which is illustrated herewith, is intended for machine shops, steel warehouses, structural steel works, etc., and is designed to do rapid and accurate work. It will cut 6-inch round machinery steel in 20 minutes and 12-inch I-beams in 10 minutes. The capacity is given as 0 to 12 inches, although the machine can be furnished to take stock measuring 12 to 15 inches. The blades used can vary in length from 17 to 24 inches.

The blade is lifted clear of the work on the return stroke by means of an automatic device. This prevents the blade from dragging on the non-cutting stroke, thereby greatly increasing the life of the blade and the output of the machine. There is a quick-acting vise which swivels to an angle of 45 degrees and can be adjusted so that the entire length of the blade can be used. With a 24-inch blade, stock measuring 11 to 12 inches can be cut at an angle of 45 degrees. The blade holders are made from a 1- by ⅜-inch flat bar fitted into a

milled slot which holds the blade secure with the work. There is also a blade tightener which enables the operator to vary the tension without using a wrench. A cutting compound is supplied to the blade by a geared, circulating pump. The saw frame automatically holds itself at any height, which is very convenient when placing stock in the machine. When the machine is cutting to its full capacity, only about ¾ horsepower is required for driving.

CINCINNATI FRICTION-DRIVEN SWIVEL-HEAD LATHE

The latest development of the Cincinnati Precision Lathe Co., Fosdick Bldg., Cincinnati, Ohio, is a bench lathe equipped with a swivel-head which can be located at any angle with relation to the ways of the bed. This machine, a general view of which is shown in Fig. 1, has a friction drive similar to the one employed on this company's precision bench lathe which was illustrated in the department of New Machinery and Tools for May, 1912. The swivel-head has angular graduations on the base for setting it in any required position, and it is securely held by an eccentric bolt at the left end and a hardened bolt at the front or right end. The position of the head is accurately maintained by a hardened and ground circular ring inserted in the upper base and fitting closely in a circular slot in a plate that is bolted to the lathe bed. This swivel-head, in conjunction with a combination external and internal toolpost grinder and a double swivel slide-rest, makes the machine a universal precision grinder and lathe.

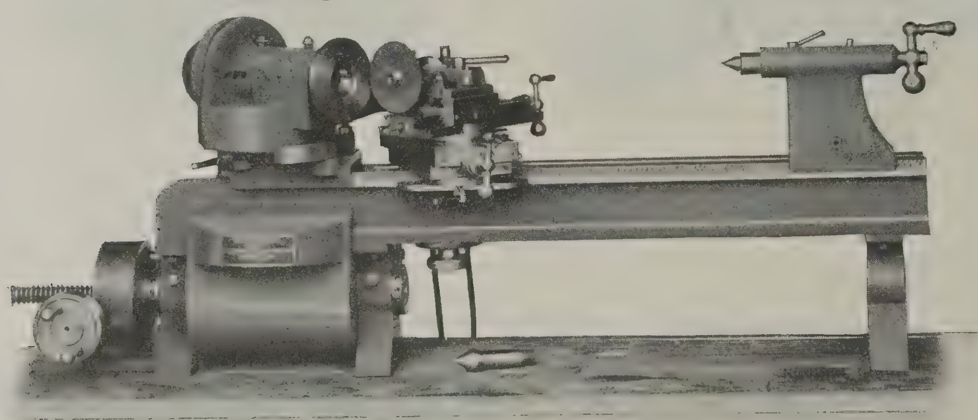


Fig. 1. Swivel-head Lathe arranged for Face Grinding

Fig. 1 shows the position of the headstock and slide-rest for face grinding. The head is set at an angle of 30 degrees, and each swivel rest is also set to the 30-degree position, thus giving a total angle of 90 degrees. Fig. 2 shows the machine arranged for angular grinding, the operation in this case being that of truing the lathe center. Fig. 3 is a rear view of a lathe equipped with a standard head and serves to show

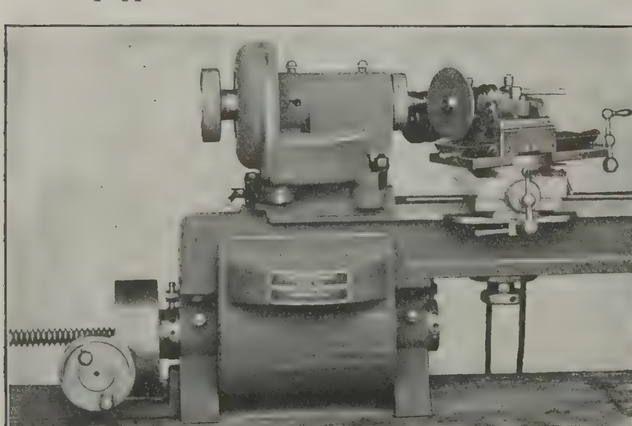

Fig. 2. Angular Grinding on Swivel-head Lathe

the clutch lever (which is also applied to the swivel-head type) for controlling the starting and stopping of the spindle. The friction driving wheel (which is also clearly shown in this view) is first located on the horizontal driven disk for the required speed, as shown by a speed indicator on the outer edge of the hand adjusting wheel. The main spindle can then be engaged instantly for operating at this speed, by a downward pressure on the clutch lever previously referred to, whereas an upward movement of this lever disengages the

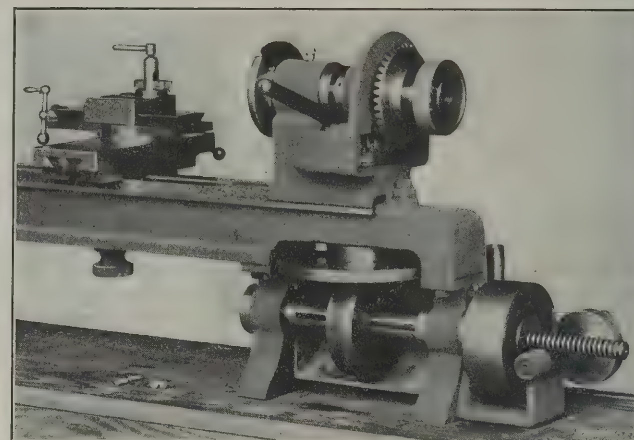

Fig. 3. Rear View of Lathe having Standard Head

spindle. The application of this device makes a countershaft unnecessary for operating the lathe. For the operation of a grinder, a combination countershaft for the lathe and grinder is employed.

The construction of the spindle control clutch is shown by the sectional view, Fig. 4. There is a hardened taper member *A* which, when raised by lever *B*, forces four hardened pins outward against a split ring *C*, thus bringing the latter into engagement with the miter gear *D*. As soon as this engagement takes place, all the working parts of the clutch are revolved with the gear and vertical driving spindle in the center. This engagement is effected with a very slight pressure on the hand lever and the weight of the lever is balanced by a small spring as shown, which causes the inner or forked end to "float" in the circular lifting slot, thus eliminating friction and wear.

The split ring *C* is slightly under size in its released position so that there is no friction at this point when the clutch

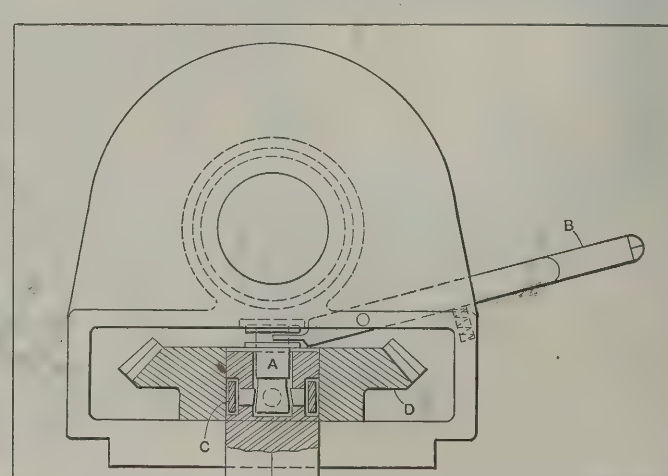

Fig. 4. Clutch for Starting and Stopping Lathe Spindle

is disengaged. The entire clutch mechanism is constantly lubricated and the application of the clutch is uniform and powerful. Moreover, the gear is engaged in such a way that its alignment is retained. The clutch handle is located conveniently for the left hand of the operator, so that the ma-

chine can be stopped and started easily and quickly. Provision has also been made for starting and stopping, independently of the driving belt, by placing the friction driving disk into a slight depression in the center of the horizontal driven disk. When the driving disk is in this position, the entire machine is stationary, excepting the driving friction shaft which, in this case, acts as a self-contained countershaft.

This friction drive eliminates a cone pulley and permits spindle bearings that are practically continuous. The direction of rotation is easily reversed, and wear between the friction members is taken up by means of eccentric bushings which enable the driving shaft to be raised or lowered parallel with the face of the driven disk. The location of the belt pulley makes it possible to apply power from beneath the bench, as well as from the side or overhead. The grinder can also be driven from beneath the bench, if desired. This lathe has a swing of 8 inches; a 32-inch bed; and a maximum distance of 15 inches between the centers. With the constant-speed driving pulley revolving at 1000 revolutions per minute, speeds ranging from 850 to 2500 revolutions per minute are available.

AJAX RECLAIMING ROLLS

The reclaiming rolls illustrated in Fig. 1 were designed for re-rolling scrap iron and steel, in order to reclaim the large amount of material which is thrown on the scrap pile and sold at scrap prices. The waste represented by the scrap heap is a very important item on railroads, but by means of these rolls, all discarded parts, such as truss rods, arch bars, draw-bars, center pins, etc., can be reclaimed by heating and re-rolling them into round or flat stock from which bolts, car fittings or similar parts can be made. These reclaiming rolls are built by the Ajax Mfg. Co., Cleveland, Ohio.

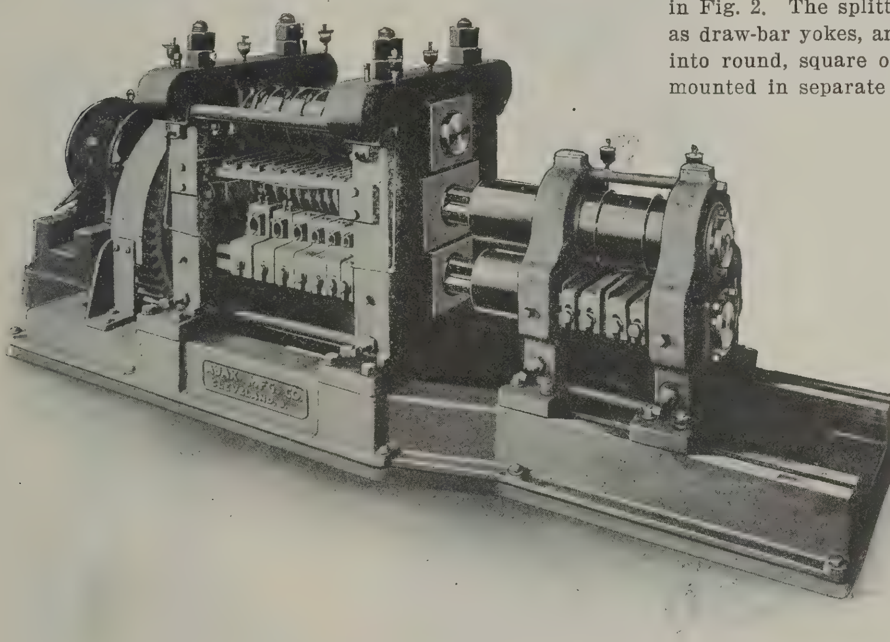

Fig. 1. Ajax Reclaiming Rolls for Re-rolling Round, Square or Flat Bars from Scrap Iron or Steel

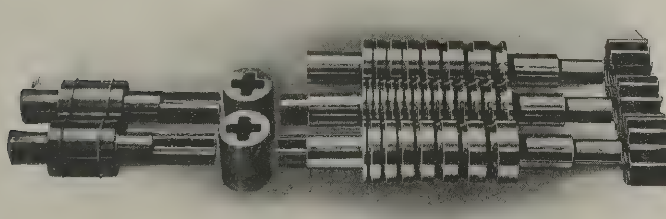

Fig. 2. The Three Reducing Rolls and the Splitting Rolls for Splitting Flat Stock Longitudinally preparatory to Re-rolling

The machine shown in Fig. 1 is a "three-roll-high" type and is provided with an auxiliary or secondary set of rolls for splitting flat stock longitudinally preparatory to re-rolling it in the main reducing rolls. The scrap bars are ordinarily cut into lengths varying from two to five feet. The length depends upon the section, and is decreased as the size of the bar increases. These bars are heated in suitable furnaces and are then started through the rolls. The first pass reduces the bar to an elliptical shape and it is then rolled round on the return pass. This process is repeated until the stock is reduced to the required size.

The rolls used in this machine are turned from forged steel of special analysis and are mounted in phosphor-bronze bushed bearings. A set of three main reducing rolls for rounds, and a pair of splitting rolls with the crab connection, are shown in Fig. 2. The splitting rolls shear lengthwise such flat stock as draw-bar yokes, arch bars, etc., and thus facilitate re-rolling into round, square or flat stock. These two sets of rolls are mounted in separate housings, as shown in Fig. 1. The yoke over each of the main housings insures ample strength and rigidity. The smaller housings are seated on T-slot ways so that the splitting rolls can easily be removed. The baseplate of the machine is cast in one piece. Two sets of main reducing rolls are furnished, one being for rounds and one for squares or flats, as may be specified. The solid bearings of the main rolls can be adjusted vertically by means of double wedges. The main housings have bronze adjusting pieces which are located against the sides of the bearings and provide lateral adjustment for the main rolls. These bronze pieces are slightly tapered and adjustment is effected by shifting them in or out.

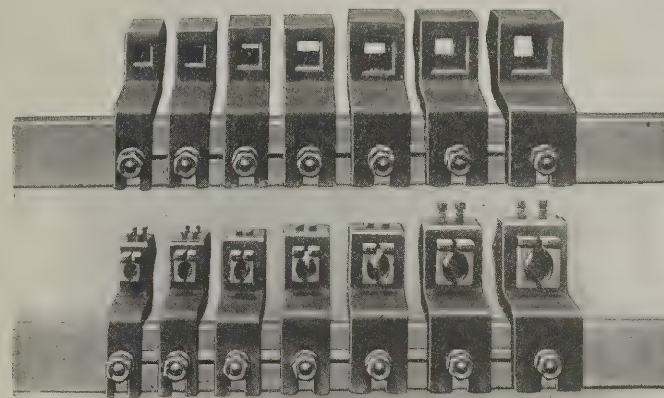

Fig. 3. The "In-and-Out" Guides for Round Stock

The main reducing rolls are 12 inches in diameter and 40 inches long between the housings and are grooved to reduce 2-inch rounds from 1¾ inch down to ½ inch, inclusive. The range of the main rolls for producing flats depends upon the nature of the scrap, although an idea of the capacity can be obtained from the foregoing figures. A steel channel or trough should be provided back of the machine for receiving the bars when they finally leave the rolls. Against the side of this channel the bars are straightened and allowed to cool.

The machine is equipped with suitable "in-and-out" guides for either round or flat stock. Fig. 3 illustrates sets of in-and-out guides for round stock. The first pass is through an "in" guide (see upper view) between the upper and middle roll, and the bar, rolled to an elliptical shape, comes out through an "out" guide. The bar is then returned through an "in" guide (see lower view) between the bottom and middle roll and comes out round. This process is repeated until the stock is reduced to size. The main rolls have a peripheral speed of approximately 300 feet per minute.

Ample heating capacity should be provided for heating the scrap stock, and two furnaces are recommended, one being a heating chamber for bars up to four feet long and the other for bars up to eight feet long. These furnaces should be

placed in front of the rolls and at right angles. The production of these rolls varies according to the nature and size of the scrap bars and the size to which the bars are re-rolled. The heating furnace equipment also affects the production so that it is difficult to give an accurate estimate. The average production, however, ranges from six to eight tons in ten hours, and the fuel cost averages about $6.00. The operating crew consists of from four to five men, including a roller and assistant roller, a heater, a helper and a man to carry the re-rolled bars to the cooling and straightening tables. The power required to operate the rolls, when driving by belt from a lineshaft, will range from 20 to 40 horsepower, whereas if a direct-connected motor drive is employed a 50-horsepower motor is recommended.

BEAUDRY POWER HAMMER

Beaudry & Co., Inc., 141 Milk St., Boston, Mass., have brought out a new design of power hammer. This new hammer is applicable to general forging work and it is especially adapted for plating and drawing steel, or for use in the manufacture of cutlery, edge tools, files, agricultural implements, spindle and general toolmaking or any forging operations requiring an extremely quick blow. The hammer can be operated at a high rate of speed and is designed for continuous service.

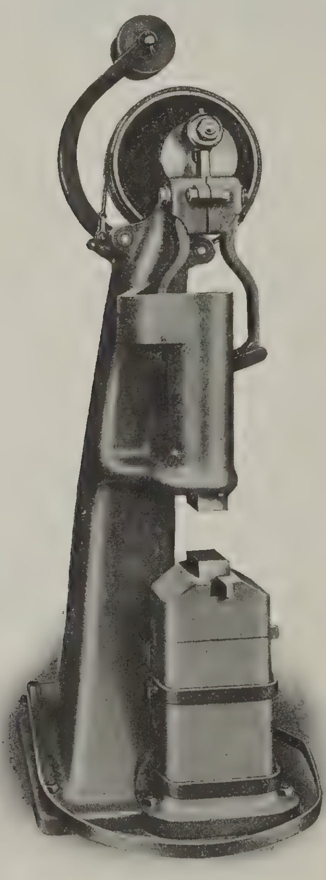

Fig. 1. Beaudry "Peerless" Power Hammer

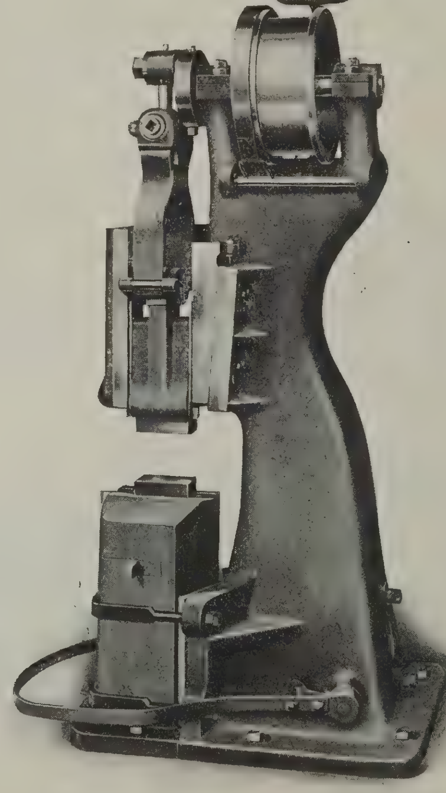

Fig. 2. Side View of Beaudry Hammer

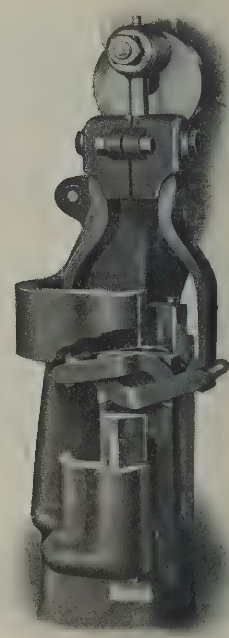

Fig. 3. Sectional View of Hammer

Front and side views of this hammer are shown in Figs. 1 and 2. The ram is connected by means of spring arms and two long steel links which are arranged to occupy a minimum space and, at the same time, give a maximum freedom and lift of the ram, as well as an elastic and cushioned but powerful blow. The tension on the spring arms and links is maintained and adjusted by means of tension nuts in a spring box. These working parts are clearly shown in the sectional view, Fig. 3.

The hammer is started, stopped and regulated by a foot-treadle extending around the base. By varying the pressure on this treadle, any desired speed or force of blow is instantly obtained. The idler pulley for the driving belt, and the brake band, are reversible so that the hammer can be run in either direction. The anvil is a separate casting and a wood filler is inserted between it and the frame to eliminate vibration. The anvil is secured to the frame by strap bolts and, as shown in Fig. 1, it is offset so as to clear the main frame casting, thus allowing long bars to be held on the dies in any position. The anvil has an independent and adjustable shoe die.

The frame is cast in one piece, is very rigid and occupies little floor space. The ram is of steel and is carefully fitted into heavy V-shaped guides. It is adjustable on the connecting-rod for varying the height above the dies and is at all times almost entirely contained within the guides, thereby insuring accurate alignment of the dies and a true, square blow. The ram guides are cast solid with the frame and to one of them is fitted an adjustable, composition, taper gib for taking up wear. The steel crankshaft is of large diameter, has long bearings and runs in babbitted bushings chambered for oil. The crankpin is adjustable for varying the length of the stroke.

The steel connecting-rod operates on a hard, bronze sleeve and is connected with the spring box. The latter is also of steel and into it are fitted the two spring arms to which the links are hooked. These spring arms are held in place by tension nuts, which, as previously mentioned, serve to maintain and vary the tension on the arms. The spring arms are forged from Swedish steel and are carefully tempered. The links are steel castings.

The brake (which is clearly shown in Fig. 2) will hold the hammer in any position. The treadle working in conjunction with the belt-tightening pulley and band brake, serves to instantly stop or start the hammer. The belt pulley is large and has a wide face, thus giving the driving belt ample contact area. This new hammer is made in seven different sizes. The ram of the smallest size weighs 25 pounds, and the largest size, 200 pounds; whereas the approximate weights of the smallest and largest hammers are 1200 and 4400 pounds, respectively.

WAHLSTROM AUTOMATIC DRILL CHUCK

Where a drilling job requires the use of a number of different sized drills, a lot of time is lost in changing from one size to another. The Wahlstrom automatic drill chuck, made by the Wahlstrom Tool Co., 346 Carroll St., Brooklyn, N. Y., and illustrated in Figs. 1 and 2, has been designed to avoid this waste of time. Reference to Fig. 2 will show that this chuck consists of a body D surrounded by a shell E. This shell is knurled on the outside and when it is desired to change drills, it is merely necessary to grasp the shell and

hold it against the drive of the drill press. This opens the jaws so that one drill can be removed and another inserted in its place. When the change has been made, the shell is released and the new drill is in position ready for use.

The drill is secured in the chuck by means of three rockers *A* which are pivoted in jaws *B;* the latter are carried in the body of the chuck. When the shell is held back in order to open the chuck, it is twisted against the tension of spring *F*, a suitable stop being provided between the body of the chuck and the shell in order to stop the chuck when it has been opened to its maximum capacity. When a drill is inserted and the shell released, the tension of the spring *F* twists the shell around in relation to the chuck body. In so doing, the jaws *B* are forced in toward a common center through their bearing on three eccentric surfaces on the inner side of the shell. This brings the rockers *A* against the shank of the drill and holds it in position ready for use. When the drill is fed up to the work, the rockers *A* swing on their pivots and the eccentric faces of these rockers are forced in against the shank, the gripping being in direct proportion to the force which is required to drive the drill.

Fig. 1. The Wahlstrom Automatic Drill Chuck

In the design of any drill chuck acting upon this principle, it is necessary that the eccentricity shall be very small in order to secure the required grip. This has been the reason for the limited range of previous types of chucks which have been designed along these lines. In the present case, the provision of the jaw extensions *C* have made it possible to greatly increase the capacity. Reference to the two end views shown in Fig. 2 will make it clear that when the jaws are reduced for the smaller sizes of drills, the jaw extensions *C* are located between the jaws and the eccentric surfaces of the shell. This is the case until the jaws have been opened to about one-half of their capacity. In this position the jaw extensions come up against the shoulders in the shell as shown, and the jaws then come into direct contact with the eccentric surfaces of the shell. They are in this position until the chuck has been opened to its full capacity.

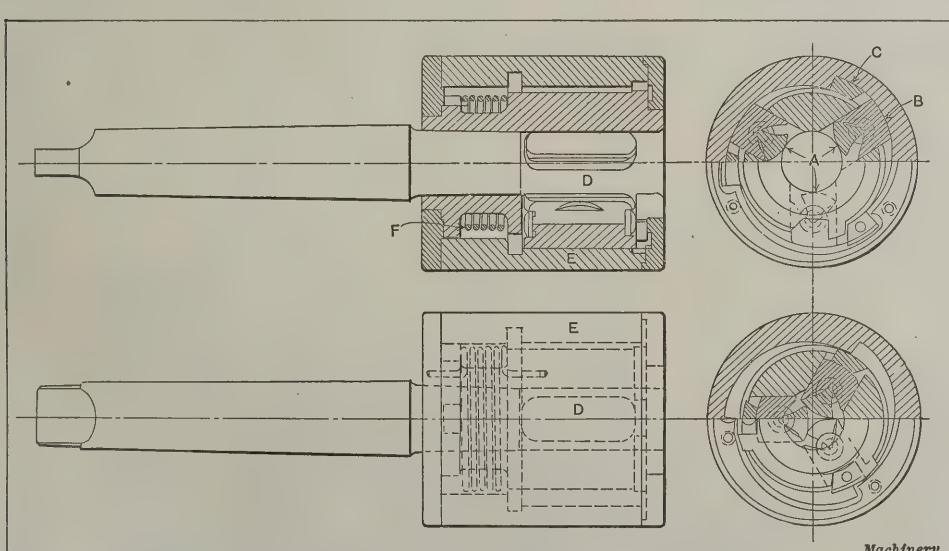

Fig. 2. Cross-sectional View showing Arrangement of Gripping Mechanism

This chuck is suitable for all kinds of drilling, reaming, tapping and counterboring operations where straight shank tools are used. In the case of tapping, it is necessary to grind three flat surfaces on the shank of the tap to provide the necessary drive for backing out the tool. The range of the chuck shown in the illustrations is from a ¾ inch drill down to a No. 33 drill. The chuck will also be placed upon the market in a larger and smaller size. It is constructed entirely of high carbon tool steel with the exception of the jaws *B* and rockers *C;* these are made of high-speed steel. The ¾ inch chuck is commonly made with a No. 3 Morse taper shank, but any other taper can be furnished.

THE WAHLSTROM OIL CUP

Difficulty is sometimes experienced with small oil cups from two causes: first, the cups are difficult to install in cramped positions; and second, the covers in use render it difficult to fill the cups without spilling considerable oil.

The Wahlstrom Tool Co., 346 Carroll St., Brooklyn, N. Y., has recently placed a cup upon the market designed to eliminate these difficulties. Instead of applying a hexagon at the base, which requires the use of a wrench to screw the cup into place, the Wahlstrom oil cup has been provided with a slot *A* as shown in Fig. 1. This makes it possible to use an ordinary screw-driver when installing the cup. This is generally a more convenient method and it has a further advantage of not marring the outside of the cup. The type of cover used is pivoted at *D*. This enables the cover to be lifted as shown in Fig. 2, thus providing plenty of room for adding fresh oil or for the admission of a screw-driver when installing. The provision of this pivoted cover also makes it easy to use a wire to clean out the oil channels, should they become clogged.

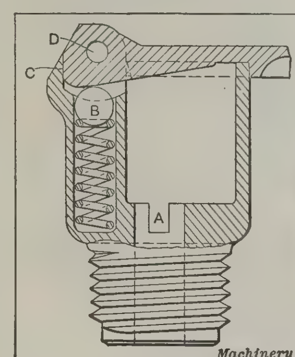

Fig. 1. Cross-sectional View of the Oil Cup

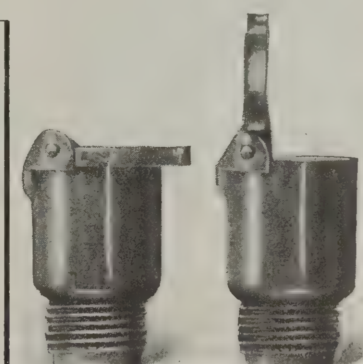

Fig. 2. Oil Cup with Cover Closed and Open

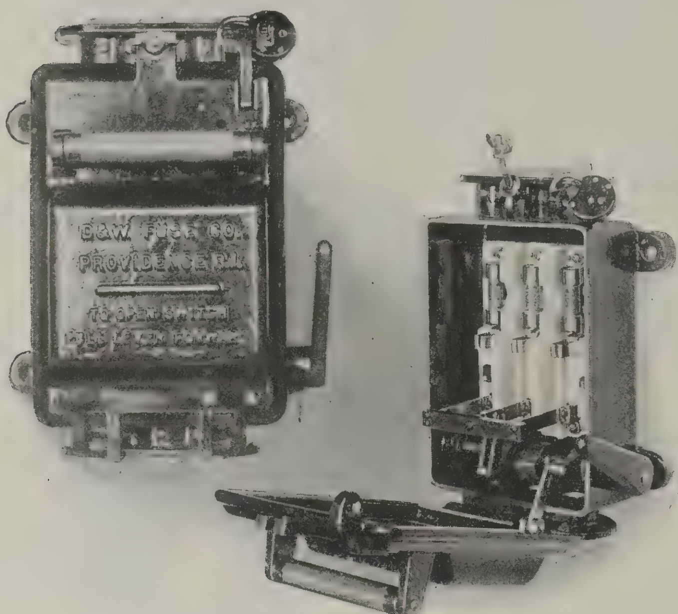
Reference to Fig. 1 will show that there is a spring and ball *B* located in a hole at the left-hand side of the cup. This spring serves the double purpose of holding the cover down when the cup is supposed to be shut, and also of holding it up when the cover is lifted to add fresh oil. In the latter position, the ball *B* is in contact with the surface *C*. The use of this spring does away with the necessity of holding the cover up with one hand while oiling. Where cups are located in close places, this cover design is particularly useful in that it allows the spout of the oil can to be used to lift it. The cup is also made practically dust-proof by the liberally proportioned flange on the cover, which comes down over the top of the cup as shown in the cross-sectional view. These cups are made in seven regular commercial sizes with diameters ranging from ¼ inch to ½ inch.

COMBINED SWITCH AND FUSE BOX

The D. & W. Fuse Co., Providence, R. I., has brought out a new line of fused switch boxes for 250-volt, direct-current circuits. These boxes are particularly adapted for mill service

since they can be locked after the fuses are installed, thereby preventing any tampering with the connections or increasing the capacity of the fuses. They can also be used as a switch, as the circuit can be opened or closed at will, by simply moving the lever located at the side of the box, as shown in the accompanying views. When the cover is opened, as illustrated to the right, the circuit is also opened which makes it impos-



D. & W. Combined Switch and Fuse Box with Safety Lock

sible to re-fuse the circuit when the switch is closed. The construction of these boxes is simple but substantial, and they will last indefinitely. They are provided with rubber gaskets which make them waterproof, provided the terminal wires are "taped in" at the bushings or protected by outlet hoods when conduit connections are made. To facilitate installing these boxes, removable porcelain bushings are used, through which the cable terminals can be readily passed.

THE HALE LOOSE PULLEY

The Cleveland Clutch Co., Cleveland, Ohio, is manufacturing a loose pulley that is quite different from the usual form. The pulley proper has a large hub which fits over a bearing sleeve that is locked to the shaft by a set-screw. When placing the pulley on a shaft, the bearing sleeve is first fastened in position. The pulley is then slipped over the sleeve and the side retaining cover or plate is screwed on. Fig. 1 shows the pulley assembled, and Fig. 2 illustrates the different parts,

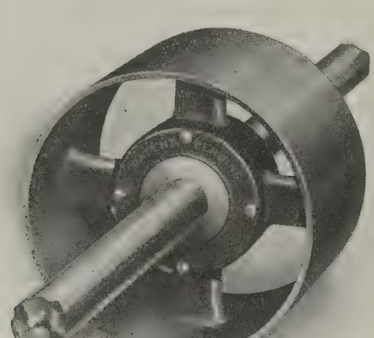


Fig. 1. Hale Loose Pulley

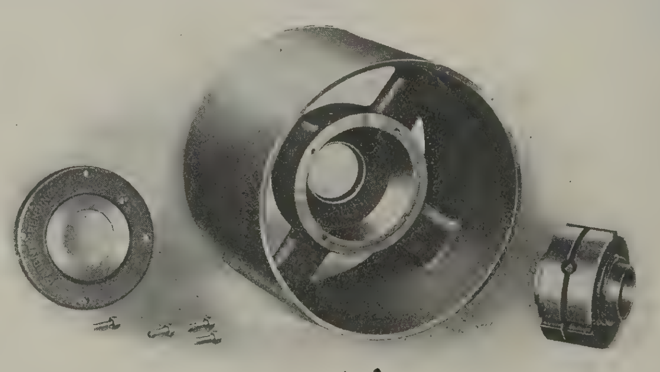

Fig. 2. Parts of the Hale Loose Pulley

the retaining cover being to the left and the bearing sleeve to the right.

One of the noteworthy features of this pulley is the efficient method of oiling the bearing surfaces. The oil is not wasted and the lubricant always remains on the bearing, regardless of whether the pulley is idle or revolving at high speed. The particular pulley illustrated is a 12-inch size and has an 8½-inch face, and the friction surface has the same area as that of an ordinary loose pulley of the same dimensions. The principal features claimed for this pulley are, that it is self-oiling; durable; dust- and dirtproof; oil-tight; economical in the use of lubricant; prevents oil from being thrown on the belt; eliminates wear of the shaft; keeps the lubricant constantly on the bearing; is easily mounted on a damaged shaft; and, when once oiled, requires no attention for months.

ELECTRIC PRECISION GRINDER

The portable, electric, precision grinder shown in Figs. 1 and 2, is the product of the Chicago Pneumatic Tool Co., 1014 Fisher Bldg., Chicago, Ill. This electric grinder is known as the "Duntley No. 6," and is adapted to a large variety of work, being designed for both external and internal grinding. A commendable feature is the adjustable frame, which is milled convex on its lower surface, and rests on a concave shoe, as shown in Fig. 1. When the grinder is applied to a

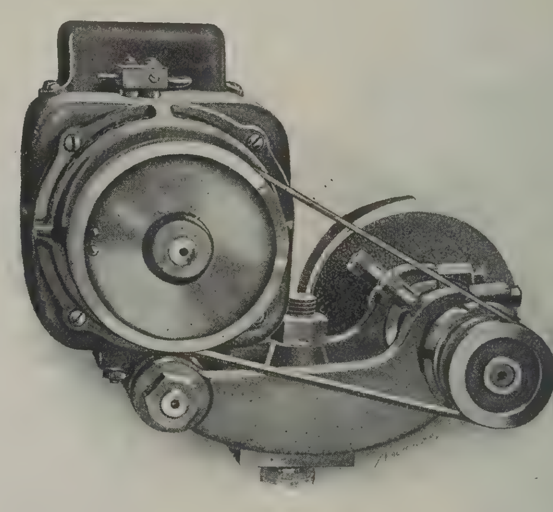

Fig. 1. Chicago Pneumatic Tool Co.'s Electric Grinder

lathe, this concave shoe rests on the tool-post base and is clamped to it by the bolt and nut shown. The center of the grinding wheel arbor is brought in line with the center of the work, by simply pushing the frame back or forth on the concave shoe and then tightening the clamping bolt when the grinder is set in the desired position. This adjustment makes it possible to use this grinder on lathes having a swing of from 16 to 42 inches, inclusive.

The arbor for external grinding carries a 5-inch wheel (see Fig. 1) and is provided with a split-sleeve bearing, which is tapered on the outside, and can be accurately adjusted for wear. The heads of the cap-screws for fastening the straps which hold the arbor sleeve to the frame, extend only a slight amount beyond the arbor housing itself. This is an important feature, as it permits the emery wheel to be worn down to a small diameter, and allows sufficient clearance between the grinder and the tailstock of the lathe—this is a requirement not found in most grinders of the tool-post type.

The arbor for the internal grinder (see Fig. 2) runs in

Hess-Bright ball bearings, which are located at the ends of the arbor and provide a support close to the wheel and driving pulley. The arbors for external and internal grinding can be

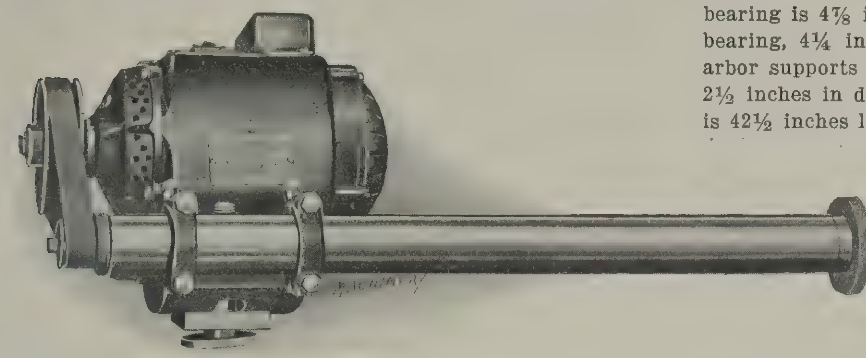

Fig. 2. Grinder illustrated in Fig. 1 arranged for Internal Grinding

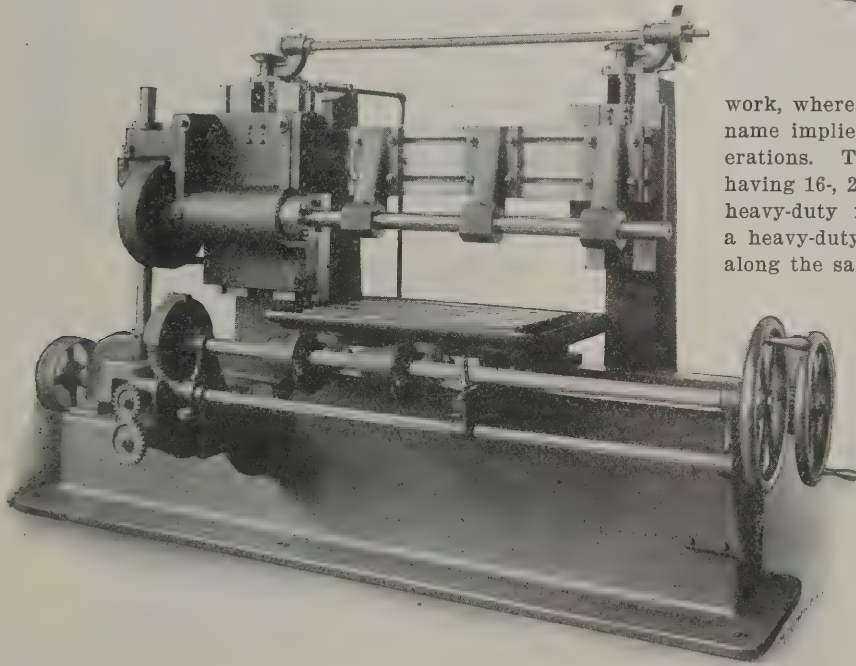
changed in a few minutes by simply removing the cap-screws of the straps which hold the arbor sleeve to the frame.

The motor is mounted on a hinge-pin, permitting it to be swung back to tighten the belt. Pulleys of the desired size to give the proper wheel speeds are furnished, and the motors can be obtained in a variety of types for either direct current or alternating current of the single, two, or three-phase systems.

SPECIAL BEAMAN & SMITH MILLING MACHINE

The milling machine shown herewith has been designed by the Beaman & Smith Co., Providence, R. I., for milling the ends of crankshaft bearings on crankcases. It has a horizontal bed upon which is mounted a work-table that can be traversed laterally on its saddle and longitudinally along the ways of the bed. Two uprights are attached to the bed which support the spindle-saddle and cross-rail. The cross-rail is attached directly to the spindle-saddle and it can be raised or lowered by hand. The horizontal shaft connecting the vertical adjusting screws, carries at the right-hand end a dial graduated to thousandths of an inch to facilitate setting the cutters accurately to depth.

The spindle is driven by a single pulley seen at the left of the machine from which power is transmitted to the spindle through shafting and gearing. The table has a hand movement of 32 inches in line with the spindle, and a cross-move-



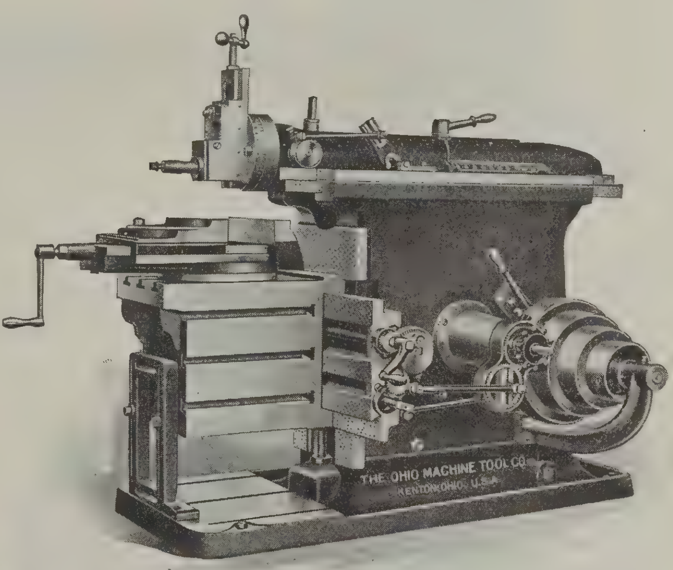
Special Machine for Milling End of Crankshaft Bearings on Crankcases

ment of $11\frac{1}{2}$ inches. There are positive geared feeds for the cross-movement and five changes are available, ranging from $1\frac{1}{2}$ to $6\frac{1}{2}$ inches per minute.

The table has a working surface 18 inches wide and 32 inches long, and it is surrounded by a large oil channel. The spindle is of crucible steel and runs in boxes of hard bronze which can be adjusted to compensate for wear. The front bearing is $4\frac{7}{8}$ inches in diameter, 6 inches long, and the rear bearing, $4\frac{1}{4}$ inches in diameter and $5\frac{1}{2}$ inches long. Three arbor supports are provided having phosphor-bronze bearings $2\frac{1}{2}$ inches in diameter and $5\frac{3}{8}$ inches long. The arbor itself is $42\frac{1}{2}$ inches long and $1\frac{7}{8}$ inch in diameter. The machine is driven by a 4-inch belt, and the ratio of the gearing is 2.7 to 1, giving a spindle speed of 250 revolutions per minute. Lubricant for the cutters is provided by means of a pump. The distance between the uprights is 44 inches, and the minimum and maximum distances from the center of the spindle to the top of the table are, $10\frac{1}{2}$ and $16\frac{3}{4}$ inches, respectively. The weight of the machine is approximately 10,300 pounds.

OHIO STANDARD AND HEAVY-DUTY SHAPERS

The Ohio Machine Tool Co., Kenton, Ohio, has brought out two types of shapers. One is known as the "standard" shaper and is intended for ordinary tool-room and machine shop



Ohio 24-inch Heavy-duty Shaper

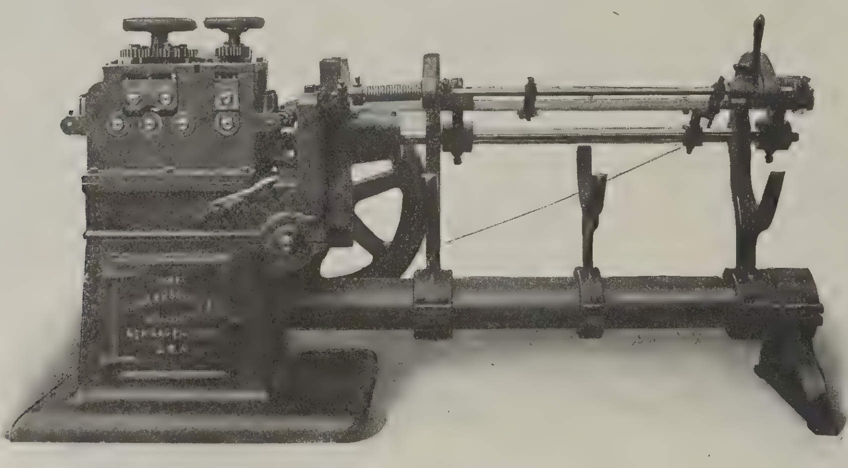
work, whereas the other is a "heavy-duty" type which, as the name implies, is designed especially for heavy machining operations. These shapers, in both styles, are built in sizes having 16-, 20- and 24-inch strokes, and there is also a 28-inch heavy-duty machine. The accompanying illustration shows a heavy-duty 24-inch size. The standard type is constructed along the same lines but is lighter in weight.

The bull gears of these shapers are of large diameter and the crank-arms are extra long and heavy, in order to transmit power to the cutting tool with a minimum of vibration. The 20- and 24-inch sizes have a variable, automatic, vertical power feed for the table. The vertical power feed for the head, which is shown applied to the machine illustrated, is a special attachment. This device feeds the tool either up or down and gives feed variations ranging from 0 to 3/16 inch. It is actuated by a tumbler movement that is positive in its operation. The standard 20-inch machine has a keyseating capacity of three inches, and the heavy-duty type, $3\frac{1}{2}$ inches; whereas the 24-inch sizes in both types have keyseating capacities of $3\frac{5}{8}$ and $4\frac{5}{8}$ inches, respectively. Motor drives are applied to any size shaper and on the 20- and 24-inch machines, the motor is attached to the back of the column. By having these two types, the manufacturers can supply a shaper adapted to the requirements of the shop in which it is installed.

SHUSTER STRIP-METAL STRAIGHTENER AND CUTTER

The accompanying illustration shows an automatic strip-metal straightener and cutter built by the F. B. Shuster Co. of New Haven, Conn. This machine is larger than similar types previously built by this company and embodies several improvements. It is designed for straightening and cutting to accurate lengths (from the coil) such metal as brass, copper, steel, iron, etc. The machine has a capacity for widths up to three inches and will take stock up to 1/8 inch thick. The particular machine illustrated will cut lengths up to four feet but it can be built for any length desired.

There are five straightening rolls and a pair of feed rolls, all of which are enclosed by the housing instead of being outside, which is the construction of the smaller sizes. All the rolls are geared and the upper ones are adjustable to suit the shape and temper of the stock passing through the machine.



Shuster Automatic Strip-metal Straightener and Cutter

This adjustment is effected by the handwheels shown on the top of the housing and can be made while the machine is in motion. There are suitable guides at the rear for taking care of various widths and thicknesses of metal.

This machine has a mechanism which stops the feeding of the material while it is being severed. When operating the machine, the metal is placed on a suitable reel at the rear, from which it passes through guides into the straightening and feed rolls. Continuing, it moves past the stationary dies and cutters out into the guide-bar until it strikes a gage previously set for the length to be cut. This throws the feed-releasing mechanism into operation, thus causing the feed to stop and the cutters to come into action. At the same time, the cover of the guide-bar is thrown off and the severed piece drops into the fork-shaped brackets shown. The extension of this machine is similar to that applied to the straighteners and cutters for round, square and hexagon stocks, except that the guide-bar is designed and grooved for strip metal.

LARGE NIAGARA DOUBLE-CRANK PRESS

The large double-crank press shown in Figs. 1 and 2 was recently designed and built by the Niagara Machine & Tool Works, Buffalo, N. Y. This press is adapted for a wide range of work, such as heavy blanking, shearing, forming, embossing, and cold-drawing operations. It is equipped with the Niagara combination friction clutch and brake. The friction clutch is of the multiple-disk type and the friction surfaces are lined with end-grain, hardwood blocks. The clutch is entirely encased and all projecting rotating parts which might endanger the operator when oiling the clutch, are eliminated. The clutch is operated by four sets of toggles and links which are made of steel.

The brake, which works in unison with the clutch, consists of two brake levers which are actuated by a pair of toggles. An interesting feature of the construction is that the pressure on the brake blocks is always equalized, thus avoiding transmitting the pressure of the brake arms to the shaft bearings. The clutch can be started by a foot treadle actuating an automatic device which will stop the press when the slide reaches the highest position. This self-acting device can be quickly thrown out of action and the motion of the press controlled by a hand lever. This lever permits starting and stopping the machine at any part of the stroke.

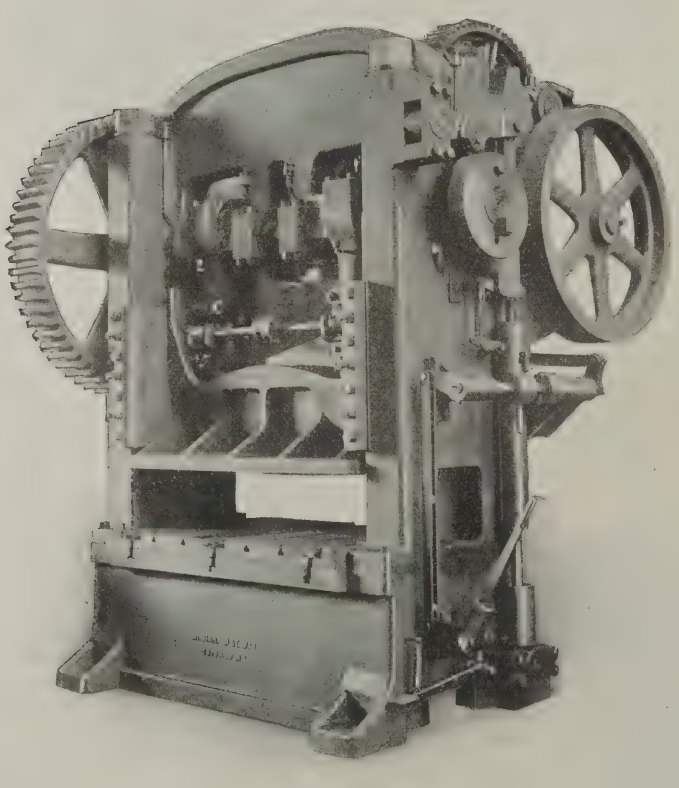


Fig. 1. Niagara Double-crank Press

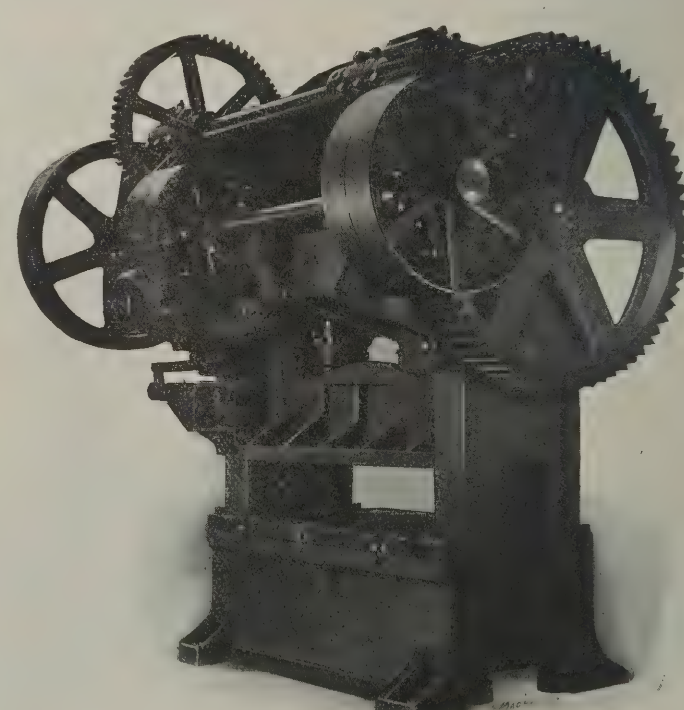

Fig. 2. Rear View of Niagara Press

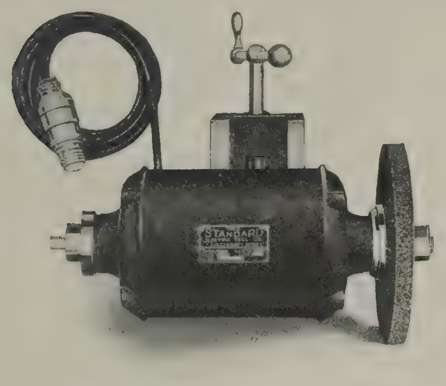
To guard against breakage, in case the press is accidentally overloaded, there is a safety coupling on the pinion shaft. The housings and arch are held together by four steel tie-rods, 5½ inches in diameter, which are shrunk into place. The slide and gibs have the same means of adjustment common to

all large presses built by this company. The press measures 72 inches between the housings and weighs 60,000 pounds. It covers a minimum amount of floor space, as the drive is located overhead and outboard bearings are eliminated.

PORTABLE ELECTRIC GRINDER

The portable electric grinder shown herewith is made by the Standard Electric Tool Co., Cincinnati, Ohio. This grinder is mounted on an angle-plate and is attached to a lathe by bolting this plate to the toolpost rest. A shank can be furnished instead of the angle-plate attachment, if desired. There is a vertical dovetail slide on the angle-plate which gives an adjustment of four inches for locating the grinding wheel in line with the lathe centers. This grinder can be used for grinding rolls, shafts, bushings, and similar work. It is also adapted for surface grinding on the planer and can be used to advantage on the boring mill for certain classes of work. The bearings are made of phosphor-bronze and are dust-proof and adjustable. The motor is force-ventilated or air-cooled by a special fan mounted on the armature shaft. The armature and poles are built up of the best grade of soft, electrical, sheet-steel laminations, uniformly insulated. This grinder is made in one-half and one horsepower sizes.



Standard Portable Electric Grinder

BAKER BROS. HIGH-SPEED DRILLING MACHINE

Baker Bros., Toledo, Ohio, have added to their line of drilling machines the powerful high-speed, heavy-duty type shown in Fig. 2. A glance at this illustration will give one a better idea of the massiveness and rigidity of the construction than a whole page of description. The machine has a heavy box column and also a box-type, screw-elevating table. It has a single belt drive and the driving train is composed of all hardened steel gears. The shafts are large and are mounted in Hess-Bright ball bearings. A minimum number of gears consistent with the necessary speed changes are in mesh at one time. On the four direct speeds, only three pairs of gears are meshed simultaneously, and there are never more than five pairs engaged at one time.

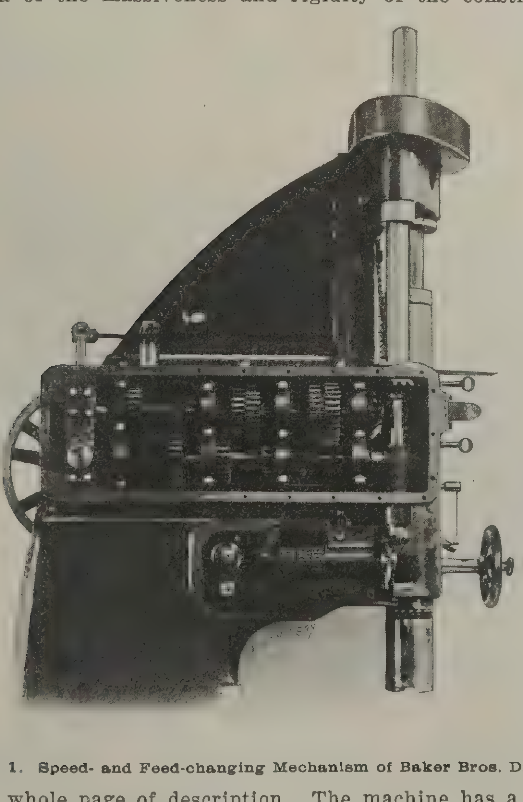


Fig. 1. Speed- and Feed-changing Mechanism of Baker Bros. Drill

There are twelve changes of feed ranging from 0.006 to 0.032 inch per revolution of the spindle. In addition, the feeding mechanism has an attachment which enables any one of the drilling feeds to be increased 3½ times, when the machine is to be used for reaming. All of the control levers are centralized and in convenient positions.

There are eight speed changes controlled by two interlocking levers in such a manner that all of the speed changes can be successively engaged; that is, the machine can be run on each of the eight speeds, beginning at the slowest and increasing to the highest, in eight seconds. A detail view of the machine is shown in Fig. 1 with the gear-case cover removed in order to show the arrangement of the speed- and feed-changing mechanisms. The spindle speeds range from 35 to 351 revolutions per minute and the changes are effected by sliding gears controlled by a lever at the front. There are no dive keys or tumbler gears in the driving train, and the entire mechanism is enclosed in an oil-tight case.

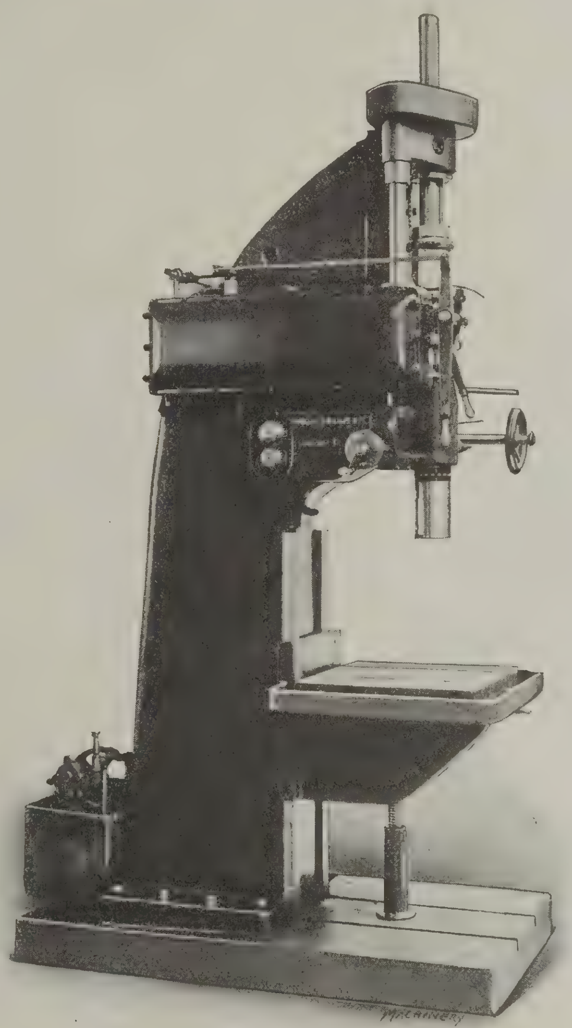

Fig. 2. Baker Bros. Heavy-duty Drilling Machine

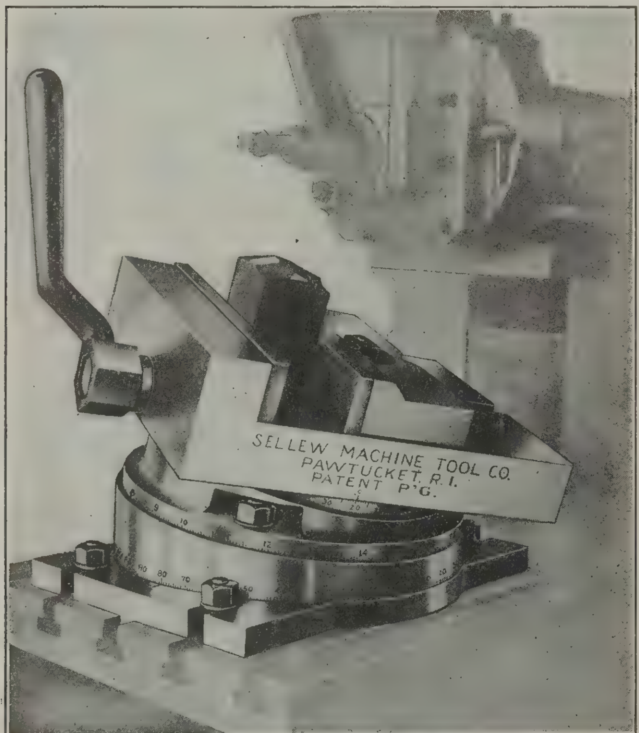
The spindle has a vertical feeding movement of 20 inches and is equipped with a depth stop. All feed changes are obtained by means of a powerful dive key and quick-change slip gears. A safety device on the spindle feed shaft is provided to protect the feeding mechanism from injury and to provide uniform wear for the large worm-gear. The spindle has the usual hand lever feed and a quick-return movement. This machine has a capacity for driving 3-inch, high-speed steel drills in solid steel. The spindle is made from high-carbon, hammered, spindle steel forgings and has a minimum diameter of 3 inches and a maximum diameter of 4¾ inches. The thrust is taken on high-duty bearings having ¾-inch balls. The end of the spindle is bored for a No. 5 or No. 6 Morse taper.

The table has a working surface of 20 by 30 inches and a vertical travel of 30 inches. The maximum distance from the end of the spindle to the top of the table is 46 inches. The swing of the machine is 36 inches, that is, 18 inches from the center of the spindle to the column. The drive is by a 3½-inch belt running on an 18-inch pulley. An oil pump, tank and the necessary piping is provided in the equipment. The weight of the complete machine is about 4750 pounds. A compound table of the box knee type can be furnished if desired. The lateral and longitudinal screw adjustments of this type of table enable the work to be positioned quickly and accurately, the handles being so located that the operator can move both simultaneously. Micrometer dials are provided on the screws for accurate adjustment.

UNIVERSAL VISE FOR MACHINE TOOLS

The Sellew Machine Tool Co., of Pawtucket, R. I., is manufacturing a vise for use on shapers, planers, drilling machines, etc. This vise can be set in any plane within the range of its angular adjustment. It is exceptionally low and provides a rigid unyielding support for the work. The vise proper is mounted on two tapering or oblique disks, and by changing the relative positions of these disks, the angular adjustment is obtained. When the thin side of the upper disk is directly above the widest or highest part of the base, the vise is in a horizontal position. By turning the upper disk, any angle



Universal Vise applied to a Shaper

within the maximum represented by the combined angles of both disks, can be obtained. The entire vise can be adjusted about a vertical axis for machining compound angles in connection with tool and die work, and the vise proper can also be turned about an axis perpendicular to the top of the upper disk.

The two oblique disks are graduated on the peripheries so that direct readings can be obtained for the angular adjustments, and radial readings for the adjustment about a vertical axis. Graduations are also provided just under the vise itself to permit adjusting the latter a definite amount regardless of the position of the base. The use of oblique disks for obtaining the angular adjustment makes the vise simple in construction and unusually low. The vise also has a solid metal support direct from the base which makes it rigid, and is conducive to accurate work. It has hardened and ground jaws and is made, at present, in 10- and 12-inch sizes. The 10-inch size has a capacity of 6½ inches, and the 12-inch, a capacity of 9 inches. The weights of the two sizes are 185 and 225 pounds, respectively. One of these vises is shown applied to a shaper in the accompanying illustration.

SHOP AND DRAFTING-ROOM LAMP ATTACHMENTS

A simple form of adjuster for regulating the height of the drop light, is shown in Fig. 1. This fitting can be attached to any flexible cord and it enables the light to be raised or lowered and automatically held at any desired height. This adjuster is made entirely of porcelain and is without springs, latches or winding drums. It operates on the double-pulley tackle principle, there being removable and stationary pulley blocks. The upper stationary member is a disk-shaped block, whereas the lower member is a ball-shaped counterbalancing device. The upper block is held by supporting chains, thereby relieving the rosette and intervening cord of all strain. Any lamp and shade not weighing over two pounds can be balanced by placing the proper number of removable lead weights inside the counterbalancing member.

Fig. 1. Adjuster for Drop Lights

This adjuster can be quickly attached to a flexible cord, either before or after the light is in place. The lamp cord from the rosette is clamped in the upper block and continues downward around the sheave of the pulley member, up over the sheave of the upper block and then through a central channel in the counterbalancing ball. Each adjuster is provided with enough removable weights to balance a lamp and shade weighing one pound. The all-porcelain construction insures good insulation and the well proportioned cord channels and sheave surfaces reduce the friction and abrasive action. This adjuster can be applied to any twisted or solid flexible cord.

Another attachment for the electric lamp is shown in Fig. 2. This is simply a clip having a forked end engaging the neck of the socket, and a hook at the other end for catching

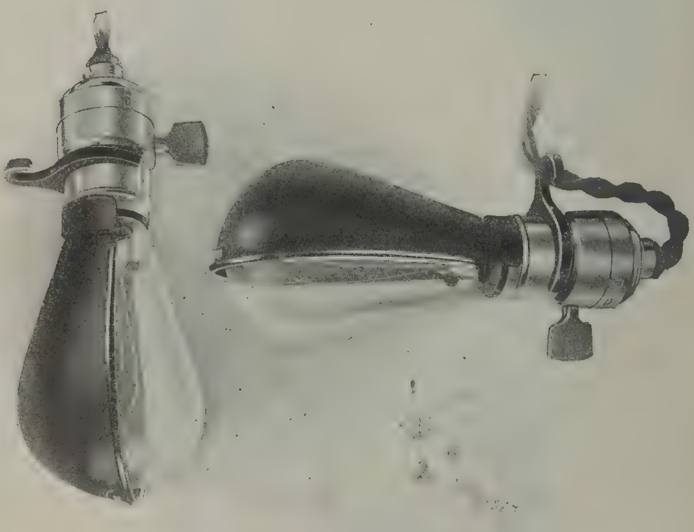


Fig. 2. Clip for Holding Lamp in Horizontal Position

the lamp cord (as shown in the view to the right) when it is desired to hold the lamp in a horizontal position. With this device, a drop-light having a side reflector, can be quickly set to throw the light downward as well as sidewise. The clip is made of a resilient insulating material and it can be applied by snapping the large end over the socket shell. This clip is made to fit any standard socket. Both of these devices are manufactured by the Sachs Laboratories, Inc., 103 Allyn St., Hartford, Conn.

THE ROBERTSON NO. 1 "ECONOMY" POWER SAW

The W. Robertson Machine & Foundry Co., of Buffalo, N. Y., is now building the hacksaw machine here illustrated. The compact design of the base of this machine will be appreciated in shops where floor space is at a premium. This is a No. 1 size, having a smaller capacity than the No. 2 power saw manufactured by this company. It cuts on the draw stroke and is equipped with the regular Robertson type of mechanical lift for the idle or return stroke. There is a quick-starting clutch and an automatic stop which comes into action when the cut is completed. The farme is mounted on a finished steel bar and has a bearing of 7 by 2 inches, which is provided with means of adjustment to compensate for wear. The machine has a capacity of 4½ inches in the vise and is driven by a 15-inch pulley of 2½-inch face. It uses either 10-inch or 12-inch saw blades and has a total weight of 180 pounds.

Robertson No. 1 Power Saw

REED-PRENTICE HIGH-SPEED GEARED-HEAD LATHE

The geared-head lathe shown in Fig. 1 is the latest product of the Reed-Prentice Co., Worcester, Mass. This lathe embodies several new and important features and is designed to give a high production with a minimum of power consumption. Formerly there was considerable friction in the bearing which supported the driving pulley, due to the high tension of the driving belt necessary because of the heavy cuts incident to the use of high-speed steels.

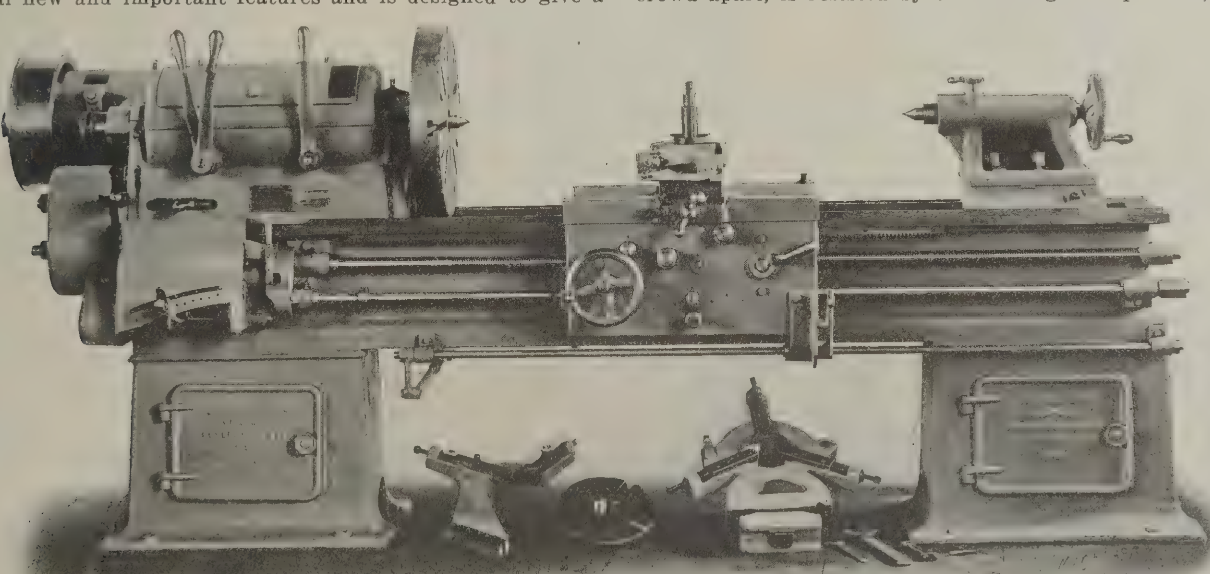

Fig. 1. Reed-Prentice 20-inch Geared-head Lathe

In the design of this new lathe, the hood *A* for the reversing mechanism (which is used principally for screw cutting purposes) and the support *B* for the pulley, are cast integral with the main head casting, as shown in Fig. 2. This gives a very rigid construction. The flanged pulley is mounted at the left end of the head, and ball bearings *C* of the "double purpose" type are used so that both radial and end-thrust loads will be provided for. The bearings are so designed that wear can be compensated for, although there is not likely to be trouble from this source. The bearings and balls are of the best alloy steel and are accurately made.

The pulley has offset or curved spokes in order to locate the rim and center of the belt, directly over the center of the supporting ball bearings. To prevent the driving belt from becoming oil-soaked and losing a large part of its pulling power, there is an annular ridge *D* on the hub of the pulley and in the center of the bearing recess, so that whether the pulley is at rest or in motion, the oil dropping into this recess will not work its way along the spokes to the face of the pulley and then onto the belt.

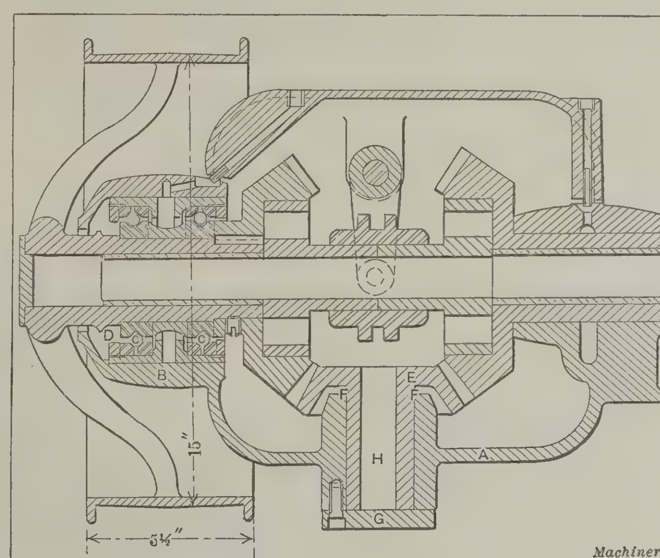

Fig. 2. Reversing Mechanism of Reed-Prentice Lathe

The method of mounting the intermediate bevel gear provides a very substantial support. When subjected to a working load, whatever tendency there may be for the bevel gears to crowd apart, is resisted by the bearing at a point *F*, close to the bevel faces and directly opposite the line of pressure. The thrust piece *G* is made oil-tight so that the hole *H* through the bevel gear can be filled with oil. This oil flows through a series of holes drilled through the hub of the gear and lubricates the bearing surface. The oil also forms a cushion be-

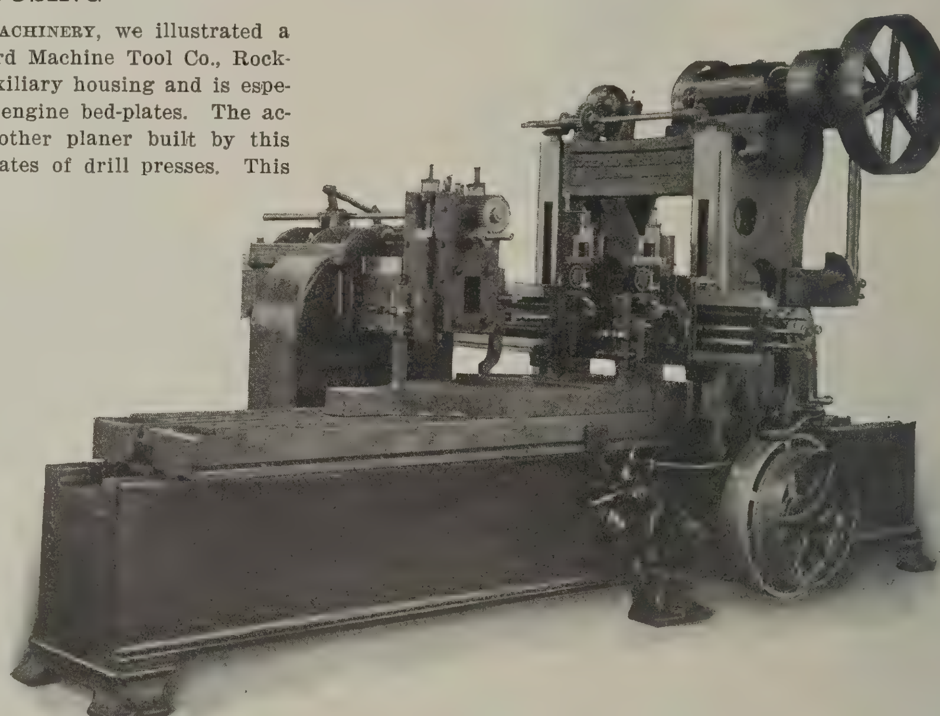
tween the walls and is said to eliminate, to a great extent, the metallic vibration between the revolving parts.

With this form of drive, any size or type of motor can readily be applied. The motor is fastened to a vertically adjusted bracket on the rear side of the leg and by means of the mechanical adjustment, the tension of the belt can be adjusted to any degree required. When equipped with a motor drive, the lathe is a complete unit having its power plant, reversing mechanism for thread cutting, and a complete range of thread and feed changes. The headstock is heavier than that of former designs and has several improvements. There is a larger hole through the spindle, larger centers and a heavier spindle nose, etc. There is also a better arrangement for overcoming the centrifugal force of the friction fingers, which has a tendency to open the friction at high speed and cause it to drag in its cup.

ROCKFORD FOUR-HEAD PLANER WITH SPECIAL HOUSING

In the September number of MACHINERY, we illustrated a special planer built by the Rockford Machine Tool Co., Rockford, Ill. This machine has an auxiliary housing and is especially designed for machining gas engine bed-plates. The accompanying illustration shows another planer built by this company for machining the baseplates of drill presses. This planer also has a special housing, although the construction differs considerably from the machine formerly described.

By referring to the illustration, it will be seen that there is a special housing carrying two tool-holders which are mounted on a ram of square construction. This ram is supported by the housing and has a lateral feeding movement, whereas the tool-slides are adjustable vertically. The power feed for the ram is obtained from a friction at the rear of the machine, which is mounted on the intermediate shaft of the planer. This friction transmits the motion to the horizontal shaft seen at the top of the housing, which connects through gearing with the horizontal feed-screw of the ram. The feeds are controlled and reversed by a trigger gear located in front of the head within easy reach of the operator. The machine is equipped with this company's standard four-speed drive giving four cutting speeds with a constant return. It is arranged for a belt drive direct from the lineshaft, eliminating the usual countershaft.

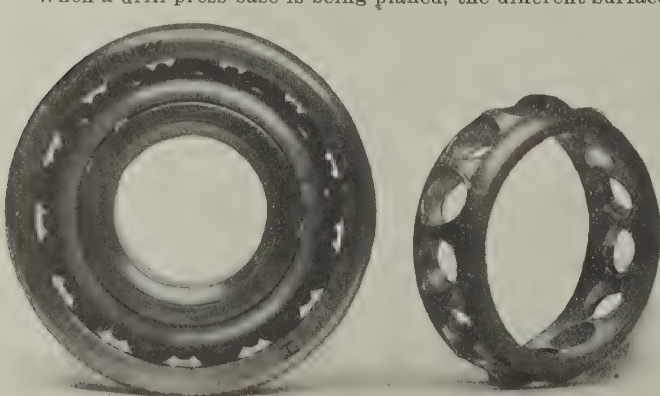


Special Planer for Machining Upright Drill-press Bases

When a drill press base is being planed, the different surfaces are machined as follows: The flat T-slotted base is planed by the two heads on the regular cross-rail. While this is being done, the rear head of the special attachment planes the top surface of the hub for supporting the drill press column, while the front head planes the pad for the outer bracket at the rear end of the base. By the use of this special attachment, three separate surfaces which vary in height are planed simultaneously. This machine is said to handle this work very satisfactorily and the castings are planed in one-half the time previously required on a similar machine without the special attachment. Of course, when an ordinary planer is used, it is necessary to plane the work at three different settings, inasmuch as the surfaces are on different planes.

GURNEY ANNULAR BALL BEARING

The Gurney Ball Bearing Co., Jamestown, N. Y., has recently placed upon the market the form of annular ball bearing herewith illustrated. The balls of this bearing are carried in a solid cast separator, which is shown beside the assembled bearing. In mounting these bearings, the inner races should have a light driving fit on the shaft, while the outer races are made a free fit in the housing. No filling slots are used and the method by which the balls are held between the races is such that the bearing is capable of carrying light thrust loads. The inner races are stamped with a number and the outer races with the corresponding number, and also the name "Gurney." The bearings are assembled in such a way that the markings on the inner and outer races are on opposite sides, and when a thrust load is to be carried the arrangement should be such that the thrust on either race comes against the stamped sides.



Gurney Ball Bearing and Alloy Retainer

NEW MACHINERY AND TOOLS NOTES

Ink Wash: W. G. Bond, P. O. Box 229, Wilmington, Del. This wash is applied by dampening the surface to be erased with a moist cloth. The ink is softened in one or two minutes and can then be wiped off. The wash is put up in one-ounce and four-ounce bottles.

Rotary Chucks: Pratt & Whitney Co., Hartford, Conn. Double and quadruple rotary chucks for the vertical spindle surface grinder built by this company. The double chuck enables two pieces to be ground simultaneously and the quadruple chuck, four pieces. The double chuck is adapted to concave grinding.

Stand for Portable Drills: Chicago Pneumatic Tool Co., Chicago, Ill. Drilling stand built to hold the Duntley portable electric drilling machines. The drill can be attached or detached very quickly and the stand will take either of the standard portable machines having capacities for drilling 3/16 or 1/4-inch holes in steel.

Radial Drilling Machine: Fosdick Machine Tool Co., Cincinnati, Ohio. New design of radial drilling machines built

in sizes having 2½- and 3-foot arms. These machines have a geared feed of the drive-key type, instead of the belt feed formerly used. The reverse and rapid traverse frictions have been made more powerful and the round table has been replaced by a box table.

Bench Filing Machine: Edge & Edwards, 34 N. 11th St., Newark, N. J. Bench filing machine, the table of which can be adjusted to any desired angle by means of two thumb-screws. The reciprocating file-holder slides in two bearings placed five inches apart. The upper bearing is bronze-bushed and can be adjusted for wear. The file-holder carries with it a cap which entirely covers the upper bearing.

Cutting-off Machine: The W. P. Davis Machine Co., Rochester, N. Y. Six-inch cutting-off machine having a geared scroll chuck on the rear end of the spindle, which is operated by a handwheel instead of a pin, as formerly. This handwheel enables the operator to make adjustments quickly. A splash guard has also been placed over the front chuck to prevent the cutting compound from flying about.

Aloxite Cloth Rolls: The Carborundum Co., Niagara Falls, N. Y. Aloxite rolls of abrasive cloth having widths varying from one-half to two and one-half inches. The cloth is tightly rolled on metal spools, each containing fifty yards. These rolls can be kept on a rack or in any convenient place in the shop. They prevent waste of material and loss of time. The Aloxite cloth is clean and sharp and cuts fast. It is made with various grades of grit.

Telpherage System: Westinghouse Electric & Mfg. Co., East Pittsburg, Pa. Telphers for handling miscellaneous packages in freight terminals, transfer stations, etc. The telpher train runs on an elevated, single-rail track and consists of a motor-driven tractor with one, two or three trailers. Each trailer is equipped with a motor-operated hoist. The tractor motor and trailer-hoist motors are controlled by an operator stationed in the cab of the tractor.

Convertible Open-side Planer: Detrick & Harvey Machine Co., Baltimore, Md. This planer is primarily a double-housing type, but by removing the outer housing or post, the machine can be converted into an open-side planer, thus greatly increasing its range and adaptability. The note published in the September number relating to this machine, was incorrect in that it referred to the planer as an openside type which could be converted into a double-housing machine.

Belt Shifter: The W. P. Davis Machine Co., Rochester, N. Y. Belt shifter applied to this company's lathe countershafts for shifting the belt from one step of the pulley to another. The device is located on the shifting rod and it leads the belt from one step to another without injuring it. In shops where the ceilings are high, it is difficult, with the usual arrangement, to change the speed of a belt-driven lathe without the use of a pole. This belt shifter is now a part of the company's standard equipment.

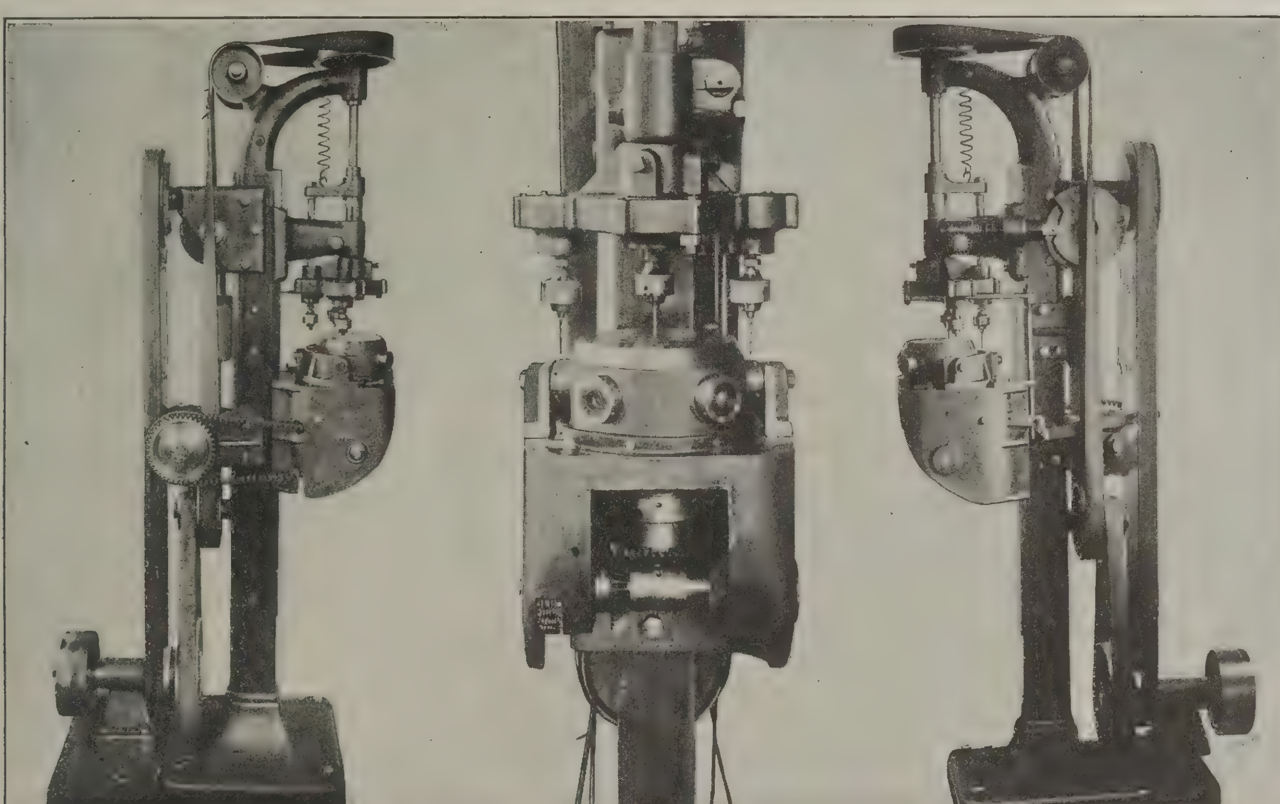
Portable Slotting Machine: Newton Machine Tool Works Inc., Philadelphia, Pa. Portable slotting machine driven by a ten horsepower Westinghouse reversing motor. The saddle has a power cross-feed of 48 inches, and if a greater traverse is required, the upright or vertical column can be adjusted by hand on the base. The length of the stroke is controlled by a master switch operated by adjustable trips or by hand. This tool has a cutting speed on the downward stroke ranging from 20 to 37½ feet per minute and a quick return varying from 42½ to 75 feet per minute. The complete weight of the machine is 23,000 pounds.

Thread-rolling Machine: E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y. Automatic machine for rolling threads on round shells having flanges or steps. It is also possible to handle straight, cylindrical pieces. The shells to be threaded are placed in a chute and are released by an automatic trip. The chute is made in two sections and the lower half swivels and carries the shells in line with the lower chuck. An automatic pusher forces the shell into the chuck where it is held by a retainer, while the upper chuck moves in and rolls the thread. At the completion of the thread-rolling operation the finished shell is automatically ejected. This machine has a capacity of 30,000 shells in ten hours, and will roll diameters varying from ½ to 3 inches.

* * *

FRANKLIN AUTOMATIC CAP-SCREW DRILLING MACHINE

An automatic cap-screw drilling machine, which reduces the work of four men to one, is the latest product of the tool-construction department of the H. H. Franklin Manufacturing Co., 203 So. Geddes St., Syracuse, N. Y. This automatic cap-screw drilling machine, three views of which are shown herewith, has the capacity of drilling holes in two thousand cap-screws a day. It is a continuously operating drill which drills three cap-screws at a time. Formerly the cap-screw holes were drilled on four separate machines. Each machine drilled one hole at a time, and two minutes was required to drill the holes in one cap-screw. This new machine not only drills three cap-screws at a time but, after the cap-screw is completely drilled, it is automatically forced from the machine and all the operator has to do is to insert another cap-screw. This one machine will take care of the drilling of all the cap-screws needed in the manufacture of Franklin automobiles.



Automatic Machine that will drill Holes in 2000 Cap-screws a Day—built by the H. H. Franklin Mfg. Co.

The turret in which the cap-screws are inserted, holds five at a time. There are three drills operating simultaneously and each one drills a hole through one cap-screw. After the holes have been drilled and the drills back out, the turret revolves and, at the same time, each cap-screw is turned over

so that when it arrives at the next drill, a hole is drilled through another side. In this way each cap-screw has a hole drilled through it by each one of the three drills. After the third drill has finished its work and the turret revolves again, the screw is ejected from the machine automatically.

The turret revolves through an arc of 72 degrees for each indexing and the screws are revolved through an arc of 120 degrees. The turret is worked about by a cam. As the turret revolves, an automatic spring-plunger ejects the cap-screw which has been completely drilled. The drilling head is also fed by a cam which is shown in the view to the right. This cam engages a horizontal spring-plunger having a rack cut on the front end which meshes with a pinion connecting with the spindle quill. At the back of the turret there is a guide which holds the three cap-screws being drilled, firmly in their places. The machine uses 3/32-inch drills and will drill cap-screws from 5/16 inch to 1/2 inch in diameter.

These cap-screws are used in all parts of the Franklin motor and car. The object in drilling holes through the heads of the cap-screws is for locking them. When the engine has been assembled, a wire is drawn through the holes in the cap-screws, completely locking them and preventing their working out, thus providing a perfect safety device.

F. A. GEIER TWENTY-FIVE YEARS WITH CINCINNATI MILLING MACHINE CO.

Frederick A. Geier, president of the Cincinnati Milling Machine Co., gave a dinner on Friday evening, September 13, in Cincinnati to some of his friends and business associates to celebrate the twenty-fifth anniversary of his connection with the business. The growth of the Cincinnati Milling Machine Co., which operates one of the two or three largest and best equipped machine tool works in the world, has been coincident with the advance of the machine tool industry in this country, and illustrates in a striking manner what can be accomplished by energy, perseverance and business ability. For the steady and continued development of this great enterprise from small beginnings, Mr. Geier is responsible, although he has had the help of able mechanics from the outset; and it is fitting that his twenty-fifth anniversary should be celebrated in company with several of the men who helped him to achieve success, as well as others well known in the machine tool industry and in Cincinnati business circles. Those present at the dinner were: H. T. Atkins, Albert Bettinger, George H. Bohrer, E. M. Chace, George D. Crabbs, A. L. DeLeeuw, E. F. DuBrul, Lewis N. Gatch, Frederick V. Geier, Dr. Otto P. Geier, P. O. Geier, C. S. Gingrich, Louis J. Hauck, Prof. F. C. Hicks, J. C. Hobart, Robert Hochstetter, Fred Holz, Sr., F. W. Jaeger (New York), George H. Kattenhorn, Ernst Krause (Vienna), Louis S. Levi, William Lodge, P. G. March, Alfred Marshall, George E. Merryweather, James P. Orr, George Puchta, B. B. Quillen, H. M. Ramp, Sherman Schauer, Prof. Herman Schneider, Murray Shipley, Nelson W. Strobridge, Dr. C. W. Tangeman, A. H. Tuechter, C. Wood Walter, Dr. J. M. Withrow.

JOINT MEETING OF A. S. M. E. AND V. D. I.

The council of the American Society of Mechanical Engineers has accepted an invitation from the council of the Verein Deutscher Ingenieure to hold a joint meeting with them in Leipzig, June 23-25, 1913. The meeting will be followed by an official tour of the industrial centers of Germany and will include a trip on the Rhine and special opportunities for a comprehensive study of the Great Museum of the Technical Arts and Industries at Munich. Many establishments will be thrown open that could not be visited under other auspices, and extraordinary and unique opportunities will be afforded the members of the party to familiarize themselves with the latest developments in every industry. Invitations to visit firms throughout Germany have been received.

It is desired that the party be large enough to warrant chartering an entire steamer. This would afford a minimum expense with a maximum of pleasure and personal comfort. Past President E. D. Meier is chairman of the committee on arrangements.

DIE CASTING AUTOMOBILE MOTOR BEARINGS

The manufacture of die castings is one of the numerous lines of manufacture which has advanced rapidly with the growth of the automobile industry. The production of die castings originated with the H. H. Franklin Mfg. Co., Syracuse, N. Y., about nineteen years ago. As is generally known, die castings are produced in steel dies instead of sand molds. By the substitution of steel dies for the sand molds and the use of pressure for conveying the metal from the pot into the die, a degree of smoothness and accuracy is secured which equals, and often surpasses, that obtained by the usual machining operations. The result is that the castings are practically ready for assembling without additional machine work.

At first the die-casting process was confined to the manufacture of electrical instruments, phonographs, computing machines, etc., for producing small, accurate parts which were expensive to finish by the common methods of machining. When the Franklin Co. entered the automobile field, experiments were made with die casting in order to determine to what extent it could be used in automobile construction.

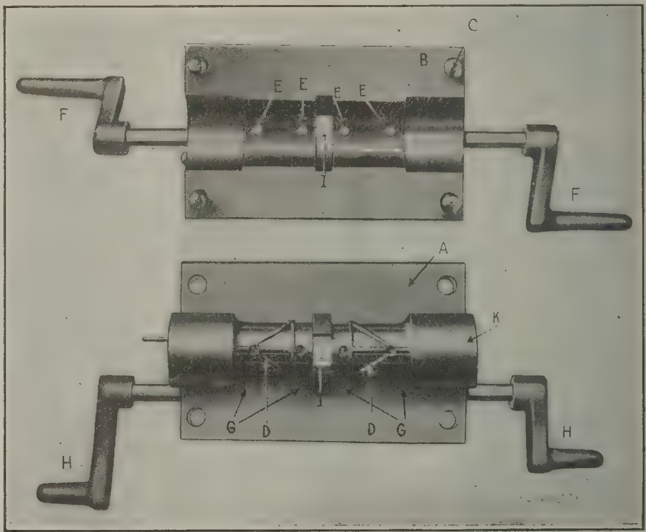

Fig. 1. Die used by H. H. Franklin Mfg. Co. for Producing Bearings by the Die-casting Process

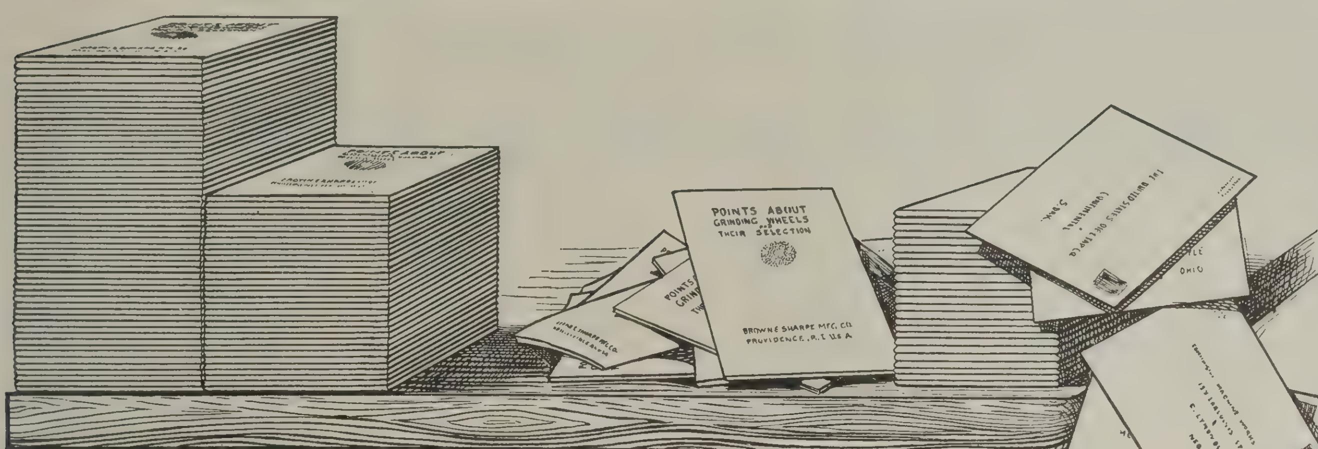
For most automobile parts, either because of their size or intended use, the process was not practicable, but for the production of bearings it was found ideal. The accuracy of the die-cast bearings makes additional machining operations unnecessary and only such scraping and reaming as is customary in the assembling of machined bearings, is required. The high pressure of the die-casting process, combined with the chilling received from the die, gives a hard, close-grained bearing surface, which is of considerable value.

The first die-cast bearings used in automobile construction were for the connecting-rods of the Franklin 1904 motors. These bearings were made of hard babbitt and replaced machined phosphor-bronze. Their success was so marked that babbitt has almost entirely replaced phosphor-bronze as a bearing material in the Franklin motor. It is probably true that one grade of babbitt will not meet all conditions, yet the range of babbitt metals would seem to be sufficiently wide to insure satisfactory results. For instance, in an engine where the heat generated is purely frictional, the addition of a small percentage of lead is probably an advantage, although in engines where the bearings are subject to external heat, a tin, antimony and copper babbitt, devoid of lead, is imperative.

The construction of one of the Franklin dies is illustrated in Fig. 1. The die consists of upper and lower plates which are held rigid by dowels *C*. On the lower half is located the main core *K* and in this are the cores *D* for the oil grooves. These oil-groove cores are either formed by cutting down the main core so as to leave the oil-groove cores raised in relief, or by slotting the main core and "letting in" small cores, which are then located securely. The lower half also contains a set of ejector pins *G* operated by levers *H*. The upper half is more simple. The depression conforms to the outside



Is Your Name on the List?

We are ready to mail out to everyone interested a copy of our New Book, entitled

Points about Grinding Wheels and their Selection

This **forty page**, attractively and serviceably bound book treats of the subject in a concise manner, and contains information that it would be difficult to gain short of an extensive study.

Do you know what wheels to select for facing shoulders, for disc grinding, or for internal grinding? Have you at hand any ready means of determining how to order wheels?

These and many other points are taken up thoroughly in the book; in fact it is a regular treatise on grinding wheels. **It contains useful information for everyone from owners to operators of machines.**

Occupation..............................

of the bearing, and contains the cores *E* for the dowel holes. These cores are operated by levers *F*, and also act as ejectors in case the bearings stick in the upper half of the die.

Both halves contain corresponding gate holes *I* in which the gate operates. When in operation, the closed die is fastened between the upper and lower halves of the die vise, which is placed directly over the casting machine. The cores for the dowel-pin holes are thrust forward and the ejector pins are drawn back even with the face of the die plate, after which the gate is turned back to allow the metal to enter. The metal is then forced in, and when the die is full the gate is sheared off and only a slight mark (which is sometimes imperceptible) is left instead of the usual heavy sprue common in sand castings. The die remains closed only long enough for the casting to set. When it is opened and the ejector pins are thrust forward by means of levers *H*, the casting is loosened from the main core where it usually sticks

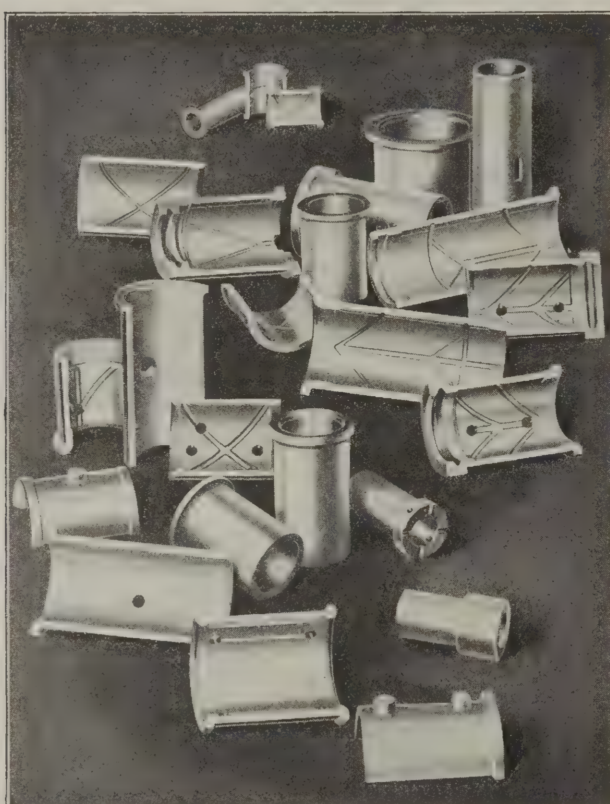

Fig. 2. Group of Die-cast Bearings

somewhat. Fig. 2 shows a number of bearings produced by the die casting process.

The construction and working of the various dies differ, of course, in accordance with the parts to be produced. On account of the effect of high temperature on the dies, the metals available are limited. At present, lead, and tin and zinc base alloys are chiefly employed.

The accessory manufacturers have found die castings, especially of the harder alloys, well adapted to such parts as timer bodies, and the framework of magneto and lighting systems. In addition to the bearings, the automobile manufacturers are using die castings extensively for such parts as oil and water pumps. As the process is constantly being developed, both in regard to materials used and the size of the castings made, it is probable that die castings will in the future, have an even greater place in automobile construction than at present.

* * *

MACHINERY's tenth annual outing will be held on October 19, following the National Machine Tool Builders Association convention. It will be of a similar character to the previous outings, comprising a steamer trip in the waters around New York.

* * *

In selecting the number of teeth in a gear, care should be taken to select such numbers as can be obtained by ordinary indexing methods, without the use of special gears.

PERSONALS

Lucius I. Wightman, a well-known publicity man, recently joined with Joseph A. Richards & Staff, Tribune Bldg., New York, forming the firm of Wightman & Richards.

George W. Burley, instructor of machine shop practice in Sheffield University, England, and a well-known contributor to the British and American mechanical journals, sailed for home September 5, having spent a month in the United States.

F. G. Kretschmer of F. G. Kretschmer & Co., Frankfort-on-Main, representative in Germany of many well-known American machine tool builders, will visit the United States early in October. His address during his stay will be Hotel Astor, New York.

Louis L. Burghoff, lately connected with the New England Watch Co., Waterbury, Conn., as assistant superintendent, has taken a position with the Remington Arms–Union Metallic Cartridge Co., as assistant equipment engineer of the gun works at Ilion, N. Y.

Dr. Conrad Matschoss, lecturer at the Royal Technical Institute (dozent der Konigliche Technische Hochschule) Charlottenburg, Berlin, Germany, and a writer on industrial science, is making a tour of American manufacturing centers as representative of the Verein Deutscher Ingenieure (Society of German Engineers). Dr. Matschoss is keenly interested in the comparative average intelligence and educational qualifications of German and American workmen.

Prof. George B. Thomas of Colorado College, Colorado Springs, Colo., was selected by the Westinghouse Electric & Mfg. Co., to take charge of twenty-eight representatives of the engineering faculties of twenty-four colleges in the United States who were on the payroll of the company at the works during the past summer. These instructors were studying the practical side of engineering so as to be better fitted to instruct their students. They were engaged as regular employes and were assigned check numbers the same as other workmen. The work made them familiar with the requirements of engineering work and the advances that are being made in the design of electrical apparatus.

OBITUARIES

Milton G. Puffer, inventor of the machine for making envelopes, died recently at Willimantic, Conn., aged ninety-three years.

John Hope, inventor of the pantograph engraving machine and other devices used in engraving, died at his home in Providence, R. I., September 8, aged ninety-two years.

William S. Lamson, inventor of the Lamson carrier system for store service, and treasurer of the Lamson Consolidated Store Service Co., died at his home in Lowell, Mass., August 16, aged sixty-six years.

Charles F. Putnam, president of the Putnam Machine Co., Fitchburg, Mass., and one of Fitchburg's best known business men, died August 29 at Massapequa, L. I., aged sixty-seven years. Mr. Putnam had been in poor health for a year and a half but attended to his daily duties with the Putnam Machine Co., up to the time of going to Brooklyn, N. Y., in May, where his daughter lived. His entire business life was devoted to the Putnam Machine Co., with which he was connected in various capacities during his earlier life. Shortly after the death of his father, Salmon W. Putnam, in 1872, the company was reorganized, at which time the deceased was elected president, his brother Salmon W. Putnam, Jr., vice-president, and the late Henry O. Putnam, treasurer. Mr. Putnam was married in 1872 to Miss Coralie J. Lawrence of Pepperell. A daughter, Mrs. Edith Ormsbee of Brooklyn, a brother and four sisters survive him.

WILLIAM J. FLATHER

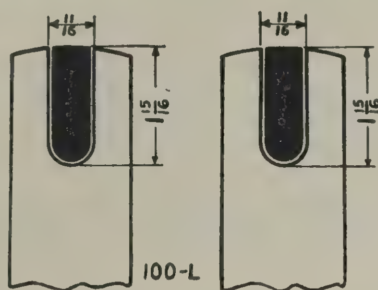
William J. Flather, one of the founders of the Flather machine tool companies of Nashua, N. H., died at his home in Nashua, September 10, 1912, of heart failure, following a short illness caused by arterial sclerosis.

Mr. Flather was born in Norwich, England, in 1841. The family moved to Bradford in 1849, where, after receiving a common school education, he entered the employ of his uncles, William and Henry Hodgson, manufacturers of worsted machinery. His father being in poor health was advised to come to America, which he did, sailing for Philadelphia in 1856. The following year William followed with other members of the family, soon after settling on a farm near Rainsboro, Highland County, Ohio. During the next few years he was employed as a machinist at Harpers Ferry, Va.; Lowell Machine Shop, Lowell, Mass.; Chase & Co., Nashua; and the Grover & Baker Co., Boston. After the Civil War broke out he enlisted in a Pennsylvania company, but on account of his mechanical ability was transferred to the Frankfort Arsenal at Bridesburg, Philadelphia, where he remained throughout the war.

In 1866 Mr. Flather with his brothers moved to Parkersburg, W. Va., and established a shop for the manufacture and

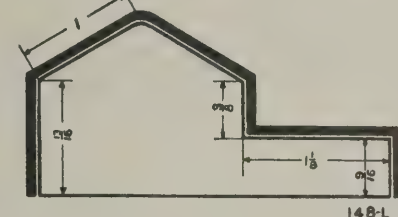
Some Examples of Work done on the

No. 2 Plain Cone Driven Cincinnati Miller



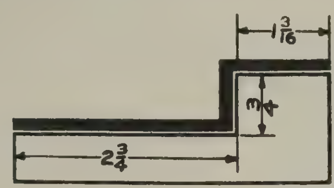
100-L

Material, 40 Carbon Steel.
Size of cut, 11-16" wide, 1" deep, 1 15-16" long.
Cutters, 6" in diameter.
Two Pieces are milled at one time.
The work is held horizontally and fed directly into the Cutter at a travel of 1" per minute.



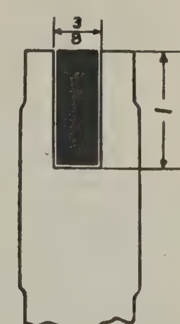
148-L

Material, Cast Steel.
Total width of cut, 5".
Depth of cut, 1-16" to 3-32".
Thickness of piece, ⅞".
Largest Cutters, 5½" diameter, 53 revolutions.
Feed, 2.9" per minute.
Four Pieces are held in a jig at one time.
Total time per piece, 1¼ minutes.



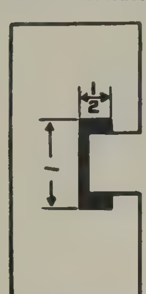
190-L.

Material, Cast Iron.
Total width of cut, 4 11-16"; depth of cut, ⅛"; length of cut on each piece, 1⅛".
Cutters, 4½" and 3" diameter.
Twenty-four Pieces are held in a string jig at one time.
Feed, 1⅞" per minute.
Finished surfaces are accurate within .001."



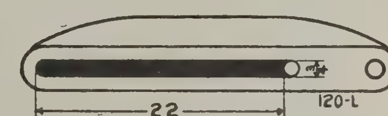
169-L

Material, Steel Forgings.
Cut consists of a slot 1" deep, ⅜" wide at a table travel of 4" per minute.
Cutter, 3½" in diameter, ⅜" face, 53 revolutions.
The pieces are of irregular form and 5 of them are held in a string jig at one time. The length of cut in each piece is approximately 1".



168-L.

Material, Cast Iron.
Cut consists of undercutting T slots, with a Cutter 1" diameter, ½" face, running 286 revolutions. Our average rate of feed on this work is 15¾" per minute.



120-L

Material, Cast Iron Bars. 1" thick.
A slot ¾" wide is cut through the solid at one cut, starting from a drilled hole with a ¾" diameter, 3 fluted end mill at 3⅝" table travel per minute.
Metal removed per minute is equivalent to a bar 1" x ¾" x 3⅝" long. Actual cutting time for slots 22" long, 6 minutes.

For the usual Tool Room work; for repair work; for manufacturing small machine parts—in fact, for all work on which the cutting is light, a modern Cone Driven Miller will bring you bigger returns for your investment than a Single Pulley Drive Machine.

We have redesigned ours, brought them up to date, made them handier than ever before, and we are offering a full line for all that work for which they are especially adapted. we also make a full line of single pulley High Power Millers for the heavier classes of milling.

The Cincinnati Milling Machine Company

CINCINNATI, O., U. S. A.

repair of oil-well tools. As this venture did not prove remunerative he returned to Nashua, and with his brothers entered a partnership with the late J. K. Priest who at the time manufactured sewing machines but who later established himself under the title of The American Shearer Co., as a manufacturer of clippers of all kinds. It was the intention of Mr. Priest and the Flather brothers to build lathes also, but the lines were so dissimilar that the partnership was soon dissolved, the Flathers taking over the manufacture of lathes under the firm name of Flather Brothers. Later the name was changed to Flather & Co., the concern consisting of Mr. Flather and his brother Joseph, as active members, and Edward Flather as a silent partner. The high quality of their hollow spindle engine lathes, then somewhat of a novelty, secured them such agents as Hill, Clarke & Co., of Boston, and a certain amount of success. In September 1876 their factory was destroyed by fire, being practically a total loss. With the small amount of insurance received, it was with difficulty that they rebuilt. They had, however, exhibited their lathes at the Centennial Exposition in Philadelphia, which attracted favorable notice from several European manufacturers, resulting in their initial foreign business. After the panic years of the late 70's, their success was firmly established and the business steadily grew in size to its present capacity.

Mr. Flather was also one of the founders of the Mark Flather Planer Co., Flather Foundry Co., and the E. J. Flather Mfg. Co., withdrawing in 1901 from Flather & Co., and the Mark Flather Planer Co. At the time of his death he was president of the Flather Foundry Co., and was actively identified with the E. J. Flather Mfg. Co. He had marked mechanical ability, sound judgment and a faculty of quietly impressing his convictions on his business and other associates. Although a man of retiring disposition, he had an extensive acquaintance in this country and Europe. He was much interested in civic and state affairs, having served as a member of the city government, board of education, state legislature and constitutional convention. He was also a thirty-second degree Mason and prominent in financial circles, being a director of the Indian Head National Bank for twenty-five years. Mr. Flather was actively interested in religious work, being an officer and trustee in several Methodist Episcopal church societies and institutions, including Tilton Seminary. In May of this year he was chosen one of the two lay delegates from New Hampshire to the Methodist Episcopal General Conference at Minneapolis, at which he took an active part. While his early education was interrupted by the migrations of his father's family he was a student all his life, attending evening schools when employed at Philadelphia and devoting much of his leisure time to study and travel, both in this country and Europe. He is survived by his widow; a daughter, and two sons, Ernest J. and Harry E. Flather.

* * *

COMING EVENTS

October 4-26.—International Machinery Exhibition at Olympia, London, England, organized by the Machine Tool and Engineering Association, Ltd.

October 7-11.—Annual convention of the American Electric Railway Association and allied associations in Chicago, Ill. The exhibit will be at Dexter Pavilion, 43d and Halstead Sts. H. C. Donecker, secretary-treasurer, 29 W. 39th St., New York.

October 16-18.—Annual convention of the National Machine Tool Builders' Association in New York; headquarters, Hotel Astor. James H. Herron, general manager, Cleveland, Ohio.

December 3-6.—Annual meeting of the American Society of Mechanical Engineers in New York. Calvin W. Rice, secretary, 29 W. 39th St., New York.

SOCIETIES, SCHOOLS AND COLLEGES

Pratt Institute, Brooklyn, N. Y. Circular describing the evening technical courses conducted by the School of Science and Technology at Pratt Institute. These courses offer unusual opportunities to young men who would devote their evenings to studying mechanical drawing and machine design.

Michigan College of Mines, Houghton, Mich. Year book 1911-1912 and announcement of courses for 1912-1913. The year book contains the usual information relating to admission to the college, courses and departments of instruction. It also contains a map of the Portage Lake mining district showing the location of the college in the midst of an active mining territory. Another map shows the mineral district of the upper Michigan peninsula, with the various iron and copper ranges accessible from the college.

NEW BOOKS AND PAMPHLETS

Natural Gas: Its Properties, Its Domestic Use, and Its Measurement by Meters. By P. F. Walker. 38 pages, 6 by 9 inches. 10 illustrations. Published by the University of Kansas, Lawrence, Kans.

This engineering bulletin No. 2, published by the Engineering Experiment Station of the University, contains a report on the subject of natural gas prepared for the Public Utilities Commission of the State of Kansas. The most interesting part of the bulletin is that which relates to the meters for gas, showing the effect of different rates of flow and pressure differences on different makes of meters.

High Explosives. By W. R. Quinan. 210 pages, 6 by 8½ inches. Published by Critchley Parker, Melbourne, Australia. Price, 21 shillings, net.

This book is a treatise on high explosives, mainly from a scientific point of view. The contents of the book are as follows: Historical; Velocity of Detonation; Industrial Explosives; Australian Conditions; Theory of Explosive Energy; Available Energy or Maximum Work; Useful Work; Strength of Explosives; Theories of Explosion; Dissociation; Detonation of Gaseous Mixtures; Dissociation of Explosives—Specific Heats—Boyle's Law at High Densities.

Strength of Materials. By Mansfield Merriman. Sixth Edition. 169 pages, 5 by 7½ inches. Published by John Wiley & Sons, New York. Price $1.

This is one of the standard references on this subject which has become generally known to the profession in its previous edition. In the sixth edition a new chapter on combined stresses has been added. Numerous changes have also been made throughout the text and ninety new review problems added to illustrate the principles treated in each chapter of the book. The number of illustrations has also been increased from forty-eight to fifty-four and the number of articles from seventy-two to ninety-one. It is hoped that the book in its new form may be even more valuable in furthering the progress of technical education than it has been in the past.

Materials and Construction. By James A. Pratt. 196 pages, 5 by 7 inches. Published by P. Blakiston's Son & Co., Philadelphia, Pa. Price 90 cents.

The material in this book has been published with the view of presenting an elementary text for students in technical schools; also as a reference on the more simple problems of construction. Each chapter of the book concludes with problems of a practical nature which not only explain the preceding principles but give the student practice in applying them on the class of problems which he is likely to meet with in engineering practice. One of the notable features of the presentation of material in this book is the method of illustrating. In many cases rough sketches are used, the idea being to familiarize the student with this practice which is followed in many factories, rather than to let him rely entirely upon accurate working drawings.

Manual for Engineers. By Charles E. Ferris. 248 pages, 3 by 5¾ inches. Published by the University of Tennessee, Knoxville. Price 50 cents.

This useful pocketbook which has passed into the seventeenth edition was compiled with the view of interesting the controlling men of the South in technical education as a means of developing the undeveloped resources of their section. Following the pages devoted to the courses of study offered by the University of Tennessee and its equipments and facilities, the book is devoted to the presentation of useful technical data. This section includes mathematical tables, the properties of engineering materials and data pertaining to the transmission and generation of power, to electric wiring, to hydraulics, and to the effect of heat on various materials. Especial attention is called to the excellent presswork and binding which make it attractive to the user.

American Machinist's Grinding Book. By Fred H. Colvin and Frank A. Stanley. 383 pages, 6¼ by 9¼ inches. Published by McGraw-Hill Book Co., New York City. Price $3 net.

The wide application of grinding machines of suitable forms to adapt them for a variety of operations in the manufacture of machinery and of finished metal parts in general, suggested the desirability of presenting material on the subject of grinding in the form of a reference book. The idea in so doing was to present reliable data on the machines, wheels and methods, that is likely to be of interest and service to those engaged in the grinding department. In presenting their subject the authors have dealt separately with the different types of machines in regard to their application in different classes of manufacture. The methods of mounting the wheels and of dressing them are then taken up, and later a number of particular classes of work are dealt with in detail. The authors have drawn upon the columns of different technical papers and also acknowledge assistance received from the manufacturers of grinding machines in securing the data which they have presented.

Shop Arithmetic. By Earle B. Norris and Kenneth G. Smith. 187 pages, 6¼ by 9¼ inches. Published by McGraw-Hill Book Co., New York. Price $1.50.

Many a good mechanic is held back by a lack of mathematical knowledge which makes it necessary for him to "ask the boss," whenever there is any figuring to be done. Such men find it difficult to acquire knowledge that is of much value to them from an ordinary textbook on arithmetic. This is largely due to trouble in applying arithmetical methods to practical problems. In the present book, the mechanic should be saved from this difficulty by the practical problems which follow the discussion in each chapter. Thus the treatment of addition of fractions is followed by exercises in finding the overall dimensions of drawings scaled off in the usual way. A discussion of the micrometer caliper follows the chapter dealing with decimals. Similarly the treatment of methods to find the areas and volumes of different shaped figures is followed by practical problems. The latter section of the book deals with problems occurring in the simpler branches of mechanics. Treated in this way, the mechanic should be able to acquire the knowledge of arithmetic he requires in his work without the aid of an instructor.

Practical Descriptive Geometry. By William Griswold Smith. 208 pages, 6 by 9 inches. 132 illustrations. Published by McGraw-Hill Book Co., New York. Price, $2.

The author of this book, who is assistant professor of descriptive geometry at the Armour Institute of Technology, has endeavored to emphasize the relation which exists between descriptive geometry and drafting. In preparing the book, his aim has been to present the subject in such a manner as to arouse the interest of the student. A large number of exercises are provided, the author believing that a thorough knowledge of the subject is achieved not through much study of the text, but through working exercises. The book is divided into four specific parts, the first dealing with definitions, notations, preliminary theories and exercises; the second, with problems relating to points, lines and planes; the third, with curved lines and surfaces; and the fourth, with perspective and isometric projection. The extent to which the idea of presenting a great number of exercises has been carried can be best understood by noting that there are 860 different problems presented, of which about one-quarter are of such a nature as may be met in actual practical drafting. Most of the exercises are dimensioned so as to require the student to make his drawing according to some predetermined scale.

Machine Design; Hoists, Derricks, Cranes. By Henry D. Hess. 368 pages, 6½ by 9⅜ inches. Published by J. B. Lippincott Co., Philadelphia, Pa. Price $5.

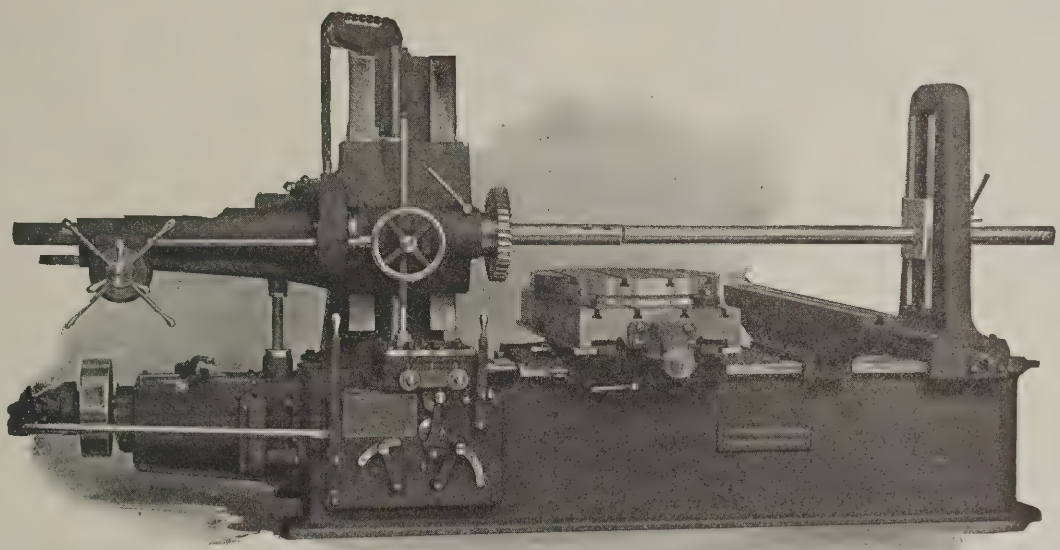
The details comprising the structure of a crane include a large variety of the simpler forms of mechanism met with in many classes of machinery. The stresses which occur in both the frames and machinery are also such that they are readily determined by analytical methods. These conditions have made the presentation of methods used in crane design valuable in two directions: The general reader can acquire accurate data on the design of the common forms of mechanism met with in most classes of machinery. Those seeking specific information on the subject of crane design will also welcome the book as a reliable source of information. The first four chapters are devoted to a discussion of the properties of various materials used in machine construction and to the design of the types of mechanism and structural members applied in cranes of the different forms that are treated. The eight succeeding chapters cover the standard practice followed by the designing departments of leading American crane builders. The book is expected to meet the requirements of the field of machine design covered in technical colleges. Drafting-rooms work-

Some Expert has said: "Don't Advertise the Obvious"
but we wish to break this rule enough
to say that the

"PRECISION"

Boring, Drilling and Milling Machine

was ALWAYS the BEST, and is now
BETTER THAN EVER



It has *feeds* in every direction and a *constant speed quick return* for every feed; *one* handle starts whichever feed is wanted, and the *reverse* motion of the *same* handle starts the quick return always in the opposite direction from the feed.

The constant speed Quick Power Movement is accomplished by separate mechanism and does not operate through the feed change gears.

AGENTS—C. W. Burton, Griffiths & Co., London. Alfred H. Schutte, Cologne, Berlin, Brussels, Paris, Milan, Barcelona, Bilbao. Donauwerk Ernst Krause & Co., Vienna, Budapest, Prague. Overall, McCray, Ltd., Sydney, Australia. Andrews & George, Yokohama, Japan. Williams & Wilson, Montreal, Can.

CONTENTS FOR OCTOBER

The first column of page numbers applies to the Engineering and Railway Editions: the second to the Shop Edition.

ing upon general classes of machine design should also find it of value, and the careful attention to detail which has been observed in the preparation of this book should make it favorably received in a variety of designing establishments.

NEW CATALOGUES AND CIRCULARS

Geuder Paeschke & Frey Co., Milwaukee, Wis. Circular of "Cream City" electric butt and spot welding machines.

Electric Controller & Mfg. Co., Cleveland, Ohio. Bulletin No. 1026 entitled "The Youngstown Safety Limit Stop for Direct-current Motors."

R. D. Nuttall Co., Pittsburg, Pa. Supplement to catalogue No. 10 on forged steel motor gears and pinions, containing twenty-nine pages of gear lists.

Brown Hoisting Machinery Co., Cleveland, Ohio. Catalogue E of "Brownhoist" buckets and tubs for handling ore, coal, gravel, sand, earth and other materials.

Vulcan Engineering Sales Co., 2014 Fisher Bldg., Chicago, Ill. Circular of the "Mumford" jolt ramming machines for foundries, enumerating their advantages.

Electro-Dynamic Co., Bayonne, N. J. Data sheets Nos. 3, 4 and 5 on wiring diagrams of interpole motors with Cutler-Hammer compound non-reversible and reversible drum controllers.

Gurney Ball Bearing Co., Jamestown, N. Y. Catalogue of annular ball bearings having full complement of balls, unbroken raceways, and full depth of raceways; also ball thrust bearings of the plain and grooved types.

Foote Bros. Gear & Machine Co., 210-220 N. Carpenter St., Chicago, Ill. Catalogue and price-list No. R on "IXL" speed reducers which are made of the spur gear and worm gear types in a large number of sizes.

C. W. Hunt Co., West New Brighton, N. Y. Catalogue No. 12-8 on manila rope for transmission and hoisting, being a brief treatise for engineers on the manufacture and characteristics of ropes, with formulas, tables and data useful in mill engineering.

Walter B. Snow, 170 Summer St., Boston, Mass. Booklet entitled "Publicity Engineering," outlining the scope of Mr. Snow's activities in engineering publicity work and showing in what radical respects they differ from those of the typical advertising agencies.

General Electric Co., Schenectady, N. Y. Bulletin No. 4995 on direct current switchboards, double polarity, 125, 250 and 600 volts; No. 4996 on alternating current switchboards with oil switches, three-phase, three-wire 240, 480 and 600 volts, 25 to 60 cycles.

Racine Tool & Machine Co., Racine Junction, Wis. Circular illustrating No. 7 high-duty metal cutting machine of the hacksaw type, having capacity from 0 to 12 inches and using blades 17 to 24 inches long. The machine is especially adapted for structural work, being arranged for cutting I-beams, angles, channels, etc.

D. & W. Fuse Co., Providence, R. I. Leaflet describing D. & W. fused switch boxes, being an improved combined switch and fuse box particularly adapted for mill service, etc., inasmuch as it may be locked after the fuses are installed, thereby preventing tampering with the connections and increasing the capacity of the fuses.

National Tube Co., Pittsburg, Pa. Pamphlet entitled "Modern Welded Pipe" illustrating and describing the processes from the mining of the ore through the reduction of the ore to steel, rolling the skelp, lap welding, butt welding, testing, threading, etc. The illustrations are effectively printed in colors, thus showing the metal being worked in the hot state.

Davis-Bournonville Co., 97 West St., New York. Folders Nos. 6 and 7 illustrating examples of locomotive repair work and Davis-Bournonville style C oxy-acetylene welding and cutting torches. The examples of locomotive repair work comprise welding broken frames, firebox cutting and welding, welding firebox cracks, building up thin spots, welding broken driving wheel spokes, etc.

Westinghouse Electric & Mfg. Co., E. Pittsburg, Pa. Descriptive leaflet No. 2480 giving directions for ordering motors for driving machine tools. In addition to giving the characteristics of voltage of direct-current circuits and voltage, phase and frequency of alternating-current circuits, it is necessary also to specify the horsepower and speed. The Westinghouse engineers will advise regarding the power and speed of motors for any type of machine tool.

Standard Mfg. Co., Bridgeport, Conn. Catalogue of gear cutting, milling and slitting machines, consisting of twenty-four pages, 6 by 9 inches, with embossed cover. The catalogue illustrates and describes "Standard" machines Nos. 1, 2, 3 and 5, showing examples of typical commercial work performed; also machines with special attachments adapting them to cutting worms, racks, slitting dials, cylinders, etc. The special work to which these machines can be adapted makes them of unusual interest to manufacturers generally.

Charles H. Besly & Co., 118-124 N. Clinton St., Chicago, Ill. "Besly's Modern Disk Grinding Practice," a treatise on the art of disk grinding, with special reference to reducing cost of flat surfacing in machinery construction, illustrating and describing the extensive line of grinding apparatus made by the company. The growth of the disk grinding art in the past few years and its present importance can be somewhat appreciated by referring to this comprehensive and interesting publication. The first edition containing 40 pages and 23 illustrations was issued two years ago. The present edition contains 111 pages and 103 illustrations.

Westinghouse Electric & Mfg. Co., E. Pittsburg, Pa. Descriptive leaflet No. 3516 listing machine tool motor applications and giving horsepower ratings and classes of motors used. This leaflet covers applications to bolt and nut machinery, boring and turning mills, bulldozers, buffing lathes, drilling and boring machines, cylinder boring machines, pipe threading and cutting-off machines, planing machines, rotary planing machines, hydrostatic wheel presses, punching and shearing machines, punches, shears, shaping machines, bending rolls, cold saws, horizontal boring, drilling and milling machines, multiple spindle drilling machines, emery grinders, grinding machines, gear cutting machines, engine lathes, milling machines, etc.

Hill, Clarke & Co., 125 N. Canal St., Chicago, Ill. "Machinery Bluebook of Modern Machine Tools," describing the line of boring machines, broaching machines, chucks, die heads, drilling machines, grinding machines, gear hobbing machines, key-seating machines, lathes, metal sawing machines, milling machines, patternmaking machines, pipe machines, planing machines, power hammers, presses, shaping machines, screw machines and turret lathes sold by the company. The descriptive matter is unusually complete for a comprehensive catalogue like this, being illustrated with halftones and drawings showing details to which references are made in the text. The book is too costly for general distribution, and will be sent chiefly to manufacturers, or their official representatives, using machine tools.

TRADE NOTES

Bardons & Oliver, Cleveland, Ohio, manufacturers of turret lathes, are building a large addition to their plant and expect to have it completed January 1, 1913.

Charles H. Sawyer, 7 Lake St., Worcester, Mass., has been appointed New England representative for Bardons & Oliver, Cleveland, Ohio, manufacturers of turret lathes.

Greenfield Tap & Die Co., Greenfield, Mass., has placed the contract for the erection of four reinforced concrete machine shops with the Aberthaw Construction Co., Boston.

H. W. Johns-Manville Co., Madison Ave. and 41st St., New York, furnished about 400,000 square feet of "J-M" asbestos roofing to the Memphis Union Stock Yards, Memphis, Tenn.

Gardner Machine Co., Beloit, Wis., has been made the exclusive distributor and selling agent for the entire output of abrasive disks manufactured by Hermann Behr & Co., Inc., New York.

Pratt & Whitney Co., Hartford, Conn., has opened an office and salesroom for small tools and gages at 336 W. 4th St., Cincinnati, Ohio. The office will be in charge of Mr. C. M. Pond.

Van Dorn & Dutton Co., Cleveland, Ohio, has appointed William E. Reau district sales manager for its portable tool department with headquarters in the Plymouth Bldg., Minneapolis, Minn.

J. H. Williams & Co., 61 Richards St., Brooklyn, N. Y., makers of drop forgings, have opened an office and warehouse at 40 S. Clinton St., Chicago, Ill., where a large stock of drop-forged specialties will be carried.

Kerr Turbine Co., Wellsville, N. Y., has opened an office in Pittsburg to take care of its increasing business in that district. The office will be located at 2137 Oliver Bldg., and will be in charge of Mr. R. M. Rush, formerly with the Drave-Doyle Co.

MACHINERY

Railway Edition for Locomotive Construction and Repair Shops

NOVEMBER, 1912

SOUTHERN PACIFIC ELECTRIC LOCOMOTIVES

THE first of the fifteen sixty-ton Baldwin-Westinghouse electric locomotives under construction for the Southern Pacific Co. has been completed, and is shown in Figs. 1 and 2. Twelve of these are so equipped that they can be operated on 600 or 1200 volts direct current, and three are for 600–1500 volts. They will all be used by the Southern Pacific Co. on its Pacific Coast properties in freight haulage and switching service. The mechanical parts for the engines were built by the Baldwin Locomotive Works, at their Philadelphia shops, while the electrical equipment was constructed and installed by the Westinghouse Electric & Mfg. Co. in its works at East Pittsburg.

While designed primarily for freight service, these locomotives may be used for passenger train service if necessary. The trucks, one of which is shown in Fig. 4, are of the equalized pedestal type, with rectangular frames which are forged in one piece. The bolsters are steel castings, rigidly secured to the frame with tapered bolts, and the pedestals are protected by shoes, which can easily be replaced when worn. The wheels have cast-steel centers with the tires held in place by bolted fastenings. Westinghouse EL straight and automatic air brake equipment is used, and a hand brake is also provided for holding the engine when it is out of service and standing in the yards or on sidings.

The cab underframing consists of four longitudinal sills, each thirty feet in length. The frame bolsters, to which the center pins are secured, consist of plates 15 inches wide and 1½ inch thick. The longitudinal sills are strongly braced above these plates by flanged plates, which are riveted to the channels transversely. Further bracing is effected by the coverplates, which are ½ inch thick. The cab floor consists of diamond plating ¼ inch thick, which is laid on the coverplates. The end sills are of cast iron.

One of the 600–1200-volt locomotives has a step at each end, while all of the others are fitted with iron pilots. The couplers are of the M.C.B. type, fitted in pocket castings mounted on the end sills, with their centers 33½ inches above the rail. The cab is of steel, and measures 18 feet long by 9 feet, 6 inches wide. It is centrally located and is arranged for double end operation. A hood is placed at each end of the cab. There are side steps at each end of the locomotive, and the cab is entered through end doors; the hood is placed out of center, which, of course, gives room for a wide running board on one side.

These locomotives are equipped, mechanically, in accordance with trunk-line railway practice, Southern Pacific standards being followed where possible. The furnishings include an air whistle, a standard locomotive bell equipped with an automatic bell ringer, and sand boxes located in the hoods at each end with pneumatic sanders.

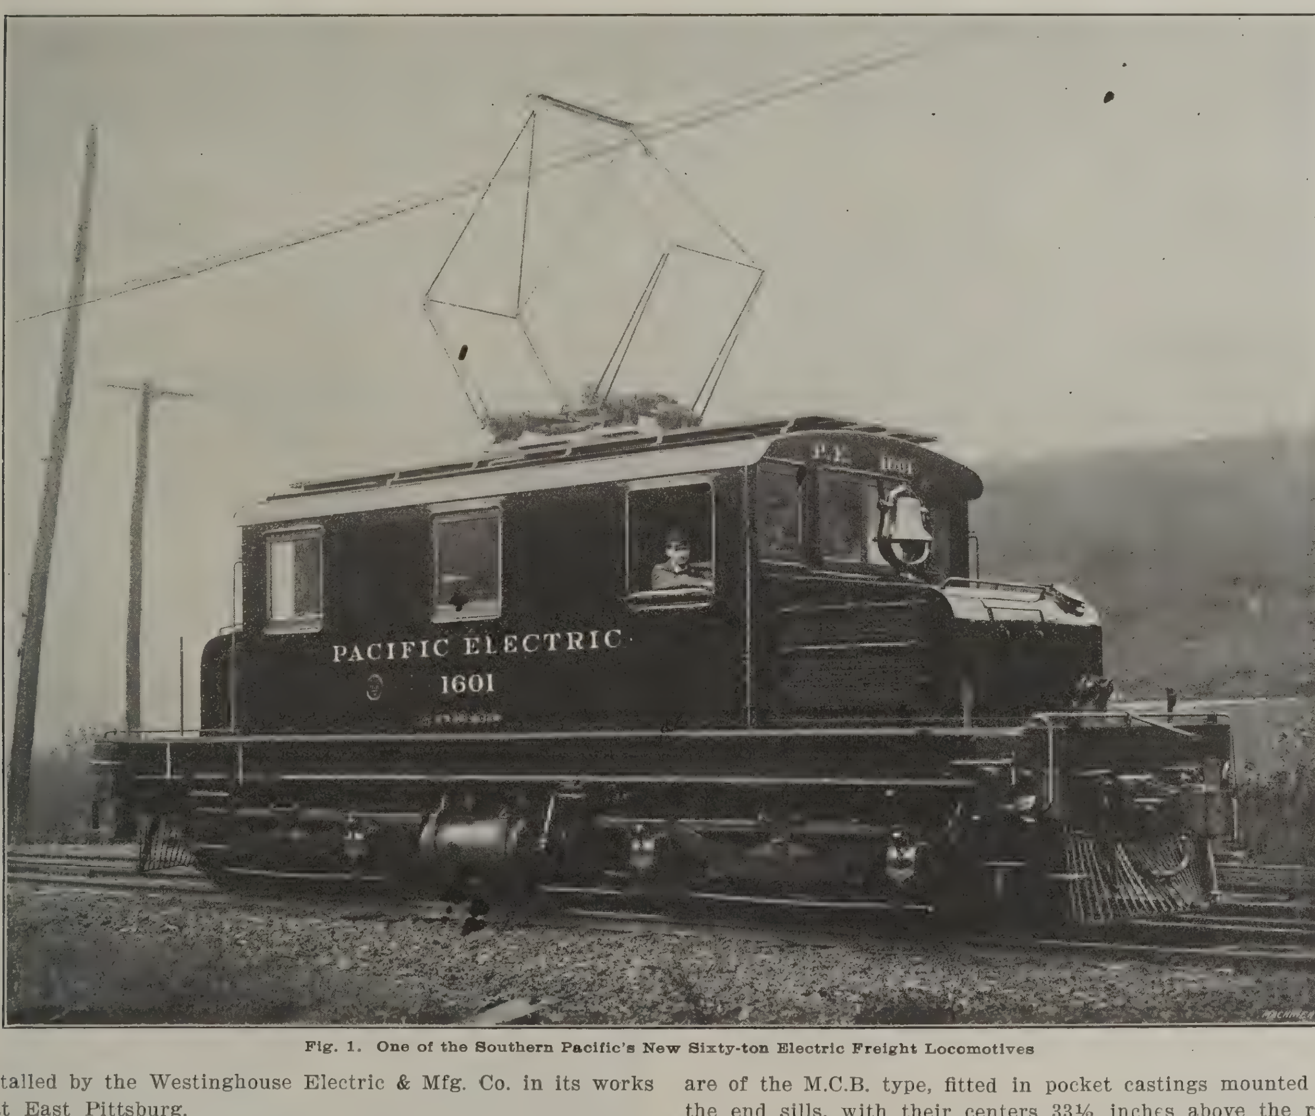

Fig. 1. One of the Southern Pacific's New Sixty-ton Electric Freight Locomotives

The principal dimensions are as follows:

Track gage, 4 feet, 8½ inches.
Wheel-base, rigid, 7 feet, 4 inches: total 25 feet.
Driving wheels, diameter outside, 36½ inches.
Journals, 5½ by 10 inches.
Distance between truck centers, 17 feet, 8 inches.
Width, 10 feet over-all.
Height to top of cab, 11 feet, 5½ inches.
Length between coupler knuckles, 35 feet.
Weight, 120,000 pounds.

Four Westinghouse No. 308-D-3 motors drive each of the engines. Each axle is equipped with an independent geared motor, the motor weight being partially carried by two axle bearings, and the remainder being supported by the nose resting directly on the truck bolster. The No. 308-D-3 motor has the same general characteristics as the Westinghouse standard 308B 600-volt motor, but is insulated for 1500 volts. Its normal rating with natural ventilation is 225 H. P. at 600 volts. The motors are provided with commutating poles and the other exclusive features of Westinghouse motors that minimize maintenance costs.

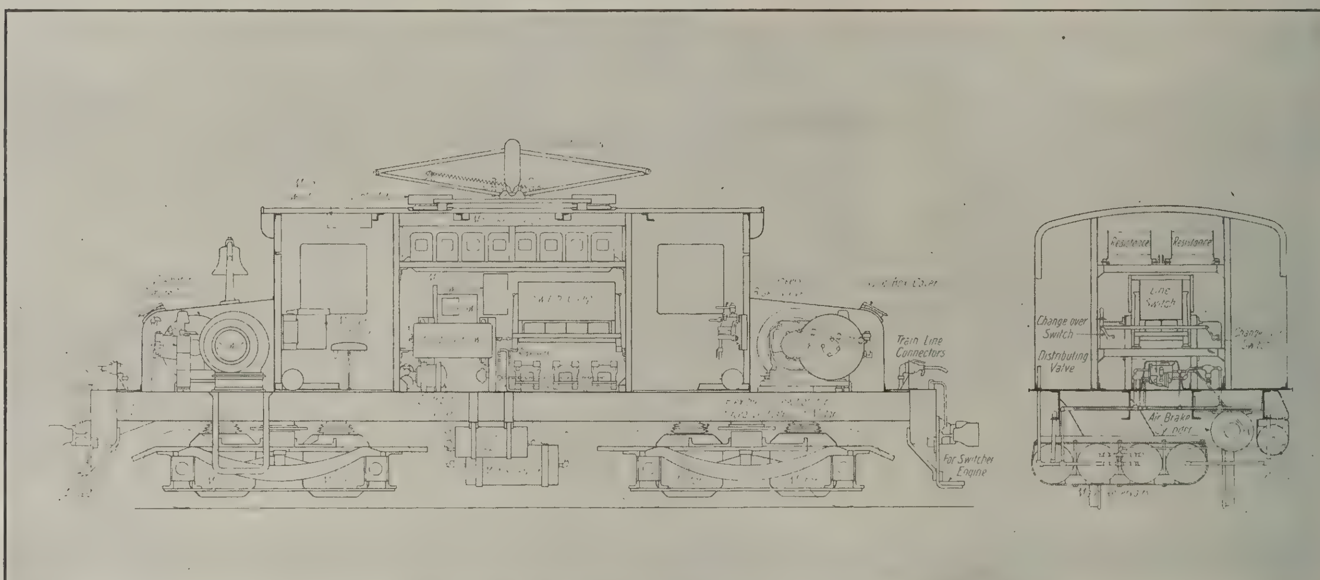

Fig. 2. Longitudinal and End Sectional Views showing Arrangement of Equipment

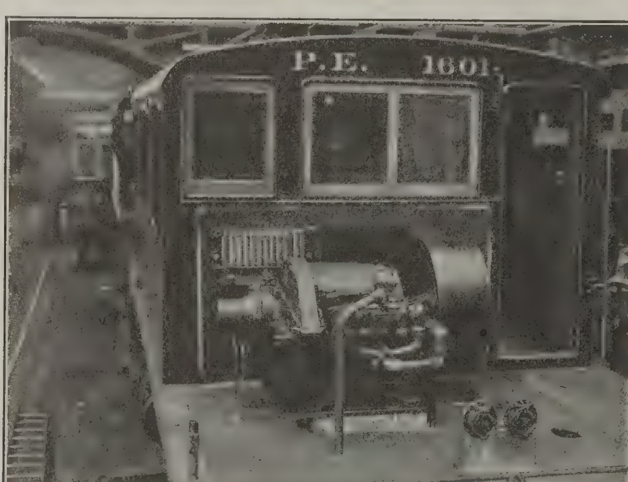

Fig. 3. Entrance to Cab with Hood removed from Dynamotor-Compressor

Westinghouse unit switch type HL control is used. Three running positions are provided for 600 volts, and two for 1200 and 1500 volts. To give the three running positions, a pneumatically operated series-parallel switch has been installed. This switch can be operated by a control switch from either end of the cab, and is so connected that the two motors comprising each pair may be arranged in series or parallel with each other, at the will of the operator. An interlocking arrangement has been provided, rendering it impossible to operate the series-parallel switch except when the circuit on the main motor is opened. There are eleven notches on the master controller with the motors in full series, nine notches with the motors in series-parallel, and nine notches with the motors in full parallel. On 1200 volts, the motors are operated only in full series and in series-parallel.

Two hand-operated drum type switches, whereby a change over from 600 to 1200 volts can be effected, have been installed in the cab. Each of these change-over switches simultaneously readjusts the divisions in the main resistance, connects the two "dynamotors" for 1200-volt operation, and locks the series-parallel switch in the series position. The same number of notches is available on the master controller for 1200-volt operation as for 600-volt operation, for full series or series-parallel positions. The control and line switches, the reverser, and the master controller are of the standard Westinghouse HL types that have been used on a great many Baldwin-Westinghouse locomotives. Each locomotive is equipped with train line receptacles and jumpers so that any number of engines can be controlled in tandem by one operator.

In addition to the standard HL control apparatus, a relay has been provided which will open all of the circuits on the motors whenever the trolley passes a specially arranged aerial brush contactor; one of these contactors is mounted on each side of every trolley wire section insulator. This device insures that there can be no current through the motors when the trolley passes the section insulator. To set the relay, and thereby remake the control circuit, it is necessary to first bring the master controller to the "off" position. A Westinghouse over-speed relay is provided, which opens the main motor circuit when the armature speed exceeds the safe limit.

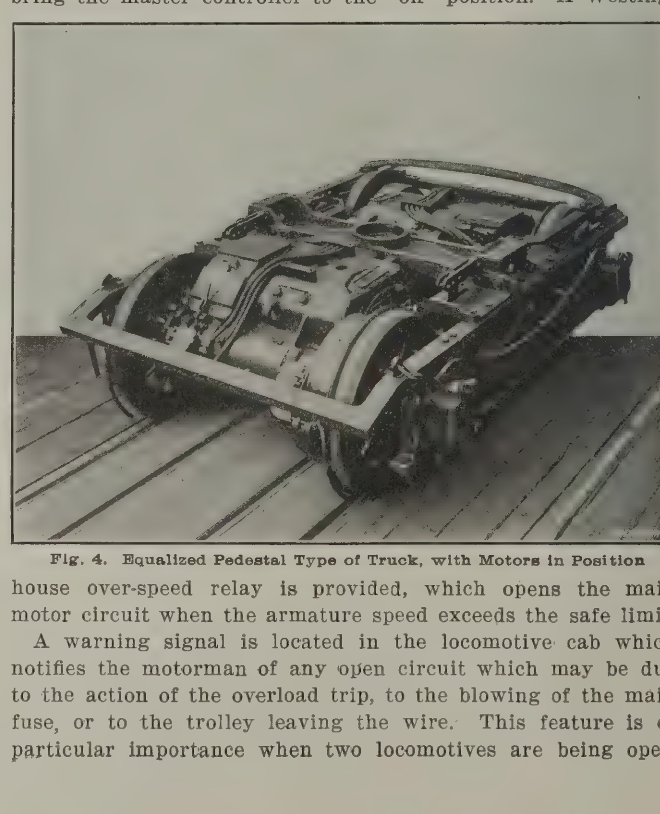

Fig. 4. Equalized Pedestal Type of Truck, with Motors in Position

A warning signal is located in the locomotive cab which notifies the motorman of any open circuit which may be due to the action of the overload trip, to the blowing of the main fuse, or to the trolley leaving the wire. This feature is of particular importance when two locomotives are being oper-

ated in tandem, as it makes sure that the operator will be notified, should the main circuit on the rear locomotive be opened accidentally.

The air brake equipment includes two D-4-K Westinghouse dynamotor driven compressors. Each of the D-4-K compressors has a displacement capacity of approximately 50 cubic feet of free air per minute. The dynamotors for operating the air compressors were supplied by the Westinghouse Electric & Mfg. Co. The dynamotor runs constantly, while the friction clutch, pneumatically operated and controlled by the main reservoir pressure, will cut in the compressor whenever necessary to maintain a predetermined pressure in the main reservoir. Each dynamotor consists of two sets of armature and field windings, which are mounted respectively in the same slots and upon the same poles. When the locomotive is operated on 1200 volts, the two windings are connected in series, and current for the lights and controller apparatus is tapped midway between the two, providing a voltage of 600 to ground. When operating on 600 volts, one set of the armature and field coils will be cut out and the remaining set will operate as in a series motor.

Two fans for supplying forced ventilation to the main motors are mounted on the extended shafts of the two dynamotors; in addition to their function of supplying cooling air, they serve as a light load to limit the speed of the dynamotors when the compressors are not in service. With natural ventilation, the motors and auxiliary apparatus on each locomotive have sufficient capacity to enable it to exert a tractive effort of 5600 pounds continuously. With blowers in operation, the locomotive will exert a continuous tractive effort of 11,520 pounds, and for a period of one hour, a tractive effort of 21,600 pounds at a speed of 17.6 miles per hour with 600 volts at the motors. With clean dry rails, the locomotive can exert a momentary tractive effort of 30,000 pounds.

* * *

HEAT TRANSMISSION THROUGH BUILDING WALLS

In considering the rate of transmission of heat through building materials, considerable uncertainty exists in regard to the accuracy of the results obtained, on account of varying conditions of wind and weather, leakage, exposure, and a number of other causes. The problem becomes especially puzzling when the engineer is called upon to deal with materials with which his profession has not had experience.

The modern tendency to construct shops and manufacturing establishments with large window areas—where the concrete or steel frame frequently forms little more than a grid—has directed considerable attention to the calculation of the heating requirements of such buildings. The Green Fuel Economizer Co., Matteawan, N. Y., has recently installed hot-blast heating equipments in a number of concrete and glass buildings, and also in buildings covered with sheet metal. This installation recently afforded an opportunity to ascertain the transmission of heat through one of the sheet-metal buildings last referred to. This shop has a continuous window space on one side 15 feet high and on the opposite side 19 feet high. The walls of the building consist of corrugated iron of single thickness and without lining. The crevices at the eaves are filled with asbestos, the corrugated iron is cemented in at the bottom, and other precautions have been taken to make the building as nearly air-tight as possible. The exposure of the windows is east and west, the smaller windows being on the east side.

The coefficients given by different authorities for the rate of heat transmission through single windows vary somewhat. Prof. Homer Woodbridge gives this coefficient for single windows with a southern exposure as 1 B. T. U. per square foot per hour, per degree difference between the inside and outside temperatures. This figure is increased 35 per cent for northern exposures, 25 per cent for western exposures, and 15 per cent for eastern exposures. The only available figure for corrugated iron without sheathing is the one determined by Rietschel, which is 2.132, but no statement is given as to whether it refers to superficial wall area or to the actual surface of the iron.

In the case of the building under discussion, the total surface is made up of approximately 7538 square feet of window space which includes the sash, 8247 square feet of wall space, and 11,925 square feet of roof. The surfaces of both walls and roof are given in superficial area, and in order to account for the corrugation in the iron, this value must be multiplied by a factor of 1.35. This gives the total area of the walls and roof as $20,172 \times 1.35 = 27,232$ square feet.

The building is heated by a Green hot-blast heater with the assistance of an engine-driven centrifugal fan drawing through a "Positiv-flo" heater made up of six sections of four rows of piping. The sections measure 7 by 8 feet. The heater is ordinarily drained of condensate and air by a Dexter vacuum system. There are altogether 6816 lineal feet of one-inch pipe in the heater, which is equal to 2272 square feet of heating surface. The air is distributed throughout the shop by circular sheet-iron conduits with their outlets directed down into the zone occupied by the workmen.

The temperature of the building was maintained constant during the test which covered a period of three hours. The fan was run at 258 R. P. M., and received 22,416 cubic feet of air per minute, figured at a temperature of 50 degrees F; this air was actually received by the heater at a temperature of 73 degrees F., and delivered from the fan at 156 degrees F. The temperature of the steam in the heater was 212 degrees F, and the temperature of the air delivered from the furthest outlet was 141.5 degrees F. Under these conditions the temperature of the building, measured at a distance of three feet from the floor, was found to be 66 degrees F., and measured in the gallery, it was 70 degrees F.; the temperature outside the building at the time of the test was 15 degrees F.

Two methods were employed for the determination of the total heat supplied. The first method consisted in calculating the heat from the rise in temperature of the air passed through the heater. By the second method, the heat was calculated from the condensation taking place in the heater. For the latter purpose the steam pipe from which the steam was introduced to the heater was carefully drained and the condensate from the heater was weighed. Figured by the air method, the consumption of heat was 2,084,000 B. T. U. per hour, and by the condensate method 2,029,730 B. T. U. per hour. Using these figures, it appears that the average rate of heat transmission through the superficial area of the building was 1.42 B. T. U. per square foot, per hour, per degree difference in temperature, and using the value obtained by the steam method, the coefficient is 1.38 B. T. U. per square foot, per hour, per degree difference in temperature.

Taking Prof. Woodbridge's figures for the rate of heat transmission through the windows, we would get 1 B. T. U. per square foot, per hour, per degree difference in temperature as the coefficient for a southern exposure. This value must be increased by 15 per cent for an eastern exposure, and 25 per cent for a western exposure, or an average value of approximately 20 per cent for the present case; this gives the value of 1.2 as the coefficient for the window surface. The value of the coefficient for the corrugated iron, merely figuring the superficial area, is 1.5. Figuring the entire surface of the iron gives the value of the coefficient as 1.13, which is less than an equivalent amount of glass surface. This result seems hardly correct, although it may be so, the explanation being that the corrugations in the iron protect the surface to a certain extent, thus making the heat transmitted from a square foot of corrugated iron less than it would be from an equal surface of flat metal.

Allowing for many indeterminate conditions, it would probably be safe in calculating the heat supply for buildings of this kind to provide for a coefficient of transmission of 2 B. T. U., per square foot, per hour, per degree difference in temperature for the whole wall and roof area.

* * *

In an article in *Gluckauf*, Mr. S. Schulte states that the erosion of the blades of a steam turbine produces changes which have a serious effect upon the efficiency of the turbine. The lateral wear of the bearings has also a detrimental effect on the efficiency, and the duration of the blade decreases with increasing steam velocity. It is pointed out that temperatures of over 480 degrees F. may totally destroy bronze blades

in from two to four years. Nickel steel with 25 per cent nickel has been found almost useless for turbine blades. The best metal for blades is nickel steel with 5 per cent of nickel. As a specific example of the decreasing efficiency of a steam turbine after use, it may be mentioned that in one case a turbine of 500 K. W. capacity running at 3000 revolutions per minute showed an increase in steam consumption of 27 per cent after it had been running for 29,700 hours. Hence, it appears that in order to maintain the initial efficiency of a steam turbine, it may require occasional re-blading.

MAKING NEW DEPARTURE BALL-BEARINGS*

MACHINING AND GAGING METHODS EMPLOYED IN PRODUCING THE "TWO-IN-ONE" BEARING

BY CHESTER L. LUCAS†

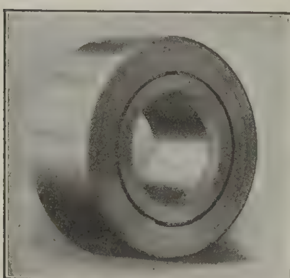

Fig. 1. The New Departure Two-in-one Bearing

THE factory of the New Departure Mfg. Co., Bristol, Conn., is now being operated to its full capacity in the manufacture of ball bearings. This healthy state of business is largely due to the increasing number of uses to which ball bearings are now being put and the realization of the economy effected by their use. But a few years ago, the principal use to which ball bearings were put was in the main bearings of the bicycle. From this, however, the field for the use of the ball bearing has broadened until it now is an important factor in the mechanism of automobiles, and is making rapid strides in the machine tool field. The future bids fair to see ball bearings in general use in machine tools. In order to give the readers of MACHINERY a general insight into the ball bearing industry,

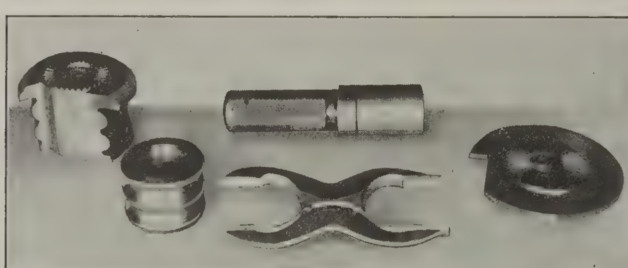

Fig. 2. Special Tools used in Machining the Cone

this article will describe briefly the machining operations connected with making the parts of a typical bearing.

The New Departure Mfg. Co. makes three distinct types of ball bearings, namely: the single-row, the double-row, and the radax. These, of course, are made in numerous sizes, and as it would be obviously impractical for us to take up the description of the manufacture of more than one, the double-row ball bearing has been selected on account of its general utility

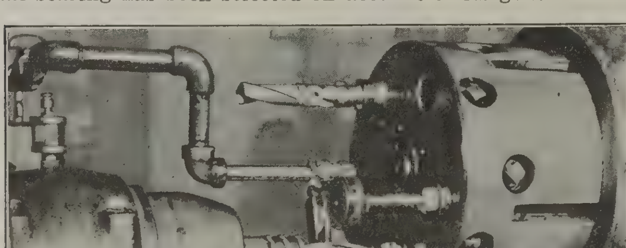

Fig. 3. Machining the Cone

as well as on account of the interesting machining operations connected with its manufacture.

The double-row ball bearing is illustrated in Fig. 1, and in Fig. 6 it has been shown in side elevation and in section in order to make the construction and relation between the several parts as clear as possible. It will be seen by a glance at the latter illustration that the bearing has been designed particularly to resist both radial and thrust stresses. Moreover, on account of the two rows of balls, its capacity for load-carrying exceeds that of any other type of bearing, and it is more efficient than two single-row bearings would be

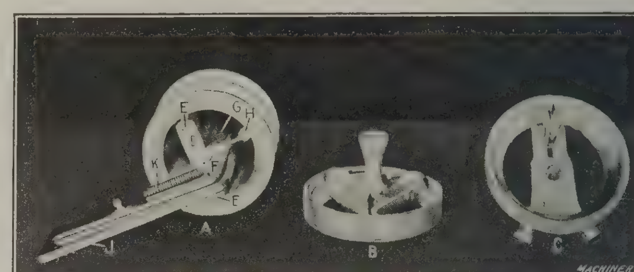

Fig. 4. Gages used on Bearing Parts

placed side by side. In the double-row bearing it is assured that each row of balls will carry a proportional part of the load, a condition mechanically impossible in two separate bearings. The parts of this bearing are, the cone or inner member, the two cups or outer members, the two bronze ball separators, the steel shell which holds the bearing parts together, and, of course, the steel balls themselves.

Turning the Cone

In taking up the machining of the parts of the New Departure bearing itself, the cone naturally comes first in order.

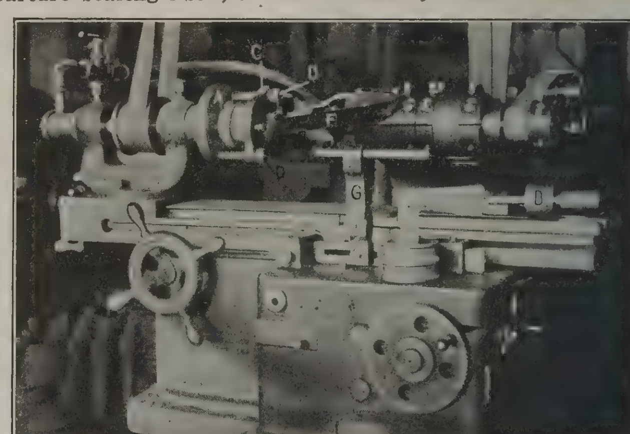

Fig. 5. Grinding the Cone Bore

This part is shown in detail in Fig. 8. By referring to the illustration Fig. 3 it will be noticed that the production of this cone is a simple screw machine job and is handled effectively on a Cleveland automatic. The working tools may be plainly seen in this illustration, and it will be noticed that circular forming tools are used. Attention is called to the fact that these forming tools are made from low carbon steel and carbonized. The cone is first formed, the forming tool being so shaped as to finish the end of the bar and partly sever the piece, as well as to turn the races for the balls. The piece is then drilled, reamed and cut off. Fig. 2 is shown to illustrate the forming tool, cut-off tool, plug gage and limit gage for the race section. It will be noticed that the sides of the cut-off and forming tool are radially serrated to facilitate holding in the forming tool fixture.

Grinding the Cone

The cone and the cups which will be subsequently described are, of course, hardened. The first operation in grinding the cone after hardening is shown in Fig. 5, in which is illustrated a special grinding machine for grinding the bore

* For additional information on this subject previously published in MACHINERY, see "Ball and Roller Thrust Bearings," August, 1912, engineering edition, and articles there referred to.
† Associate Editor of MACHINERY.

of the cone. For this purpose, the cone is held on the faceplate *A* of the machine illustrated, and it is located thereon by means of plug *B* shown on the end of the table. As will be noticed, this locating plug has a pilot which fits into a corresponding hole in the body of the faceplate. By means

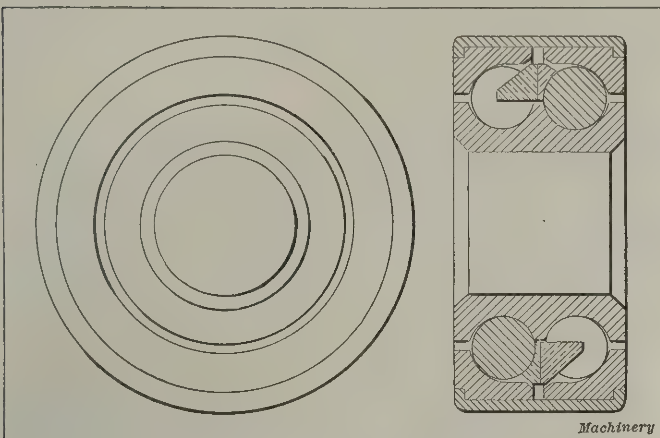

Fig. 6. Details of Bearing

of the larger section of the locating plug, which is a close fit for the bore of the unground cone, the work is located centrally under the clamping plate *C*. This clamping plate is held against the work by two retaining screws *D*. When released, the clamping plate is held back against the heads of the screws by means of spiral springs. A test indicator *F*, mounted on the bracket *G*, may be swung into position to prove the alignment of the work before grinding. For this

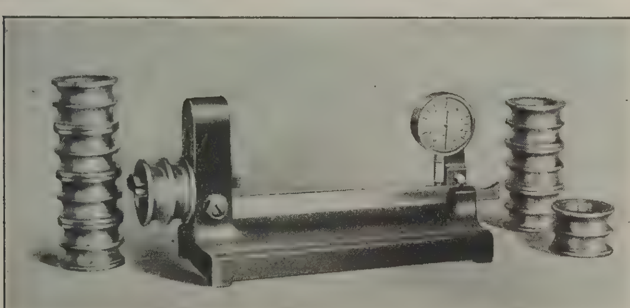

Fig. 7. Gaging Fixture for Cone Bores

and succeeding grinding operations on this class of work which will be described, the speeds used are 300 R. P. M. for the work spindle, and for the grinding wheel a peripheral speed of 5000 feet per minute is employed.

The accuracy of the grinding of the bores of these cones is held to 0.0005 inch, and this accuracy is tested from time to time by means of the special gaging device which may be seen within the bore of the cone in front of the machine. This

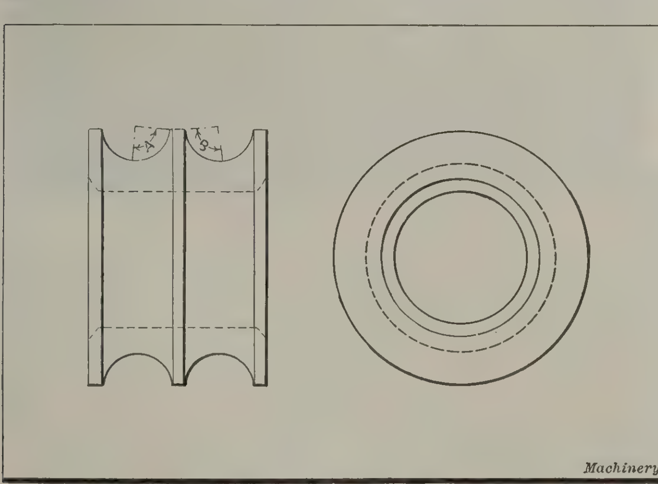

Fig. 8. Details of Cone

gage is shown in another position at *A* in Fig. 4. In this illustration it will be seen that the gage consists of a body *D*, supporting at its outer ends two hardened steel bearing pins *E*, and hinged at a central location is gaging arm *F*, fulcrumed on stud *G*. The short end of this bent lever terminates in a ball *H*, while the long arm ends in a needle point which indicates the size of the bore upon the graduated surface *J*. By means of spiral spring *K*, the gaging lever remains normally at its outermost position. Thus, by merely inserting the gage in the bore of the cone, the exact size is at once indicated upon the graduated section. By gaging from a three-point bearing, maximum accuracy is secured.

The grinding of the races in the cone is illustrated in Fig. 10, in which the cone *A* may be seen upon the arbor *B*. The grinding wheel *C* has a formed face and is used for finishing the races. By referring back to Fig. 8, it will be noticed that the balls bear only upon the two inner sides of the races along the section indicated by *A* and *B*. This, of course, facilitates meeting the requirements demanded in grinding the races, and the operation resolves itself into grinding these two sections of the cone races at correct radii whose centers are located at proper distances from each other. Referring again to Fig. 10, indicating gage *D* is used to locate the cone at the proper position upon the arbor *B*, after which one of the races is ground. Then by moving the wheel the proper distance to

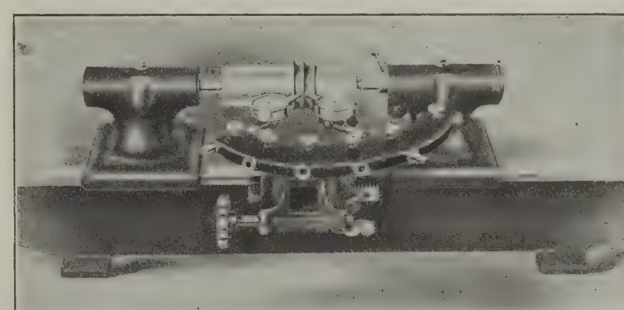

Fig. 9. Gaging Fixture for Cone Races

the left, the other radius is ground, which completes this part of the work.

Gaging Fixtures for Finished Cones

The grinding of the cones is held within close limits of accuracy. To assist in maintaining proper standards, the two gaging fixtures shown in Figs. 7 and 9 are made use of. In Fig. 7 is shown the method of gaging the cone bores. This fixture is similar to the one shown at *A* in Fig. 4, but it is far

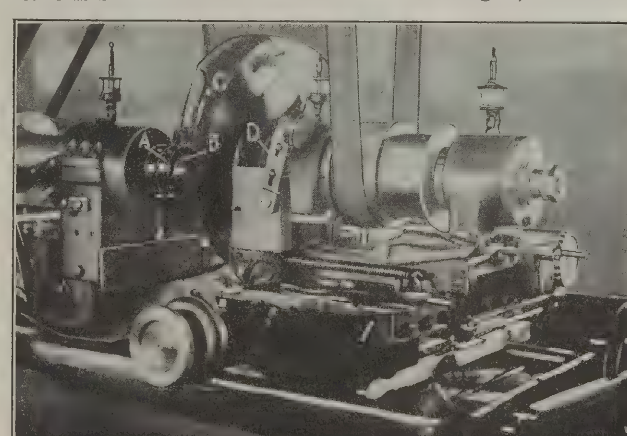

Fig. 10. Grinding the Cone Races

more accurate. The cones are slipped over the stud which may be seen at the left-hand end of the fixture. This stud is fitted with a two-point bearing, and the gaging arm forms the third point. A multiplying lever extends to the other end of the fixture and the end of this lever bears against the plunger of the dial gage shown. Any variation in the size of the bore is thus multiplied ten times and an error of 0.0001 inch is thus indicated as 0.001 inch on the dial.

The machine shown in Fig. 9 is used for determining the accuracy of the ball race grinding. This machine is fitted with two indicators connected with the dial gages shown, each of which acts upon one of the ball races. The cone is held upon an arbor centering it, and the machine indicates errors of 0.0001 inch in either parallelism or concentricity of the races.

Machining the Cups

The cups of New Departure ball bearings are made from drop forgings, and the general lines of the finished cup are

shown in Fig. 11. The first operation in the machining is shown in Fig. 12, being done on a Fay automatic lathe. In this illustration, the work *A* is shown gripped in a universal chuck, the jaws *B* holding the work firmly from the outside. Mounted on carriage *C*, is the forming tool, which is fed into

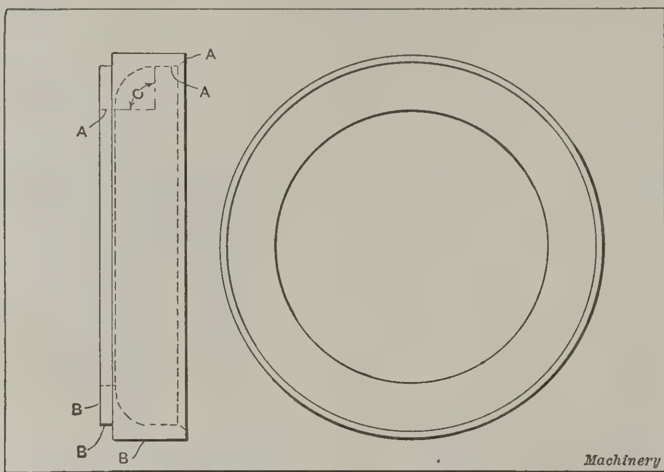

Fig. 11. Details of Cup

the work, producing the shape required for the ball race. At the same time, facing tool *D* is at work finishing the edge of the cup. Referring to Fig. 11, the surfaces indicated at *A* are finished in this operation. Two of the gages used in checking the turning operation of the inside of the cups are

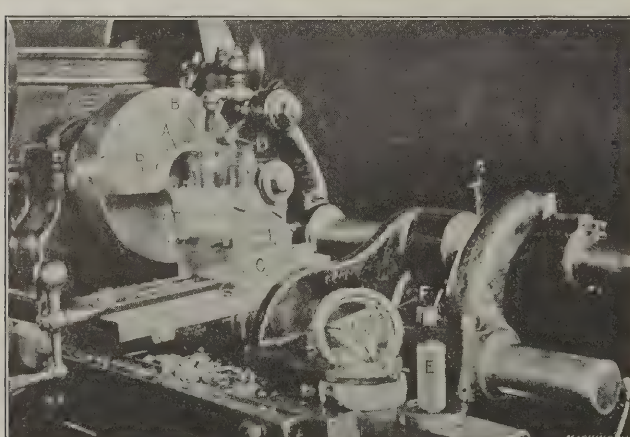

Fig. 12. Machining the Inside of the Cup

shown at *E* and *F*, *E* being the plug gage for testing the interior diameter, while *F* is the radius gage for checking the internal diameter and radius of the turning of the race.

The semi-machined cups next go to another Fay automatic lathe, where the outside parts of the work are machined.

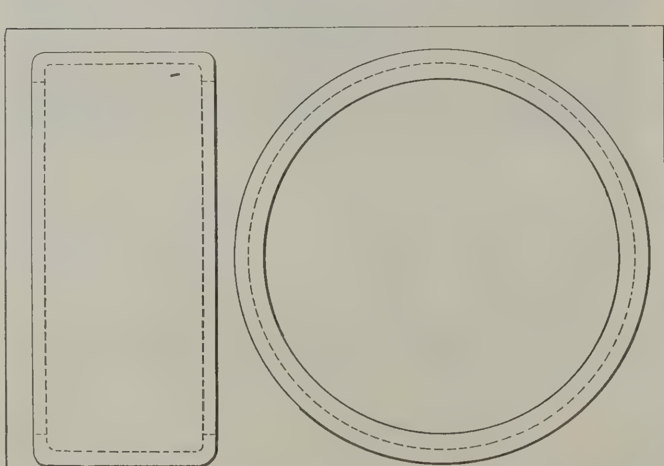

Fig. 13. Details of Shell

This operation is clearly shown in Fig. 14. The work is held in a special chuck *A*, the principal parts of which are the expanding jaws *B* which grip the work by the inside edge and are expanded when the operator turns in the central tapered screw *C*. The work being thus securely held, the outside face is turned by a combination of turning tools on the carriage *D*. These tools are located at a fixed distance apart on carriage *D* and operate simultaneously upon the work. While the edge of the cup is being turned, facing tool *E* is at work finishing the face of the cup. The accuracy of these turning operations is checked by three gages, of which the one shown in part at *F* gages the outside diameter, the one shown at *G* checks the turning of the face and edge, while that shown at *H* controls the thickness of the cup.

Grinding the Cups

The Norton automatic grinding machine shown in Fig. 19 is used for grinding the outside edges of the cups. The operation of the machine is extremely interesting, and is essentially as follows: The cups are fed into the chute *A*, dropping down against a pin whose movement is controlled by slide *B* automatically operated through link *C*. This slide is withdrawn, allowing one cup to drop between the spring

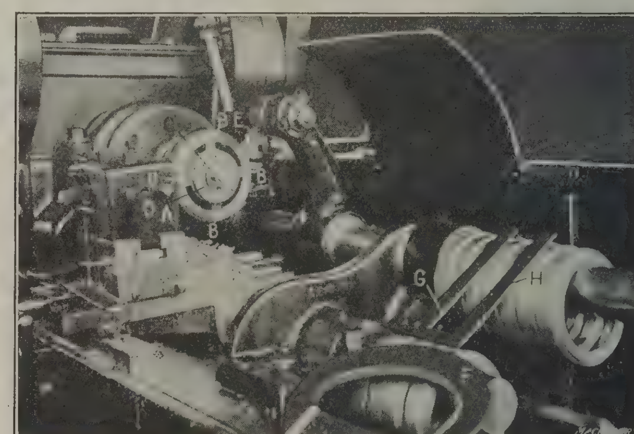

Fig. 14. Machining the Outside of the Cup

plungers of the grinding machine. These plungers correspond to centers, and their purpose is to locate and drive the work. After being chucked, the grinding wheel is passed across the face of the work, the number of times having been previously determined in accordance with the finished size desired. After the cup has been ground, the plungers automatically

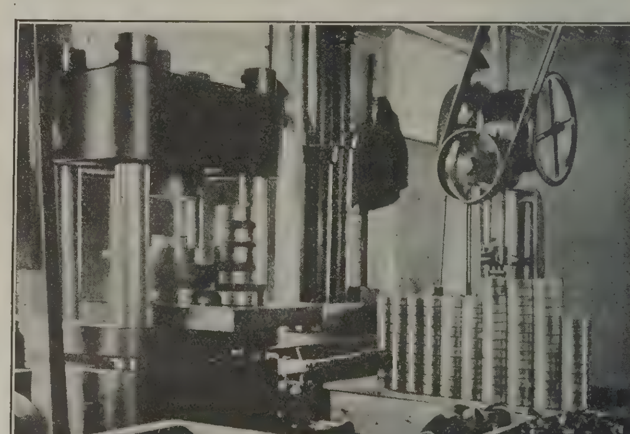

Fig. 15. Presses for Assembling Bearing Parts

open, allowing the ring to drop upon an endless belt while a new piece is being received by the plungers. The ejected piece is carried by the endless belt to the box containing the completed work, which may be seen at the left of the machine.

From time to time, the grinding of this automatic machine is checked on the Ames gage, shown on the standard at the left of the machine. The cups are slipped under the gaging arm until they reach the stop at the left. Errors of 0.0001 inch are magnified on the dial and thus easily perceptible.

Grinding the Cone Races

From the automatic grinding machine, the cups go to the oscillating machines which grind the races. Working parts of one of these machines are shown in Fig. 18. The cup is held by a magnetic chuck *A*, being located centrally thereon by means of fingers *B*. The current is supplied to this magnetic

chuck by means of feed wires C which run to a contact constantly bearing on a similar contact flange on the rear side of the chuck spindle. The wheel spindle D carries a grinding wheel whose edge has been shaped to a radius slightly smaller than that of the race to be ground. The oscillating head of the machine, which carries the chuck and work, is located so that the path traversed by the work coincides with the radius of the race. This location is reached by moving the head to or from the oscillating center upon the slide. The

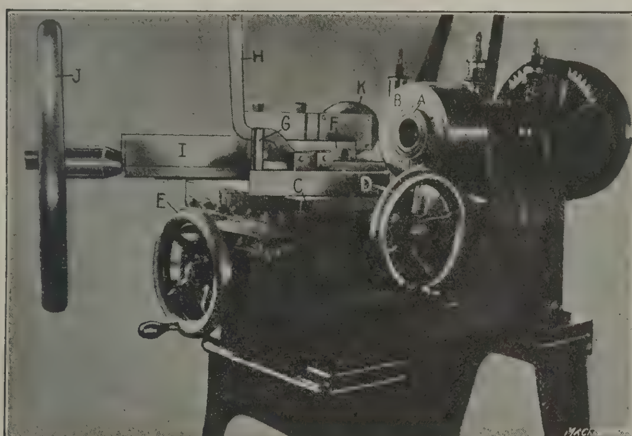

Fig. 16. Spinning the Edge of the Shell over the Assembled Bearing

oscillating mechanism consists of a crank and arm at the rear side of the machine (not shown) which causes the head to traverse a path extending over 120 degrees of a circle. Two gages are used continuously upon this work, these being shown at E and F. These two gages are shown on a larger scale in the illustration Fig. 4, where they are indicated as B and C. Gage B is for testing the accuracy of the diameter and radius of the ground race, and consists of a central triangular body from which three hardened and ground steel disks are supported. These disks are ground with knife-edges, and are of proper diameter to coincide with the curve of the race. The gage shown at C in Fig. 4 is used more especially as a check on the size of the radius and consists principally

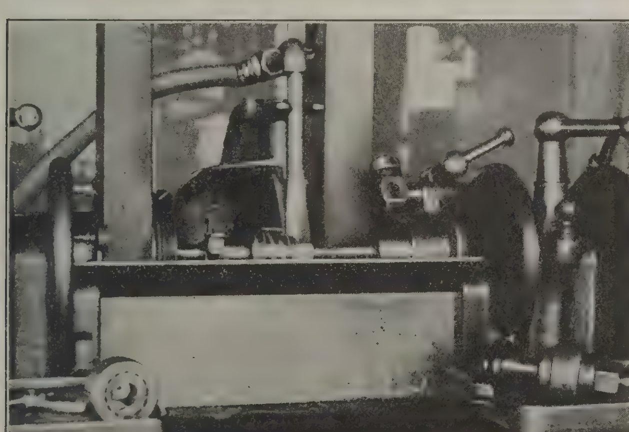

Fig. 17. Finish-grinding the Outside of the Bearing

of a base with two locating lugs and a hardened steel disk similar to those before described, but in this case the disk is mounted on the end of a lever fulcrumed in the body of the gage. Referring again to the gage as shown at F in Fig. 18, which illustrates the other view of the gage, a spring may be seen which tends to keep this disk as far as possible from the locating lugs at the other end. In Fig. 4, the gage is shown in use, and by this means it is possible to see if the race is being ground to the correct radius.

Assembling the Bearing

The parts of the bearing are kept in the proper relation to each other by means of an enclosing shell. This shell, shown in Fig. 13, is of soft sheet steel, and made by a series of ordinary press operations, consisting of cutting and drawing in combination press tools. As it leaves the press, the cup has a bottom at one end and the edges are, of course, straight and more or less irregular. The bottom is therefore punched out, leaving a flange of the proper width to complete this end of the shell. The reverse end is trimmed for a distance that will permit of its being rolled in to form the second flange.

In assembling the bearing, forcing presses are used of the two types shown in Fig. 15. The press in the foreground is a hydraulic press, and the one in the background is operated by a friction drive. A cup is first forced into the shell, after which the cone, a set of balls and a separator are dropped in; then comes the second separator, the second set of balls and the second cup. As the cups fit tightly within the shell, they are forced into their respective places by means of the presses, the second cup being inserted to a point where it just touches the second row of balls.

Rolling the Flange

The rolling-in operation now follows, being done in the machine shown in Fig. 16. The rolling-in operation, or as it is

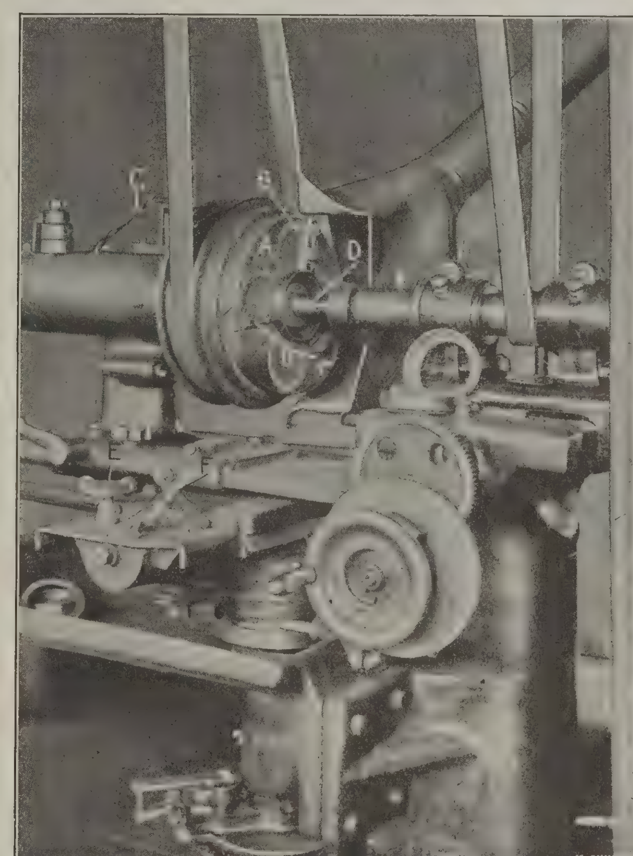

Fig. 18. "Oscillator" Grinding Machine for Cup Races

called, the spinning-over of the shell, is accomplished in three operations, all of which are performed on this machine. Referring to Fig. 16 in connection with the line engraving Fig

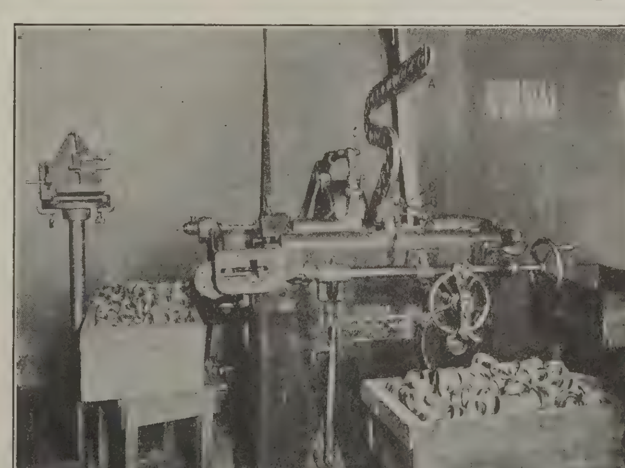

Fig. 19. Norton Automatic Cup-grinding Machine

21, the work done in these three operations may be followed. The bearing A is held within the collet chuck B, which is mounted on the spindle of the machine. The carriage C of

the machine is operated in a lateral direction by handwheel D, and in a longitudinal direction by handwheel E. Mounted upon this carriage is the rolling fixture F which may be swiveled to any one of three positions, being held in any of these positions by means of the index pin G, which is lifted by handle H. Corresponding index-pin holes are, of course, located in the body of the carriage. A slide I operates on this carriage by means of the large handwheel J. On the forward end of this slide the roll K is mounted. This roll is of hardened steel and has a face approximately 1½ inch wide.

In operation, the carriage is indexed to a position sixty degrees from the center line of the bearing, as shown at A

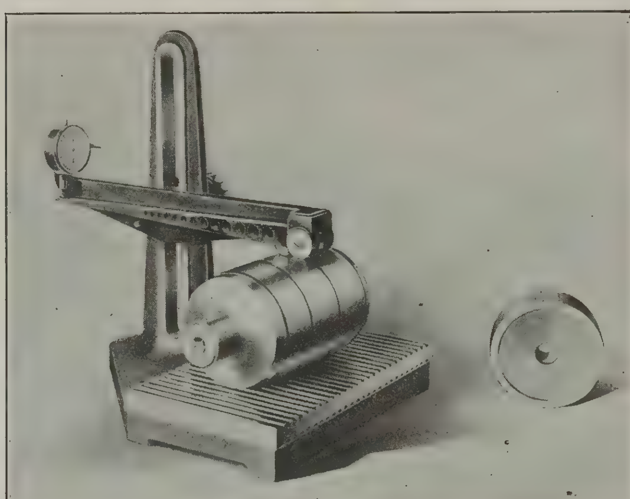

Fig. 20. Testing the Diameter of the Finished Bearing

in Fig. 21, at which position the roll is brought up to the flange, causing it to turn inward to an amount corresponding with this angle. In the meantime, the bearing is being rotated against the roll. The result of this operation is shown at B in the line engraving Fig. 21. This being done, the ratchet is indexed to the second position. In this second

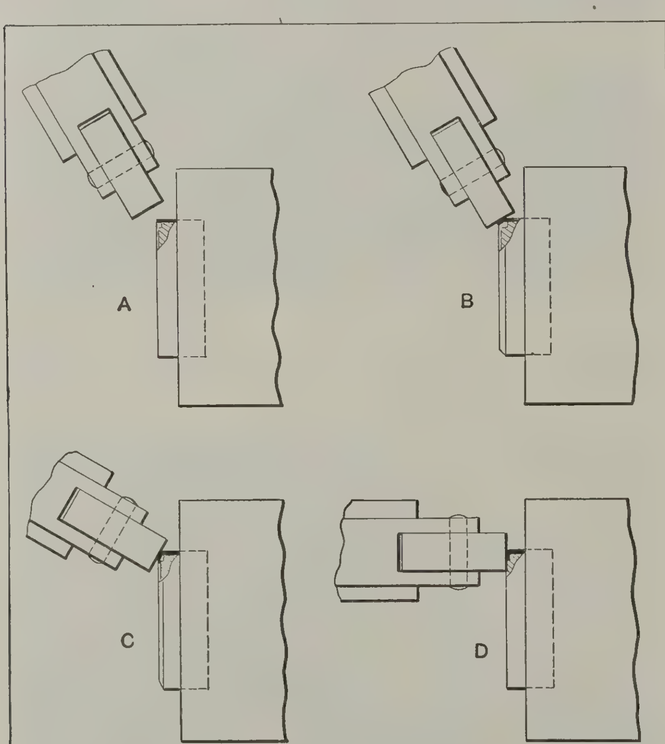

Fig. 21. Steps in Spinning over the Edge of the Shell

position, the slide on the carriage stands at a position of thirty degrees to the center line of the bearing, and, consequently, when the roll is brought into conjunction with the work by means of the large handwheel J, the flange of the shell is turned inward a corresponding amount, leaving the bearing and shell in the condition shown at C in Fig. 21. As soon as this part of the work is done, the roll is again withdrawn and the carriage swiveled to a position in line with the center line of the bearing, after which the edge of the shell is rolled down into the recess in the outer cup of the bearing, leaving it finished as shown at D in Fig. 21. During the three rolling operations, the roll is fed from the outside of the shell inward, by means of lateral feed-screw handle D.

Finish-grinding

In order to give the bearing a finished appearance, as well as a truly concentric exterior, it is ground all over after it has been assembled. These grinding operations, which face off the ends and periphery of the bearing, are comparatively simple, the first being performed in ring grinding machines, and the second upon plain grinding machines, as shown in Fig. 17. For this latter grinding operation, the bearing is held upon an arbor having a fixed collar against which the bearing is clamped by means of a washer and nut.

Finish-inspection and Test of the Bearings

Fig. 20 illustrates a gaging fixture used by the inspectors who pass upon the finished bearings. The gage consists of a multiplying lever whose outer end acts upon an Ames gage. A master testing disk is shown at the right, by means of which the reading of the gage is checked from time to time. In the illustration, three bearings are shown under test.

The master measuring machine shown in Fig. 22 is used for miscellaneous inspecting, but more particularly for the checking of the master plugs, disks and ring gages which are examined every day to insure that they are accurate. This

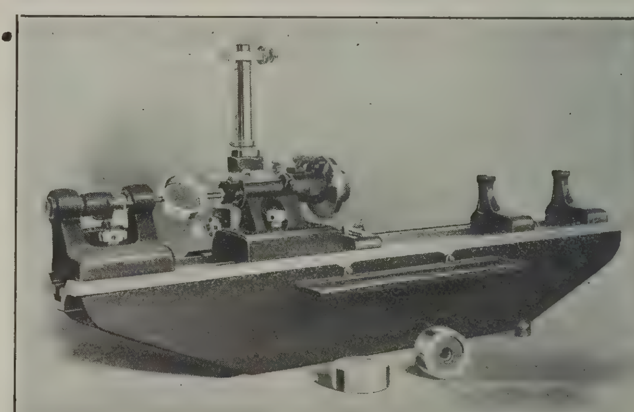

Fig. 22. Master Measuring Machine

machine is fitted with a microscope to facilitate the proper setting of the vernier. In this illustration it is shown with one of the cups between its measuring points.

* * *

LUBRICATION OF MACHINE TOOLS

In an article on machine tool lubrication abstracted from *L'Industria* in the foreign review of the *Journal of the American Society of Mechanical Engineers*, attention is called to the fact that inefficient lubrication in machine tools is the principal cause of the rapid deterioration of this class of machines. It is the minor or secondary working parts, it is stated, which most easily get out of order. The main parts are provided with sufficient and continuous lubrication, while the secondary parts are left to be lubricated by the workman squirting oil through an oil hole from time to time. These oil holes, however, often become clogged with dirt; besides, the lubrication of the minor working mechanisms of the machine is often neglected. This was of little consequence as long as the speeds of machine tools, in general, were low and the power small, but it has become a very important factor under present-day conditions. Some American manufacturers, says the writer, are beginning to design machine tools with automatic lubrication throughout, but this practice is not yet as general as it ought to be.

RESTORING OVER-EXPOSED BLUEPRINTS

C. J. Kranz of Chicago, Ill., writes that over-exposed blueprints can be restored if immersed in hot water. He has used hot water successfully for restoring blueprints when the white lines were blue and the portions that should normally be blue were steel gray.

A BETTER MAGAZINE—A PLEA FOR COOPERATION

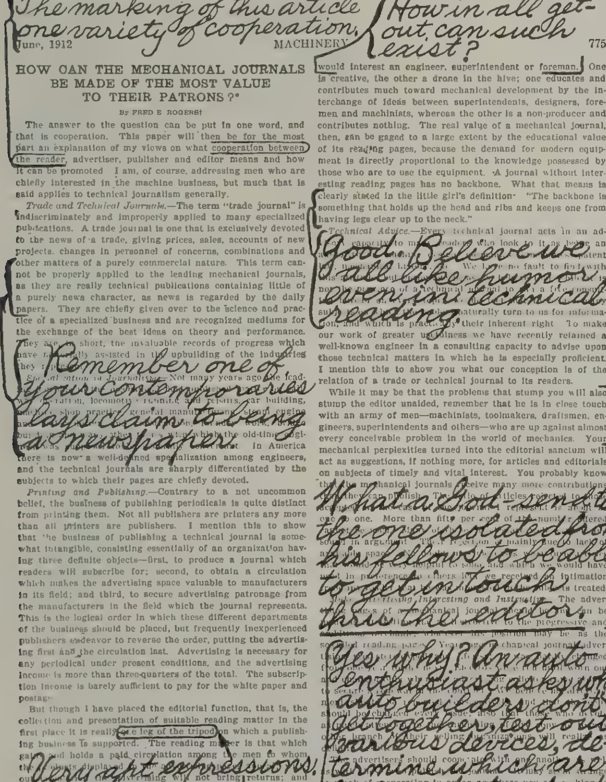
BY JOHN S. MYERS*

Am I an editor? No. Then why an editorial from my pen? Because I am a reader who understands that the reader is to a magazine what the common people are to a popular government—he's IT, or should be. Why is the reader IT? Because he is the person for whom the magazine is published. If the magazine appeals to a reader he is likely to interest his friends. This boosts the circulation, and enlarged circulation means more advertisers, hence more income for the magazine to spend on good articles.

Every triangle has three angles and three sides. In an equilateral triangle the three sides, and consequently the three angles, are equal. The conscientious publisher tries to make his enterprise an equilateral triangle, but he can do it only with cooperation. The three sides are the publishers, the readers and the advertisers; the three angles are the viewpoints of these three sides.

Now how can you obtain a better magazine? By cooperating, by making intelligent comments on the articles published, by contributing articles, by joining the staff of educators. Remember that if the magazine is not what you would have it, you are partly to blame.

One way of aiding the contributors to MACHINERY is to write your comments on the margin of the article and send them to the editor or the author. This shows at least that you have read the subject matter and were interested. Your suggestions may bring forth fruit. For example, see the accompanying reproductions of the pages of an article with comments.



The marking of this article one variety of cooperation.

How in all get-out can such exist?

June, 1912 MACHINERY 775

HOW CAN THE MECHANICAL JOURNALS BE MADE OF THE MOST VALUE TO THEIR PATRONS?*

By FRED E. ROGERS†

The answer to the question can be put in one word, and that is cooperation. This paper will then be for the most part an explanation of my views on what cooperation between the reader, advertiser, publisher and editor means and how it can be promoted. I am, of course, addressing men who are chiefly interested in the machine business, but much that is said applies to technical journalism generally.

Trade and Technical Journals.—The term "trade journal" is indiscriminately and improperly applied to many specialized publications. A trade journal is one that is exclusively devoted to the news of a trade, giving prices, sales, accounts of new projects, changes in personnel of concerns, combinations and other matters of a purely commercial nature. This term cannot be properly applied to the leading mechanical journals, as they are really technical publications containing little of a purely news character, as news is regarded by the daily papers. They are chiefly given over to the science and practice of a specialized business and are recognized mediums for the exchange of the best ideas on theory and performance. ...

Remember one of your contemporaries lays claim to being a newspaper.

... In America there is now a well-defined specialization among engineers, and the technical journals are sharply differentiated by the subjects to which their pages are chiefly devoted.
